PRINCIPLES OF INORGANIC CHEMISTRY

A TEXT BOOK

for

B.Sc., B.Sc. (Hons.) & M.Sc. Students of Indian Universities as also for Candidates appearing for Various Competitive Examinations

LATE B. R. PURI
M.Sc., Ph.D., F.R.I.C., F.N.A.,
Formerly, Prof. of Physical Chemistry,
Panjab University, Chandigarh

L. R. SHARMA
M.Sc., Ph.D., F.R.I.C. (London),
Formely, Prof. of Physical Chemistry,
Department of
Chemical Engineering &Technology,
Panjab University, Chandigarh

K. C. KALIA
M.Sc., Ph.D., (I.I.T., Kanpur)
Formerly, Prof. of Inorganic Chemistry,
Department of Chemistry,
Punjabi University, Patiala

Preface to the Thirty First Edition

The authors take pleasure in presenting the thirty first edition of their prestigious publication **Principles of Inorganic Chemistry**. The entire text has been thoroughly revised and updated in every respect. While minor but otherwise essential additions have been made in all the chapters dealing with representative elements, transition elements and inner transition elements, some important additions have been made in chapters covering group theory, organometallic compounds and inorganic polymers. The additions to group theory include additional applications of group theory covering relaxation of selection rules for electronic transitions, study of the method of descending symmetry and the study of electron absorption spectra using plane polarised light. Character tables for important symmetry groups have also been given in this chapter. A significant addition to the present edition is a new chapter describing the **quantitative treatment of crystal field theory.** Mathematical expressions have been derived for calculating V_{oct}, $V_{tetragonal}$, V_{tet} and Dq values. The fact that in an octahedral ligand field potential, the energy of e_g orbitals increases by 6 Dq while that of t_{2g} orbitals decreases by 4 Dq, has been established mathematically.

The book now adequately covers almost all the modern topics in inorganic chemistry. The publication, therefore, can be rightly called **modern inorganic chemistry.**

We take this opportunity to express our sincere thanks to all the students and fellow teachers who took pains to send us their valuable suggestions and criticism for further improvement of the text.

The authors sincerely hope that the present revised and improved edition of the book will be warmly received by the students and the teachers alike. Any suggestions for further improvement of the text would be most welcome.

AUTHORS.

CONTENTS

Chap.	Description	Page
1.	**WAVE MECHANICAL CONCEPTS OF ATOMIC STRUCTURE**	**1–57**
	Rutherford's nuclear model of the atom (1)	
	Planck's quantum theory of radiation (2)	
	Photoelectric effect and quantum theory (2)	
	Bohr's model of the atom (3)	
	Bohr's equation for the energy of electron in hydrogen atom (3)	
	Bohr's theory and the origin of hydrogen spectrum (5)	
	Sommerfeld's extension of Bohr's theory (8)	
	Particle and wave character of electron. The de Broglie equation (9)	
	Experimental verification of de Broglie equation (10)	
	Davisson and Germer experiment (10)	
	Heinsenberg's uncertainty principle (12)	
	Compton effect (13)	
	Quantum mechanics or wave mechanics (14)	
	Postulates of quantum mechanics or wave mechanics (15)	
	Schrodinger wave equation (16)	
	Formulation of Schrodinger wave equation (18)	
	Probability density and significance of ψ (20)	
	Solutions of Schrodinger wave equation for simple systems (22)	
	Particle in a one-dimensional box (22)	
	Particle in a three- dimensional box (23)	
	Schrodinger wave equation for hydrogen atom (24)	
	Energy of electron in hydrogen and hydrogen-like atoms (26)	
	Radial wave function (26)	
	Angular wave function (29)	
	Angular wave functions and shapes of orbitals (30)	
	Quantum numbers (35)	
	Zeeman effect (37)	
	Paull's exclusion principle (38)	
	Energy level diagram of a multi-electron atom (40)	
	The Slater's rules (41)	
	Applications of Slater's rules (43)	
	Electronic configurations of atoms (45)	
	Elements beyond atomic number 103 (47)	
	Electronic configuration of elements. Tables (48–49)	
	Extra stability of half-filled and completely filled orbitals (51)	
	Hund's rule - its basis and applications (52)	
2.	**PERIODIC TABLE AND ATOMIC PROPERTIES**	**58–82**
	The long form periodic table (58)	
	Cause of periodicity (60)	
	Cause of recurrence of properties (61)	
	Division of elements into *s,p,d* and *f* blocks (62)	
	Atomic properties (63)	
	Covalent radius (64)	
	Periodic trends in covalent radii (66)	
	Van der Waals radius (67)	
	Ionic radius (67)	
	Periodic trends in ionic radii (69)	
	Ionization energy (69)	
	Factors determining ionization energies (71)	
	Variation of ionization energy in the Periodic table (72)	
	Electron affinity (73)	
	Variation of electron affinity in the Periodic table (74)	
	Successive electron affinities (74)	
	Electronegativity (75)	
	Pauling's approach (75) ; Table (75)	
	Allred and Rochow's approach (76)	
	Mulliken's approach (76)	
	Factors determining electronegativity (77)	
	Applications of electronegativities (78)	
3.	**MOLECULAR SYMMETRY AND GROUP THEORY**	**83–136**
	Symmetry operations and symmetry elements (83)	
	Equivalent symmetry elements and equivalent atoms (86)	
	General relations amongst symmetry elements and symmetry operations (87)	
	Symmetry elements and symmetry operations in molecules of special symmetry (88)	
	Symmetry classification of molecules (90)	
	A complete set of symmetry operations as a mathematical group (92)	
	Classes of symmetry operations (94)	
	Representation of symmetry operations by matrices (95)	
	Character tables (102)	
	Wave functions as basis of irreducible representations (103)	
	Direct product of matrices (105)	
	Applications of group theory (105) :	
	1. Evaluation of integrals (106)	
	2. Explanation of allowed and forbidden electronic transitions (106)	
	3. Hybridisation (107)	
	4. (*a*) Nature of bonding in octahedral complexes (110)	
	(*b*) Nature of bonding in tetrahedral complexes (110)	
	5. Energy terms of strong field configuration of octahedral complexes (111)	
	6. Splitting of orbitals and terms in a chemical environment (112)	
	7. Relaxation of selection rules for electronic transitions (120)	
	8. Establishing state of symmetry by the method of descending symmetry (120)	

Chap. Description Page

9. Study of electron absorption spectra using plane polarised light (125)
Character tables for important symmetry groups (130-135)

4. CHEMICAL BONDING 137–200

Ionic bond (137)
Decrease in energy in the formation of sodium chloride (137)
Variable valency of cations (140)
Covalent bond (141)
Decrease of energy in formation of hydrogen molecule (141)
Atomic orbital overlap concept of covalency (142)
Variable covalency. Maximum covalency (144)
Coordinate covalent bond. Dative bond (145).
Polarity in covalent bond (146)
Covalent character of ionic bond. Polarization of ions (146)
Fajan's rules (146)
Effects of polarization (147)
Per cent ionic character of a polar covalent bond (147)
Dipole moment and per cent ionic character (147)
Dipole moment and structure of molecules (148)
Some important bond characteristics (149)
Bond length, bond angle, bond energy (149–150)
Wave Mechanical Treatment of Covalent Bond (150)
Approximate solution of Schrodinger wave equation (151)
The variation principle (151)
Ritz linear combination method (152)
Valence bond theory (152)
Singlet and triplet wave functions (156)
Concept of resonance (157)
Resonance energy (157)
Linnet double quartet approach (159)
Molecular orbital theory (160)
Linear combination of atomic orbitals – LCAO (161)
MO treatment of H_2^+ ion (161)
Bonding and antibonding molecular orbitals (163)
Construction of MO and VB wave functions (164)
Electron charge densities in molecular orbitals of H_2^+ ion (166)
Pictorial representation of combination of atomic orbitals to form molecular orbitals (168)
Conditions for the combination of atomic orbitals to form molecular orbitals (171)
Energy level diagram for molecular orbitals (171)
Mixing of orbitals (172)
Electronic configurations of homonuclear diatomic molecules (175)
Electronic configurations of heteronuclear diatomic molecules (179)
Term symbols for diatomic molecules (182)
Molecular orbitals of polyatomic species (183)
Walsh diagrams (184)
Walsh diagrams for AH_2 molecules (185)
Carbon dioxide molecule (187)
molecular orbitals involved (188)
Ammonia molecule (189)
Comparison betweeen VBT and MOT (189)
Metallic bond (190)
Electron sea model for metals and explanation of metallic properties (190-191)
The valence bond model (192)
The band model. MO approach (192)
Hydrogen bond (194)
Consequences of hydrogen bonding (195)
Intermolecular forces (197)
London forces (198)

5. HYBRIDISATION AND SHAPES OF COVALENT MOLECULES 201–233

Hybridisation (201)
Salient features of phenomenon of hybridisation (205)
Wave functions for hybrid orbitals (206)
Orientation of hybrid orbitals in space (210)
VSPER theory (213)
Geometry of molecules containing only bond pairs of electrons (BeF_2, BF_3, CH_4, PF_5, SF_6, IF_7 molecules) (215–219)
Geometry of molecules containing bond pairs as well as lone pairs of electrons ($SnCl_2$, NH_3, H_2O, SF_4, ClF_3, XeF_2, XeF_4, IF_5 molecules) (219–223)
Structure of CO_2 molecule (226)
Geometry of some ions (CO_3^{2-}, NO_3^-, SO_4^{2-}, ClO_4^-, ClO_3^- ions) (227–233)

6. THE STRUCTURE OF SOLIDS 234–274

Crystalline and amorphous solids (234)
Size and shape of crystals (235)
Interfacial angles (235)
Symmetry in crystals (235)
Plane, axis and centre of symmetry (236–37)
Elements of symmetry of a crystal (237)
Space lattice and unit cell (238)
Bravais lattices (239)
Seven basic crystal systems (241)
Miller indices (242)
Types of crystals (244)
Structure of diamond (244)
Close packing of identical solid spheres (246)
Interstitial sites in close packing of spheres (249)
Limiting radius ratio (250)
Radius ratio rule and the shape of an ionic crystal (254)
Structures of metallic crystals (256)
Structures of ionic crystals (257)
NaCl crystal (258)

Chap. Description Page

ZnS crystal (zinc blende and wurtzite structures) (259)
CsCl crystal (260)
CaF_2 crystal (261)
TiO_2 crystal (261)
CaC_2 crystal (261)
CdI_2 crystal (262)
Lattice energy of an ionic crystal (262)
Calculation of lattice energies of ionic solids (263)
Born equation, its applications (264)
Experimental determination of lattice energy (266)
The Born-Haber cycle (266)
Defect structures of crystals (268)
Schottky defect, Frenkel defect, metal excess defects, metal deficiency defects, thermal defects (268–71)
Semiconductors (272)
Fabrication of transistors (272)

7. NON-AQUEOUS SOLVENTS 275–294

Classification of solvents (275)
Characteristic properties of a solvent (275)
Liquid ammonia (277)
Chemical reactions in liquid ammonia (278)
Solutions of alkali metals in liquid ammonia (283)
Liquid hydrogen fluoride (283)
Chemical reactions in liquid hydrogen fluoride (284)
Sulphuric acid (285)
Chemical reactions of sulphuric acid (285)
Liquid dinitrogen tetroxide (286)
Liquid sulphur dioxide (288)
Reactions in liquid sulphur dioxide (289)
Molten salts as non-aqueous solvents (292)

8. ACIDS AND BASES 294–312

Arrhenius concept (294)
Proton transfer theory. Concept of Lowry and Bronsted (294)
Lux–Flood concept (296)
The solvent-system concept (296)
The Lewis concept (299)
Relative strengths of acids and bases (300)
effect of solvent (300)
levelling effect (300)
effect of polarity and dielectric constant (303)
effect of substituents (303)
Additional factors influencing relative strengths of acids and bases (304)
Measurement of acid-base strength in gas phase (307)
Enthalpies of acid-base reactions from empirical parameters (307)
Hard and soft acids and bases. Pearson's concept (308)
Bonding in hard–hard and soft–soft combinations (309)
HSAB principle and its applications (309)
Basis for hard–hard and soft–soft interactions (310)

9. OXIDATION AND REDUCTION 313–327

Oxidation number (313)
Galvanic cells (314)
Single electrode potential (315)
Sign of electrode potential (315)
Standard electrode potentials. Electrochemical series (316)
Nernst equation (317)
Applications of electrochemical series (318)
Source of electrical energy in a galvanic cell (318)
Hydrogen over voltage (319)
Oxygen overvoltage (320)
Redox stability in water (320)
Oxidation by atmospheric oxygen (321)
Latimer diagrams (322)
Frost diagrams (324)
Pourbaix diagrams (326)

10. METALS AND METALLURGY 328–339

Occurrence of metals (328)
Various steps involved in metallurgical processes (329)
Concentration of ore (329)
Calcination (330)
Roasting. Reduction to free metal (332)
Electrometallurgy (333)
Thermodynamics of the oxidation of metals to metal oxides. The Ellingham diagram (333)
Hydrometallurgy (336)
Refining or purification (336)
Zone refining (338)

11. HYDROGEN 339–356

Position in periodic table (339)
Resemblance with alkali metals (339)
Resemblance with the halogens (339)
Preparation, properties and uses (340–41)
Nascent hydrogen (341)
Active hydrogen (342)
Atomic hydrogen (342)
Ortho and para hydrogen (344)
Hydrides (346)
Heavy hydrogen or deuterium (350)
Tritium (350)
Heavy water (350)

12. THE MAIN GROUP ELEMENTS. THE GENERAL CHARACTERISTICS 357–373

Metallic character (357)
Polarising power and polarizability (358)
Oxidising and reducing properties (361)
Electropositive character. Electrode potentials (361)

Chap.	Description	Page
	Oxidation states (362)	
	Diagonal relationship (363)	
	Compounds of main group elements (365)	
	Some special characteristics of *p* block elements (366)	
	Reluctance of heavier *p* block elements to show maximum oxidation state (368)	
	Reluctance of heavier *p* block elements to involve *p* orbitals for pi bonding (368)	
	Participation of *d* orbitals in sigma bonding (369)	
	Participation of *d* orbitals in π bonding (370)	
	Electronegativities (371)	
13.	**THE ELEMENTS OF GROUP 1**	**374–395**
	General characteristics (374)	
	Atomic and ionic radii (375)	
	Ionization energies (376)	
	Electropositive character (376)	
	Formation of univalent positive ions (376)	
	Hydration of ions (376)	
	Reducing properties. Oxidation potentials (377)	
	Characteristic flame colouration (378)	
	Lattice energies (378)	
	Chemical properties (379)	
	Complexes of alkali metals (381)	
	The 'wrap around' complexes (382)	
	Comparison of lithium with other members of the family (383)	
	Resemblance of lithium and magnesium (385)	
	Uses of alkali metals (385)	
	Extraction of Alkali Metals (386)	
	Properties of alkali metals and their uses (387)	
	Compounds of elements of Group I (388–94)	
	Role of Na^+ and K^+ ions in biological systems (394)	
	Sodium pump (394)	
14.	**THE ELEMENTS OF GROUP 2**	**396–415**
	General characteristics (396)	
	Atomic and ionic radii (397)	
	Ionization energies (397)	
	Reducing properties : Oxidation potentials (399)	
	Flame colouration (399)	
	Chemical properties (400)	
	Gradation in properties (400)	
	Comparison of beryllium with other elements of Group 2 (401)	
	Uses of alkaline earth metals (402)	
	Extraction of elements (402)	
	Properties and uses of alkaline earth metals (404)	
	Compounds of alkaline earth metals (405–414)	
	Comparison of solubility products of hydroxides and sulphates (406)	
	Complexes of beryllium (410)	
	Chlorophyll (411)	
	Portland cement (412)	
	Role of Mg^{2+} and Ca^{2+} ions in biological systems (414)	
15.	**THE ELEMENTS OF GROUP 13**	**416–447**
	General characteristics (416)	
	Ionization energies (417)	
	Oxidation states (417)	
	Electropositive character (417)	
	Tendency to form ionic compounds (417)	
	Tendency to form covalent compounds (418)	
	Action of air and water (418)	
	Diagonal relationship between boron and silicon (418)	
	Extraction of elements (419)	
	Properties of Elements (420)	
	Compounds of Group 13 elements (422)	
	Acidic, amphoteric and basic character of oxides and hydroxides (424)	
	Relative strengths of trihalides as Lewis acids. Effect of back bonding (426)	
	Characteristic difference in the structures of trihalides of boron and aluminium (428)	
	Borides (430)	
	Boron hydrides. Boranes (431)	
	Diborane — Preparation, properties and structure (432–434)	
	Bonding in boranes (434)	
	Carboranes (440)	
	Wade's rules (441)	
	Compounds of boron with nitrogen (442)	
	Borazine or borazole (443)	
	Boric acid (443)	
	Ultrmarine (446)	
16.	**THE ELEMENTS OF GROUP 14**	**448–488**
	General Characteristics (448)	
	Ionization energy (449)	
	Metallic and non-metallic character (449)	
	Nature of bonds in compounds (449)	
	Tendency to form chains. Catenation (450)	
	Extraction of elements (451)	
	Artificial diamonds (451)	
	Artificial graphite (451)	
	Properties of Elements (452)	
	Structure of Diamond (452)	
	Structure of graphite (453)	
	Fullerenes (454)	
	Properties of Group 14 elements (454–458)	
	Compounds of Group 14 elements (458–459)	

Chap.	Description	Page
	Difference between tetrahalides of carbon and tetrahalides of other elements (460)	
	Metal carbonyls, structure, preparation and properties (464–66)	
	Metal carbides (salt-like, covalent, interstitial, iron-type) (468)	
	Applications of carbides in industry (470)	
	Intercalation compounds of graphite (473)	
	Silicides (475)	
	Silica (476)	
	Glass, manufacture, varieties (478)	
	Silicates (480)	
	Types of silicates (481)	
	Orthosilicates (481)	
	Pyrosilicates (481)	
	Chain silicates (481)	
	Cyclic silicates (482)	
	Sheet silicates (482)	
	Three-dimensional silicates (483)	
	Mica, Clay, Fuller's earth (483)	
	Zeolites (484)	
	Zeolites as molecular sieves (484)	
	Silicones (484)	
	Lead pigments (486).	
17.	**THE ELEMENTS OF GROUP 15**	**489–535**
	General characteristics (490)	
	Metallic and non-metallic character (490)	
	Variation in physical state (490)	
	Positive oxidation states (491)	
	Negative oxidation states (491)	
	Catenation or self-linkage (491)	
	Allotropy (491)	
	Chemical reactivity (492)	
	Difference between nitrogen and the rest of the family members (492)	
	Extraction of elements (493)	
	Properties of elements of Group 15 (494)	
	Allotropic forms of phosphorus (495)	
	Chemical Properties of Phosphorus (497)	
	Properties of arsenic (498)	
	Marsh test (499)	
	Gutzeit test (499)	
	Compounds of Group 15 elements – a comparative study (501)	
	Hydrides (501)	
	Halides (504)	
	Oxohalides (506)	
	Oxides (507)	
	Oxoacids (512)	
	Sulphides (521)	
	Nitrides (521)	
	Hydrazine (524)	
	Hydrazoic acid (525)	
	Hydroxylamine (526)	
	Nitrogen trifluoride, nitrogen difluoride, nitrogen tetrafluoride (527–528)	
	Trisilyamine (529)	
	Hexamine (urotropine) (529)	
	Phosphazines (529)	
	Hexachlorocyclotriphosphazine (529)	
	Fertilizers (531).	
18.	**THE ELEMENTS OF GROUP 16**	**536–565**
	General characteristics (536)	
	Oxidation states (537)	
	Molecular structure (537)	
	Extraction of the elements (538)	
	Properties of elements of Group 16 (540)	
	Anomalous behaviour of oxygen (540)	
	Ozone (542)	
	Structure of ozone (542)	
	Allotropes of sulphur (544)	
	Role of selenium in xeroxography (546)	
	Compounds of elements of Group 16 (548)	
	Hydrides (548)	
	Halides (550)	
	Oxides (552)	
	Oxoacids (555)	
	Sulphurous acid (555)	
	Sulphuric acid (556)	
	Peroxosulphuric acids (558)	
	Caros's acid (559)	
	Marshall's acid (559)	
	Oxohalides of sulphur (562)	
	Nitrides of sulphur (563)	
	Organometallic compounds (564)	
19.	**THE ELEMENTS OF GROUP 17**	**566–610**
	General characteristics (566)	
	Non-metallic character (567)	
	Colour (567)	
	Electron affinity (567)	
	Oxidation states (568)	
	Oxidising power (568)	
	Combination with metals and non-metals (570)	
	Reaction with water (570)	
	Reaction with hydrocarbons (570)	
	Preparation of Elements of Group 17 (570)	

Chap. Description Page

Properties of elements of Group 17 (573)
Pecularities of fluorine, the first element of the group (574)
Compounds of Group 17 elements (576)
Hydrides of the halogens (576)
Relative strengths of hydrogen halides (577)
Oxides of the halogens (578)
Oxoacids of the halogen (579)
Hydrogen halides (580)
Oxides of fluorine (582)
Oxides of chlorine (582)
Oxides of bromine (582)
Oxides of iodine (582)
Oxoacids of the halogens (585)
Relative strengths of the oxoacids of the halogens (589)
Interhalogen compounds or interhalogens (591)
Structures of interhalogen compounds (597)
Pseudo halides and pseudo halogens (600)
Electropositive character of iodine (602)
Fluorocarbons (603)
Chlorine oxofluorides (605)
Bromine oxofluorides (608)
Iodine oxofluorides (608)

20. THE ELEMENTS OF GROUP 18 611–628

Occurrence (611)
History of discovery of noble gases (611)
Isolation of noble gases from the atmosphere (612)
Chemico-physical method (612)
The method based on fractionation of liquid air (614)
General physical properties (616)
Uses of noble gases (617)
Compounds of noble gases (618)
Compounds known before 1962 (hydrates and clathrates) (618)
Compounds discovered from 1962 onwards (619)
Fluorides, oxofluorides and oxides of xenon (620)
Compounds of xenon (II) (620)
Structure and shape of XeF_2 molecule (621)
Compounds of xenon (IV) (621)
Structure and shape of XeF_4 molecule (622)
Structure of $XeOF_2$ molecule (622)
Compounds of xenon (VI) (623)
Structure and shape of XeF_6 molecule (624)
Structure and shape of $XeOF_4$ molecule (625)
Structure and shape of XeO_2F_2 molecule (625)
Structure and shape of XeO_3 molecule (626)
Compounds of xenon (VIII) (626)
Structures of XeO_3F_2 and XeO_2F_4 molecules (627)
Fluorides of krypton and radon (627)

Chap. Description Page

21. THE *d* BLOCK ELEMENTS. GENERAL CHARACTERISTICS 629–638

Elements of First transition series (629)
Elements of Second transition series (629)
Elements of Third transition series (630)
General characteristics of *d* block elements (630)
Metalic character (630)
Molar volumes and densities (631)
Atomic radii (632)
Ionic radii (632)
Melting points and boiling points (632)
Ionization energies (632)
Reactivity (633)
Oxidation states (634)
Standard electrode potentials (634)
Reducing properties (635)
Colour (635)
Magnetic properties (636)
Catalyatic properties (638)
Tendency to form complexes (638)

22. THE ELEMENTS OF THE FIRST TRANSITION SERIES 639–685

Scandium (639)
compounds of (640)
Titanium (642)
compounds of (642)
Vanadium (644)
compounds of (646)
Chromium (650)
compounds of (652)
Manganese (656)
Aqueous chemistry of manganese in different oxidation states (657)
Potassium permanganate (660)
Iron (662)
Cast iron (662)
Wrought iron (663)
Steel (664)
Rusting of iron (666)
Aqueous chemistry of iron in different oxidation states (668)
Cobalt (672)
Aqueous chemistry of cobalt in different oxidation states (673)
Nickel (675)
Aqueous chemistry of Ni(II) (677)
Copper (678)
Aqueous chemistry of copper (I) (680)
Aqueous chemistry of Cu (II) (681)
Zinc (682)
Aqueous chemistry of Zn(II) (684)

Chap. Description Page

23. THE ELEMENTS OF THE SECOND TRANSITION SERIES 686–701

Yttrium (686)
compounds of (686)
Zirconium (686)
compounds of (688)
Niobium and Tantalum (688)
compounds of (689)
Molybdenum (690)
compounds of (691)
Technetium (694)
compounds of (694)
Ruthenium (694)
compounds of (695)
Rhodium (695)
compounds of (696)
Palladium (696)
compounds of (697)
Silver (798)
Cadmium (700)

24. THE ELEMENTS OF THE THIRD TRANSITION SERIES 702–717

Hafnium (702)
Tungsten (702)
compounds of (704)
Rhenium (705)
compounds of (705)
Osmium (706)
Iridium (707)
Platinum (708)
compounds of (709)
Gold (711)
compounds of (713)
Mercury (714)
Comparison of the properties of the three transition series (716)

25. THE *f* BLOCK ELEMENTS. THE INNER TRANSITION ELEMENTS 718–742

The Lanthanide Series (718)
Properties of Lanthanides (719)
Electronic configurations (719)
Oxidation states (719)
Ionic radii. Lanthanide contraction (721)
Colour (722)
Magnetic properties (722)
Oxidation potentials (723)
Basic character (723)
Solubility of compounds (724)

Chap. Description Page

Double salts (724)
Chemical reactivity (724)
Extraction of the mixture of lanthanides (724)
Separation of lanthanides (725)
Lanthanum (728)
Compounds of lanthanium (728)
The actinide series (729)
Transuranic elements (729)
Properties of actinides (730)
Oxidation states (732)
Ionic radii (732)
Colour of ions (732)
Formation of complexes (732)
Comparison with lanthanides (732)
Thorium (733)
Extraction (734)
Properties (734)
Compounds of thorium (735)
Uranium (735)
Extraction (735)
Compounds of uranium (737)
Plutonium (739)
Production (740)
Properties (740)
Compounds of plutonium (740)

26. COORDINATION COMPOUNDS. PART I Werner's Theory, Nomenclatrue, Stereochemistry and Isomerism 743–772

Double salts (743)
Coordination compounds (743)
Coordination complexes and complex ions (744)
Coordination number (745)
Unidentate, bidentate and polydentate ligands (745)
Important ligands (746)
Chelating ligands and chelates (747)
Physical methods in the study of complexes (748)
Werner's coordination theory (749)
Werner's theory and isomerism (750)
Nomenclature of coordination compounds (751)
Effective atomic number (EAN) (756)
Stability of complex ions. Stability constants (757)
Factors affecting the stability of a complex ion (757)
Determination of stability constants from thermodynamic data (760)
Irving William series (762)
Stereochemistry of coordination compounds with different coordination numbers (763)
Isomerism in coordination compounds (766)

Chap. Description Page

Structural isomerism (766)
Hydrate isomerism (766)
Coordination isomerism (767)
Linkage isomerism (767)
Coordination position isomerism (767)
Stereoisomerism (767)
Geometrical isomerism (767)
Optical isomerism (769)

27. COORDINATION COMPOUNDS. PART II Modern Theories of Metal-Ligand Bond 773–795

The valence bond theory (773)
main points of (773)
Shortcomings of V.B. theory (777)
The crystal field theory (778)
Crystal field splitting of energy levels (778)
Crystal field stabilization energy (CFSE) (780)
Magnetic properties of metal complexes and crystal field theory (783)
Factors influencing the magnitude of crystal field splitting (784)
Colour of transition metal complexes (786)
Ligand field theory (786)
Evidence of covalent bonding in metal-ligand bonding (787)
Molecular orbital theory of coordination complexes (788)
Sigma bonding in octahedral complexes (788)
Pi bonding in octahedral complexes (791)
Sigma bonding in tetrahedral complexes (792)
Pi bonding in tetrahedral complexes (793)
Sigma and pi bonding in square planar complexes (793)

28. COORDINATION COMPOUNDS. PART III Quantitative Treatment of Crystal Field Theory 796–819

Metal ions subjected to octahedral crystal field potential (796)
Derivation of expression for determining V_{oct} (802)
Changes in the energies of *d* orbitals (808)
Metal ions subjected to tetragonal crystal field potential (809)
Derivation of expression for determing $V_{tetragonal}$ (810)
Metal ions in a tetrahedral crystal field potential (811)
Derivation of expression for determining $V_{tetrahedral}$ (814)
Comparision of theoretical value of Dq with experimentally observed Dq (814)
Expression for V_{oct} in terms of Cartesian coordinates (815)

29. COORDINATION COMPOUNDS. PART IV Some Thermodynamic Aspects of Crystal Field Effects and Jahn-Teller Efect 820–841

Crystal field effects (820)

Chap. Description Page

Crystal field effect on :
ionic radii (820)
lattice energies (823)
heats of ligation (826)
geometry of coordination complexes (831)
Crystal field effects and spinel structures of some oxides (832)
Jahn-Teller effect (833)
Jahn-Teller effect and electronic spectra of complexes (838)

30. COORDINATION COMPOUNDS. PART V Electron Absorption Spectroscopy and Magnetochemistry of Transition Metal Complexes 842–915

Electron absorption spectroscopy of transition metal complexes (842)
Atomic spectroscopy (842)
Orbital angular momentum and spin angular momentum of an electron (842)
Coupling of single electron angular momenta (843)
Spin-spin coupling (844)
Orbital coupling (844)
Spin-orbital coupling (846)
The energy terms (846)
Coupling schemes (848)
Russel-Saunder's coupling scheme (848)
J-J coupling scheme (856)
Effect of V_{oct} and V_{tet} on terms (857)
Basic concepts of electron absorption spectroscopy (860)
Selection rules (861)
Spin selection rule (862)
Leporte selection rule (862)
Relaxation of selection rules (864)
Widths of absorption bands (866)
Relative variation of energy levels under the influence of crystal field potential (866)
Orgel diagrams (867)
Use of Orgel diagrams (869)
Application of Orgel diagrams to electronic spectra of transition metal complexes (869)
Charge transfer spectra (876)
Electronic absorption spectra of spin-paired complexes (877)
Spectrochemical series (878)
Magnetochemistry of transition metal complexes (879)
Origin of magnetism (880)
Diamagnetism (882)
Paramagnetism (883)
Measurement of magnetic susceptibility (884)
Guoy's method (884)
Evan's NMR method (886)

Chap. Description Page

Faraday's method (887)
Quinke's method (889)
Magnetic titrations (890)
Ferromagnetism and antiferromagnetism (890)
Magnetic behaviour of transition metal complexes (893) :
valence bond approach (896)
crystal field approach (899)
Quenching of orbital angular momentum (899)
energy terms in strong field complexes (902)
Terms correlationa diagrams for d^1 to d^9 octahedral and terahedral systems (903)
Tanabe-Sugano diagrams (910)
Evaluation of 10 Dq and *B* from Tanabe-Sugano diagrams (915)

31. COORDINATION COMPOUNDS. PART VI Reaction Mechanism 920–954

Substitution reactions in octahedral complexes (920)
Unimolecular nucleophilic substitution (S_N1) mechanism (920)
Bimolecular nucleophilic substitution (S_N2) mechanism (920)
Types of intermediates formed during S_N1 and S_N2 reactions (921)
Lability and inertness of octahedral complexes (922)
Interpretation of lability and inertness of transition metal complexes (923)
Valence bond theory (923)
Crystal field theory (924)
Lability of non-transition metal complexes (926)
Factors controlling lability (926)
Mechanism of acid hydrolysis of octahedral complexes when no inert ligand in the complex is a pi donor or pi acceptor (927)
Mechanism of acid hydrolysis of octahedral complexes when the inert ligand is a pi donor (931)
Mechanism of acid hydrolysis of octrahedral complexes when inert ligand is a pi acceptor (934)
Intermediates formed during aquation of complexes containing inert pi acceptor ligands (934)
Mechanism of base hydrolysis of octahedral complexes (935)
S_N1(CB) mechanism for base hydrolysis: explanation for the observed reaction rates in different cases (936)
Stereochemistry of intermediates of base hydrolysis (939)
Substitution reactions of square planar complexes (941)
Trans effect. Theories of trans effect (943)
Oxidation–reduction reactions (945) :
through atom or group transfer (945)
through electron transfer (946)
Electron transfer and law of conservation of energy (946)
Mechanism of electron transfer reactions in solution phase (948)
Outer sphere mechanism (948)

Chap. Description Page

Inner sphere mechanism (950)
Two-electron transfer reactions (952)

32. MONONUCLEAR COMPLEXES OF Pi ACCEPTOR LIGANDS 955–963

Pi acceptor ligands (955)
Mononuclear metal carbonyls (955)
Bonding in mononuclear metal carbonyls (955)
Infrared absorption spectra of metal complexes (957)
Determination of geometries of metal carbonyls (957)
Determination of bond order of CO (957)
Differentiating between terminal CO and bridging CO (958)
Structures of some common binary metal carbonyls (959)
Carbonyls of Ni, Pd and Pt (959)
Compounds of phosphorus and arsenic as pi acceptor ligands (959)
Complexes of nitric oxide (961)

33. METAL CLUSTERS 964–973

Metal clusters (964)
Carbonyl clusters (964)
Low nuclearity carbonyl clusters (964)
High nuclearity carbonyl clusters (965)
Electron counting scheme for HNCCS (966)
Wade's rules (966)
Halides type clusters (969)
Chevrel phases (973)
Zintl ions (naked clusters) (973)

34. ORGANOMETALLIC COMPOUNDS 974–1007

Organometallic compounds (974)
Ionic organometallic compounds (974)
Organometallic compounds of :
Group 2 elements (975)
Group 12 elements (977)
Group 13 elements (978)
Group 14 elements (980)
Group 15 elements (982)
Transition metals (984)
Organometallic compounds :
with multicentre bonds (986)
with pi bonded ligands (987)
Bonding in pi metal organometallic complexes (988)
Bonding in ferrocene (990)
Aromatic character of ferrocene (993)
Reactions of ferrocene: Reactions of C_5H_5 rings (electrophilic substitution reactions) (993)
interaction of Fe atom with ring substituents (995)
Aromaticity of cyclic C_nH_n ligands (995)

Chap. Description Page

Classification of ligands in organometallic compounds (999)
18-electron rule (inert gas rule) (999)
Counting of effective numbers of electrons (999)
Basis for the 18-electron rule (1001)
Concept of isolobality and isolobal analogies (1003)
Nomenclature of organometallic compounds (1003)

35. INORGANIC POLYMERS 1009–1052

Inorganic polymers (1009)
General properties (1009)
Glass transition temperature (1009)
Phosphorus-based polymers (1010)
Phosphorus-based chain polymers (1010)
Maddrell's salts (1013)
Kuroll's salts (1013)
Phosphorus-based net work polymers (1014)
Sulphur-based polymers (1017)
Boron-based polymers (1019)
Silicon-based polymers (1021)
Properties of silicones (1025)
Coordination polymers (1026)
Natural coordination polymers (1027)
Chain coordination polymers (1027)
Two-dimensional coordination polymers (1031)
Coordination polymers with three-dimensional network (1033)
Synthetic coordination polymers (1033)
Volan and quilon polymers (1033)
Polymers with cyclopentadienyl rings (1036)
Polymers with chelating agents (1037)
Polymers of polymeric ligands, Miscellaneous polymers (1038)
Isopoly and heteropoly acids and anions (1040)
Polymerisation of molybdates, tungslates, vanadates, niobates and tantalates (1041-1049)
Heteropoly anions and heteropoly acids (1049)

36. INORGANIC NOMENCLATURE 1053–1063

Writing symbols of elements and formulae of inorganic species (1053)
Inorganic nomenclature (1054)
Affixes used in inorganic nomenclature (1054)
Names of compounds in general (1056)
Names of ions (1056)
Names of radicals (1059)
Names of Isopolyanions (1059)
Names of heteropolyanions (1059)
Names of acids (1060)
Names of salts and salt-like compounds (1061)
Names of addition compounds (1062)

Chap. Description Page

Names of neutral hydrides (1062)
Names of boron hydrides (1062)

37. BIOINORGANIC CHEMISTRY 1064–1074

Myoglobin and hemoglobin (1064)
Role of myoglobin and hemoglobin in biological systems (1065)
Cooperativity effect (1066)
Explanation for cooperativity effect in hemoglobin (1066)
Metalloenzymes (1068)
Inhibition and poisoning of enzymes (1070)
Role of alkali and alkaline earth metal ions in biological systems (1071)
Sodium pump (1071)
Calcium pump (1072)
Biological functions and toxicity of some elements (1072)
Biological fixation of nitrogen (1073)

37. ENVIRONMENTAL CHEMISTRY 1075–1105

Environmental chemistry (1075)
Pollution (1076)
Long distance movement of pollutants (1075)
Air pollution (1076)
Carbon monoxide (1077)
Carbon dioxide (1078)
Chlorine (1078)
Oxides of nitrogen (1078)
Sulphur oxides; sulphuric acid rain (1079)
Hydrogen sulphide (1080)
Depletion of ozone layer (1080)
Effects of oxides of nitrogen on ozone layer (1081)
Flurocarbons and their effect on ozone layer (1081)
Particulates (1082)
Sources of particulates (1082)
Toxic efects of particulates (1083)
Smog (1084)
Photochemical smog (1084)
Mechanism of formation of photochemical smog (1084)
Monitoring of air pollutants (1085)
Control of air pollutants (1085)
Pesticides (1088)
Insecticides (1088)
Fungicides (1090)
Herbicides (1090)
Environmental effects of pesticides (1090)
Alternative methods of pest control (1092)
Autocide technique (1092)
Chemosterilization (1092)
Use of sex-attractants (1092)
Use of juvenile hormones (1092)

Chap. Description Page

Water pollution (1093)
Sewage and other oxygen-demanding wastes (1093)
Plant nutrients (1093)
Exotic organic chemicals (1094)
Inorganic minerals and chemical compounds (1094)
Pollution problems caused by surfactants (1097)
Treatment of domestic waste water (1097)
Reverse osmosis (1099)
Industrial waste water, its contamination and treatment (1100)
Soil pollution (1101)
Causes of soil pollution (1101)

39. NUCLEAR CHEMISTRY 1106–1130

Nuclear particles (1106)
Nuclear forces (1108)
Nuclear size (1108)
Nuclear density (1109)
Equivalence of a.m.u. and energy (1110)
Packing fraction (1110)
Mass defect. Binding energy of the nucleus (1110)
Binding energies and stability of nuclei (1112)
Nuclear shell model (1112)
The liquid drop model (1113)
Nuclear fission (1114)
Calculation of energy release in nuclear fission (1114)
The fission chain reactions. The concept of critical mass (1116)
Modes of release of fission energy (1116)
Thermal reactors (1117)
Fast breeder reactors (1117)
Nuclear fusion (1119)
Nuclear fusion in sun's atmosphere (1120)
Hydrogen bomb (1121)
Radioactivity (1122)
Rate of radioactive disintegration (1122)
Nature of radiations from radioactive elements (1123)
Detection and measurement of radioactivity (1124)
Geiger-Muller counter (1124)
Wilson cloud chamber (1124)
Radioactive tracers (1124)
Rock dating (1125)
Carbon dating (1125)
Artificial radioactivity (1126)
Artificial transmutation of elements (1126)
Cyclotron (1127)
Induced Radioactivity (1127)
Preparation of transuranic elements (1128)
Q-values of nuclear reactions (1128)
Nuclear coulombic barrier (1129)

40. EVALUATION OF ANALYTICAL DATA 1131–1149

Terms used in evaluation of analytical data (1131)

Chap. Description Page

Significant figures (1131)
Rounding off of the numerical expressions (1131)
Errors (1132)
Determinate errors (1133)
Correction of determinate errors (1134)
Indeterminate errors (1134)
Precision (1135)
Average deviation from the mean (1136)
Standard deviation (1137)
Relative standard deviation (1138)
Accuracy (1139)
Difference between precision and accuracy (1139)
Propagation of determinate errors (1140)
Standard deviations of computed results (1142)
Reporting of analytical data (1143)
Statistical treatment of analytical data (1144)
Standard deviation for 'sample' and 'population' of data' (1144)
Confidence limits, confidence interval (1145)
Student's t-values for various probability levels and varying degrees of freedom (1145)
Rejection of a result : quotient test (1146)
Tests of significance (1147)

41. VOLUMETRIC TITRIMETRY 1150–1170

Terminology (1150)
Basic requirements of a titration reaction (1150)
Standard solutions. Primary standards (1150)
Expressing concentrations of standard solutions (1151)
Volumetric titration co-relations (1152)
p-Functions (1154)
Acid-base titrations (1153)
Theory of acid-base indicators (1157)
Mathematical treatment (1158)
Redox titrations (1160)
Complexometric titrations (1163)
Polydentate titrants for complexometric titrations (1164)
EDTA titrations (1165)
Indicators for EDTA titrations (1165)
Titration curves (1167)
EDTA titration methods (1167)
Cautions in volumetric titrimetry (1169)
Corrections for unavoidable errors (1169)

Long form Periodic Table

WAVE MECHANICAL CONCEPTS OF ATOMIC STRUCTURE

1

John Dalton (1809) regarded the atom as a hard, dense and *smallest indivisible particle of matter*. However, the emission of negatively and positively charged particles from radioactive elements as well as from gases on the passage of electricity at very low pressures, convinced the scientists that *atom is not indivisible but consists of smaller fundamental particles*. It is now fully established that atom consists of three major fundamental particles called *electrons, protons* and *neutrons*.

Electron is a negatively charged particle having a charge equal to $1{\cdot}60206\times10^{-19}$ C and a mass equal to $9{\cdot}1091\times10^{-31}$ kg. Since the charge on the electron is the *smallest charge of electricity*, it is usual to speak of the charge on an electron as *unit negative charge*. The mass of electron on atomic mass scale is 0·0005487 a.m.u.

Proton is a positively charged particle with charge equal and opposite to that of electron and mass equal to $1{\cdot}6727\times10^{-27}$ kg. Thus, proton carries a *unit positive charge* and on atomic mass scale has a mass equal to 1·00728 a.m.u.

Neutron is a neutral particle having mass equal to $1{\cdot}6748\times10^{-27}$ kg. Thus, neutron carries *no charge* and on atomic mass scale has a mass equal to 1·00866 a.m.u.

Since atom is electrically neutral, it contains an equal number of electrons and protons.

Rutherford's Nuclear Model of the Atom. According to Rutherford's nuclear model :

1. An atom consists of a *minute positively charged body* located at its centre. It is called the **nucleus.** The nucleus, though small, contains all the protons and neutrons. Since the mass of an atom is almost entirely due to the presence of protons and neutrons, it is evident that *almost the entire mass of an atom resides in the nucleus.*

2. The nucleus is surrounded by a suitable number of **electrons** revolving around it to balance the positive charge on the nucleus.

3. Most of the space between the nucleus and the revolving electrons in an atom is empty (the radius of the atom is about 10^5 times as large as the radius of the nucleus).

The centrifugal force arising from the circular motion of electrons balances the force of electrostatic attraction between the nucleus and the electrons. The electrons, therefore, do not fall into the nucleus.

Objection to Rutherford's Model. It was pointed out by Niels Bohr that Rutherford's atom should be highly unstable. J. C. Maxwell had shown a few years earlier that whenever an electric charge is subjected to acceleration, it emits radiation and loses energy. Bohr argued, therefore, that since an electron, a charged particle, moves round the nucleus in an orbit as in Rutherford's model, it is subjected to acceleration. The electron should, therefore, continuously emit radiation and lose energy. As a result of this, its orbit should become smaller and smaller and finally it should drop into the nucleus. This, however, does not happen. Bohr supplied a solution to this problem on the basis of the quantum theory of radiation put forth by Max Planck in 1901. Before discussing Bohr's theory, we may give a brief description of Planck's quantum theory.

Planck's Quantum Theory of Radiation. In order to explain the spectral distribution of energy radiated by a black body, Max Planck put forth his celebrated theory known as the **quantum theory of radiation.** According to this theory :

1. Radiant energy is not emitted or absorbed continuously but *discontinuously* in the form of tiny bundles of energy called *quanta.*

2. Each quantum is associated with a definite amount of energy E which is proportional to the frequency (ν) of radiation, that is, $E \propto \nu$ or $E = h\nu$, where h is a fundamental constant known as ***Planck's constant.*** The numerical value of h is $6{\cdot}626 \times 10^{-34}$ J s.

3. A body can emit or absorb energy only in whole number multiples of quantum, *i.e.*, $E = nh\nu$ where $n = 1, 2, 3$..... This means that a body can emit or absorb energy equal to $1h\nu$, $2h\nu$, $3h\nu$..... Energy in fractions of a quantum, *i.e.*, $0{\cdot}7\ h\nu$, $1{\cdot}2\ h\nu$, $3{\cdot}6\ h\nu$, $4{\cdot}86\ h\nu$, etc., cannot be lost or absorbed. This is known as ***quantisation of energy.***

Photoelectric Effect and Quantum Theory. Sir J. J. Thomson, in some of his famous experiments, observed that when light of a *certain frequency* strikes the surface of a metal, *electrons are ejected from the metal.* The phenomenon of ejection of electrons from the surface of a metal when light of a suitable frequency strikes on it, is known as **photoelectric effect.** The ejected electrons are called *photoelectrons.* It may be noted that only a few metals show this effect under the action of visible light but many more show it under the action of more energetic ultraviolet light. Cesium, which amongst the alkali metals, has the lowest ionisation energy, is also the metal from which electrons are ejected most easily. This metal is, therefore, used largely in photoelectric cells.

It is important to note that light of *any* frequency will *not* be able to cause ejection of electrons from a metal surface. Only that light which is associated with a certain minimum frequency, called *threshold frequency,* can cause ejection of electrons.

The photoelectric effect cannot be explained on the basis of the classical wave theory of light according to which energy of light is directly related to the amplitude of electromagnetic wave and hence to the intensity of the radiation irrespective of its frequency. If this view is correct, light of *any frequency,* if made sufficiently intense, can cause ejection of electrons. But this does not happen.

The quantum theory of radiation affords an easy explanation for the photoelectric effect. According to this theory, light consists of bundles of energy called *photons,* the energy of the photon being equal to $h\nu$ where ν is the frequency of the light. When a photon of light of frequency ν_0 (threshold frequency) strikes an electron in a metal, it imparts its entire energy ($= h\nu_0$) to the electron. This energy enables the electron to break away from the atom by overcoming the attractive influence of the nucleus. Thus, each photon can eject one electron. If the frequency of the light is less than ν_0, there will be no ejection of electron. Now suppose the frequency of the light falling on a metal surface is higher than the threshold frequency. Let it be ν. When photon of this light strikes a metal surface, some of its energy (which is equal to the energy binding the electron with the nucleus), is consumed to separate the electron from the metal and the remaining energy will be imparted to the ejected electron to give it certain velocity, u. The ejected electron would thus be associated with kinetic energy $= 1/2\ mu^2$.

Einstein, applying quantum theory, showed that

$$h\nu = \phi + 1/2\ mu^2 \qquad ...(1)$$

where ϕ is the binding energy of the electron. It is also known as *work function* or *threshold energy.* Expressing ϕ in terms of threshold frequency, we may write, $\phi = h\nu_0$ so that

$$h\nu = h\nu_0 + 1/2\ mu^2 \qquad ...(2)$$

or

$$1/2\ mu^2 = h(\nu - \nu_0) \qquad ...(3)$$

Eq. 3 was tested by Millikan. The kinetic energies of the emitted electrons for various frequencies of light were determined by finding the opposing potential required to stop the photoelectric current. Knowing

kinetic energy corresponding to a given incident light of frequency ν and also knowing ν_0, *i.e.*, the threshold frequency, required just to cause ejection of electrons, the value of h was calculated. It was found to be $6{\cdot}570 \times 10^{-34}$ J s. This was in excellent agreement with the value $6{\cdot}626 \times 10^{-34}$ J s obtained from experiments on black body radiations.

Bohr's Model of the Atom

Niels Bohr, a Danish physicist, put forward his model of the atom in 1913. He retained Rutherford's model of a very-small positively charged nucleus at the centre which contains all the protons and neutrons present in an atom. Bohr also agreed that the negatively charged electrons are revolving round the nucleus in the same way as the planets are revolving round the sun. But he took a bold step forward by applying Planck's quantum theory to the electron revolving round the nucleus. The **important postulates of Bohr's theory** are :

1. *The electrons in an atom revolve around the nucleus only in certain selected circular orbits.* As long as the electron remains in a particular orbit, it neither loses nor gains energy. In other words, *the energy of an electron remains constant in a particular orbit.* This leads to the idea that *each orbit is associated with a definite energy, i.e.,* with *a definite whole number of quanta of energy.* The orbits, therefore, are also known as **energy levels** or **energy shells.** Bohr gave numbers 1, 2, 3, 4, etc., (starting from the nucleus) to these energy levels . These numbers are now termed as principal quantum numbers. The various energy levels are also designated by letters K, L, M, N, etc. The farther the energy level from the nucleus, the greater is the energy associated with it.

2. As long as the electron is associated with a particular amount of energy, it continues to stay in a a particular orbit. These obits are, therefore, also named as **stationary states.**

3. *The energy of an electron cannot change continuously.* It changes only **abruptly** as the electron *jumps* from one energy level to another. The same idea has been expressed by the statement that *for a change of electronic energy, the electron has to jump and not to 'flow' from one energy level to another.*

4. *The angular momentum of an electron moving round the nucleus is* **quantised.** An electron, like any other body moving in a circular orbit, has an angular momentum given by mvr where m is the mass, v is the linear velocity of the electron and r is the radius of the orbit. Bohr postulated that the angular momentum of an electron in an atom can have only *definite* or *discrete values* given by the expression

$$\text{Angular momentum} = mvr = n\,(h/2\pi) \qquad ...(4)$$

where n is any integer (1, 2, 3, etc.) Thus, the angular momentum of an electron may be $h/2\pi$ or a simple whole number multiple of $h/2\pi$ such as $2h/2\pi$, $3h/2\pi$,...$nh/2\pi$. This principle is known as **quantisation of angular momentum.**

Bohr's Equation for the Energy of Electron in Hydrogen or a Hydrogen-like Atom. Working on the above postulates, Bohr was able to calculate the energy of the electron moving in different orbits round the nucleus in a hydrogen or a hydrogen-like atom. He assumed, as had been suggested by Rutherford, that the electron remains in its orbit because the electrostatic force of attraction exerted by the nucleus is exactly balanced by the centrifugal force arising from its circular motion.

A hydrogen atom, having one proton in the nucleus and one electron outside the nucleus, is represented in Fig. 1.

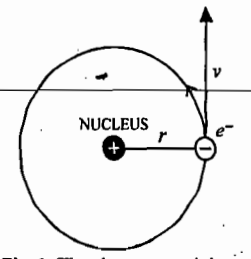

Fig. 1. The electron revolving around the nucleus in a hydrogen atom.

Let the charge on the nucleus be $+Ze$. For hydrogen atom, $Z = 1$ and for hydrogen-like atoms such as He^+ and Li^{2+}, $Z = 2$ and 3, respectively. The electron with charge $-e$ revolves round the nucleus in an orbit of radius r. Let v be the tangential velocity and m be the mass of the electron.

According to the laws of classical mechanics, the centripetal force acting on the electron in a hydrogen-like system, given by $Ze \times e/r^2$, tends to pull the electron towards the nucleus. However, the centrifugal force acting on the electron, given by mv^2/r, tends to take it away from its orbit. Under the influence of these two opposing forces, the electron keeps on revolving in its orbit. When the two forces balance,

$$Ze^2/r^2 = mv^2/r \quad ...(5)$$

Hence,

$$v^2 = Ze^2/mr \quad ...(6)$$

According to Bohr's postulate, the angular momentum, mvr, is an integral multiple of $h/2\pi$, *i.e.*, $mvr = n\,(h/2\pi)$ which leads to the expression

$$v = nh/2\pi mr \quad ...(7)$$

Squaring Eq. 7,

$$v^2 = n^2h^2/4\pi^2m^2r^2 \quad ...(8)$$

Eliminating v^2 from Eqs. 6 and 8, we have

$$Ze^2/mr = n^2h^2/(4\pi^2m^2r^2) \quad ...(9)$$

or

$$Ze^2 = n^2h^2/(4\pi^2mr) \quad ...(10)$$

According to Eq. 10, the radius r of the orbit is given by

$$r \equiv r_n = \frac{n^2h^2}{4\pi^2Zme^2} \quad ...(11)$$

Since, for hydrogen atom, $Z = 1$, hence,

$$r_n = \frac{n^2h^2}{4\pi^2me^2} \quad ...(12)$$

For hydrogen atom in the ground state ($n = 1$), the radius (r_1) is designated as the **Bohr's radius,** a_0. Thus,

$$r_1 \equiv a_0 = \frac{h^2}{4\pi^2me^2} \quad ...(13)$$

The total energy E of electron revolving in the nth orbit is equal to the sum of the kinetic energy ($= 1/2\, mv^2$) and the potential energy ($= -Ze^2/r_n$). Accordingly,

$$E = 1/2\, mv^2 - Ze^2/r_n \quad ...(14)$$

From Eq. 6,

$$mv^2 = Ze^2/r_n \quad ...(15)$$

Substituting the above value of mv^2 in Eq. 14, we have

$$E = \frac{Ze^2}{2r_n} - \frac{Ze^2}{r_n} = -\frac{Ze^2}{2r_n} \quad ...(16)$$

Substituting the value of r_n from Eq. 11 in Eq. 16, we get

$$E = -\frac{Ze^2}{2} \times \frac{4\pi^2Zme^2}{n^2h^2} \quad ...(17)$$

Thus, the **energy of electron in the nth orbit,** which we may designate as E_n, is given by

$$E_n = -\frac{2\pi^2Z^2me^4}{n^2h^2} \quad ...(18)$$

This is the famous **Bohr equation** applicable to hydrogen and hydrogen-like atoms such as He^+, Li^{2+}, Be^{3+}, etc.

In SI system, Eqs. 11 and 18 take the forms :

$$r_n = \frac{(4\pi\varepsilon_0)n^2h^2}{4\pi^2Zme^2} \quad ...(19)$$

$$E_n = -\frac{2\pi^2Z^2me^4}{(4\pi\varepsilon_0)^2n^2h^2} \quad ...(20)$$

The factor $4\pi\varepsilon_0$ is known as the **permittivity factor.** Its numerical value is $1{\cdot}11264 \times 10^{-10}\ C^2\ N^{-1}m^{-2}$.

We may now calculate some important quantities.

Bohr's Radius. According to Eq. 19, Bohr's radius of hydrogen atom (a_0) is given by

$$a_0 \equiv r_1 = \frac{(4\pi\varepsilon_0)h^2}{4\pi^2me^2} = \frac{(1{\cdot}11264\times10^{-10}\ C^2\ N^{-1}\ m^{-2})(6{\cdot}626\times10^{-34}\ J\ s)^2}{4\pi^2(9{\cdot}109\times10^{-31}\ kg)(1{\cdot}602\times10^{-19}C)^2}$$

$$= 0{\cdot}529\times10^{-10}\ m = 0{\cdot}529\ Å$$

Velocity of Electron. According to Eq. 7, the velocity of electron, say, in the first orbit of hydrogen atom, is given by

$$v_1 = \frac{(1)(6{\cdot}626\times10^{-34}\ J\ s)}{2\pi(9{\cdot}109\times10^{-31}\ kg)(0{\cdot}529\times10^{-10}m)} = 2{\cdot}188\times10^{6}\ m\ s^{-1}$$

It may be noted that this velocity is about (1/150)th of the velocity of light.

The velocity of electron in excited states, *i.e.*, when the electron is revolving in higher orbits of the hydrogen atom is obtained by putting $n = 2, 3, 4$, etc., in Eq. 7, provided the radius of the particular orbit is known. The radius can be calculated with the help of Eq. 12.

Energy of Electron. The energy of electron in hydrogen atom in ground state, *i.e.*, when it is revolving in the first orbit ($n = 1$), is easily obtained from Eq. 20. Thus,

$$E_1 = -\frac{(2\pi^2)(1)^2(9{\cdot}109\times10^{-31}kg)(1{\cdot}602\times10^{-19}C)^4}{(1{\cdot}11264\times10^{-10}\ C^2N^{-1}m^{-2})^2(1)^2(6{\cdot}626\times10^{-34}J\ s)^2} = -2{\cdot}179\times10^{-18}\ J\ per\ atom$$

$$= \frac{(-2{\cdot}179\times10^{-18}\ J\ atom^{-1})\,(6{\cdot}022\times10^{23}\ atoms\ mol^{-1})}{1000\ J/kJ} = -1312{\cdot}19\ kJ\ mol^{-1}$$

Since $1eV = 1{\cdot}602 \times 10^{-19}$ J, hence

$$E_1 = \frac{-2{\cdot}179\times10^{-18}\ J\ per\ atom}{1{\cdot}602\times10^{-19}J/eV} = -13{\cdot}6\ eV\ (per\ atom)$$

The energy of electron in excited states can be obtained by putting $n = 2, 3, 4$, etc., in Eq. 20.

Bohr's Theory and the Origin of Hydrogen Spectrum. Hydrogen atom contains only one electron. But its emission spectrum consists of a large number of lines (Table 1). Bohr supplied the reason. A given sample of hydrogen contains a very large number of atoms, of the order of several millions. Suppose energy is supplied to this sample of the gas. Now different atoms will absorb different amounts of energy. The solitary electron in different atoms will, therefore, shift to different energy levels depending upon the energy absorbed by the atoms. Some of the hydrogen atoms, for example, may absorb sufficient energy to shift their electrons to the second energy level only while some others may absorb more energy and may be able to shift their electrons to third or even to one of the higher energy levels. The electrons then tend to fall back, almost immediately, to one or the other of the lower energy levels. The various possibilities by which the electrons fall back from various excited state energy levels to lower energy levels (called

electronic transitions), are depicted in Fig. 2. During each transition, energy is released which appears in the form of radiation of specific frequency and hence of specific wave length.

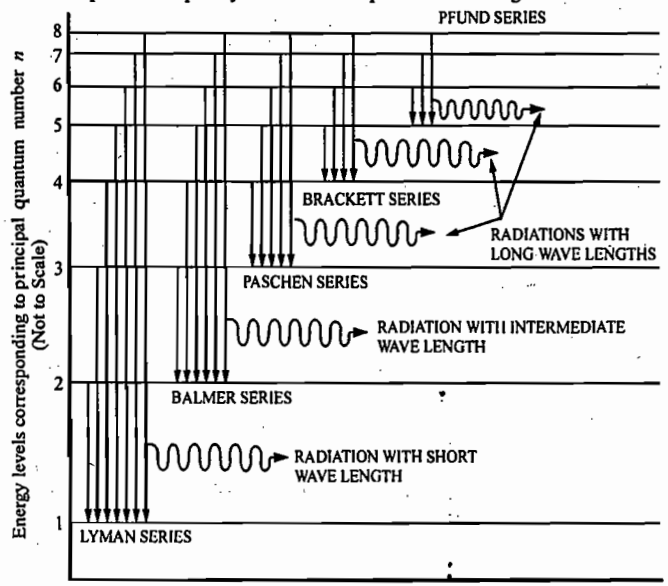

Fig. 2. The origin of hydrogen spectum.

Suppose an electron lying in energy level n_2 where its energy is E_2, jumps to a lower energy level n_1 where its energy is E_1. The energies in these two states, vide Eq. 20, are

$$E_2 = -\frac{2\pi^2 Z^2 me^4}{(4\pi\varepsilon_0)^2 n_2^2 h^2} \text{ and } E_1 = -\frac{2\pi^2 Z^2 me^4}{(4\pi\varepsilon_0)^2 n_1^2 h^2}$$

The difference in energy $\Delta E = E_2 - E_1$ would be emitted in the form of radiation of a specific frequency and hence of specific wave length. The emission spectrum of hydrogen would thus show a line at the frequency of the emitted radiation. If ν is the frequency of the spectral line, then

$$\Delta E = -\frac{2\pi^2 Z^2 me^4}{(4\pi\varepsilon_0)^2 n_2^2 h^2} + \frac{2\pi Z^2 me^4}{(4\pi\varepsilon_0)^2 n_1^2 h^2} \quad ...(21)$$

or

$$\nu = \frac{\Delta E}{h} = \frac{2\pi^2 Z^2 me^4}{(4\pi\varepsilon_0)^2 h^3}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right) \quad ...(22)$$

or

$$\bar{\nu} = \frac{1}{\lambda} = \frac{\nu}{c} = \frac{2\pi^2 Z^2 me^4}{(4\pi\varepsilon_0)^2 h^3 c}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right) \quad ...(23)$$

where $\bar{\nu}$, called the **wave number**, is the reciprocal of wave length in metres. It may be recalled that in Eq. 23, e is the charge in coulombs, m is the mass of electron in kg, h is Planck's constant in J s and c is the velocity of light in m s^{-1}.

The quantity $\frac{2\pi^2 Z^2 me^4}{(4\pi\varepsilon_0)^2 h^3 c}$ is called **Rydberg constant, *R***. Its value for the hydrogen atom is 109677·58 cm^{-1}.

The appearance of various series of spectral lines in the emission spectrum of hydrogen can be easily explained with the help of Eq. 23. The **Lyman series** are produced when the electron jumps from the second, third, fourth or a higher energy level to the first energy level. The frequencies of the various spectral lines of this series can thus be obtained by substituting $n_1 = 1$ and $n_2 = 2, 3, 4$, etc., in Eq. 23. The **Balmer series** result when the electron jumps from third, fourth, fifth, etc., energy levels to the second energy level. The frequencies of the various spectral lines of the Balmer series can, thus, be obtained by substituting $n_1 = 2$ and $n_2 = 3, 4, 5, 6$, etc. In the same way, the **Paschen series** originate from the electronic jumps from the fourth, fifth, sixth, etc., energy levels to the third energy level. The frequencies of these spectral lines can be obtained by substituting $n_1 = 3$ and $n_2 = 4, 5, 6$, etc., in Eq. 23, and so on.

The frequencies (in wave numbers) of the spectral lines of the three series calculated from Eq. 23 and those determined experimentally, are given in Table 1.

TABLE 1

Frequencies in Wave Numbers (m^{-1}) of Various Lines in the Emission Spectrum of Hydrogen

Lyman Series		Balmer Series		Paschen Series	
Experimental values	Calculated values	Experimental values	Calculated values	Experimental values	Calculated values
82·2×10^5	82·2×10^5	15·20×10^5	15·2×10^5	5·32×10^5	5·30×10^5
97·5	97·5	20·60	20·60	7·79	7·80
102·8	102·7	23·00	23·05	9·13	9·12
105·2	105·2	24·30	24·35	9·95	9·95
106·3	106·2	25·20	25·18	10·50	10·45
107·2	107·1	25·70	25·55	108·0	107·9

The agreement between the experimental and the calculated values is excellent. This offered a very strong support to Bohr's theory of the hydrogen atom.

Example 1. The electron in a hydrogen atom revolves in second orbit. Calculate : (1) The energy of the electron in this orbit. (2) The radius of the second orbit. (3) The frequency and wave length of the spectral line when the electron jumps from second orbit to the ground state. Given : mass of electron = 9·109×10^{-31} kg, charge on electron = 1·602×10^{-19} coulomb, velocity of light = 3·0×10^8 m s^{-1}, $4\pi\varepsilon_0$ = 1·11264 × 10^{-10} C^2 N^{-1} m^{-2}.

Solution : 1. Energy of Electron in Second Orbit. Energy of electron in hydrogen atom in the nth orbit is given by the expression

$$E_n = -\frac{2\pi^2 me^4}{(4\pi\varepsilon_0)^2 n^2 h^2} \quad \text{(Eq. 20)}$$

$$E_2 = -\frac{(2)(3{\cdot}1416)^2 (9{\cdot}109\times10^{-31}\text{kg})\times(1{\cdot}602\times10^{-19}\text{C})^4}{(1{\cdot}11264\times10^{-10}\text{C}^2\text{N}^{-1}\text{m}^{-2})^2\ (4)\ (6{\cdot}626\times10^{-34}\text{J s})^2}$$

$$= -\ 5{\cdot}447\times10^{-19}\ \text{J (per atom)}$$

$$= -\frac{(5{\cdot}447\times10^{-19}\text{J})\ \text{atom}^{-1}\ (6{\cdot}022\times10^{23}\ \text{atoms mol}^{-1})}{1000\ \text{J/kJ}} = -\ 328{\cdot}02\ \text{kJ mol}^{-1}$$

2. Radius of Second Orbit. Radius of nth orbit in hydrogen atom is given by the expression

$$r_n = \frac{(4\pi\varepsilon_0)n^2 h^2}{4\pi^2 me^2} \quad \text{(Eq. 19)}$$

$$\therefore \quad r_2 = \frac{(1{\cdot}11264\times10^{-10}\,C^2N^{-1}m^{-2})\ (4)\ (6{\cdot}626\times10^{-34}\ J\ s)^2}{4\ (3{\cdot}1416)^2\ (9{\cdot}109\times10^{-31}kg)\ (1{\cdot}602\times10^{-19}C)^2}$$

$$= 2{\cdot}115 \times 10^{-10}\,m = 2{\cdot}115\ Å$$

3. (a) Frequency of the Spectral Line. The frequency of spectral line in the case of hydrogen atom when the electron jumps from the second orbit to the ground state is given by

$$\nu = \frac{2\pi^2 me^4}{(4\pi\varepsilon_0)^2 h^3}\left(\frac{1}{1^2}-\frac{1}{2^2}\right) \qquad \text{(Eq. 22)}$$

$$= \frac{(2)\ (3{\cdot}1416)^2(9{\cdot}109\times10^{-31}kg)\ (1{\cdot}602\times10^{-19}\ C)^4}{(1{\cdot}11264\times10^{-10}\ C^2\cdot N^{-1}\ m^{-2})^2\times(6{\cdot}626\times10^{-34}\ J\ s)^3}\left[\frac{1}{1^2}-\frac{1}{2^2}\right]$$

$$= 2{\cdot}466 \times 10^{15}\ s^{-1}$$

(b) Wave length of the Spectral Line. Wave length of the spectral line would be given by

$$\lambda = \frac{c}{\nu} = \frac{3{\cdot}0\times10^8\ m\,s^{-1}}{2{\cdot}466\times10^{15}\ s^{-1}} = 1{\cdot}2165 \times 10^{-7}\,m = 1216{\cdot}5\ Å$$

Sommerfeld's Extension of Bohr's Theory. Bohr's theory of hydrogen atom enabled calculation of energies associated with various permissible orbits in the hydrogen atom. The calculated values were found to be in good agreement with the experimental values. Bohr's theory could also explain successfully the frequencies of various series of spectral lines in the hydrogen spectrum. The theory was, therefore, largely accepted and Bohr was awarded Nobel Prize in recognition of this work. However, a few years later, the use of spectroscopes of high resolving powers revealed the presence of *fine structures (i.e.,* groups of closely spaced lines in the spectrum of hydrogen. Bohr's theory could not explain the emission of groups of these closely spaced spectral lines. The theory was, therefore, extended by Sommerfeld by putting forward the idea of **elliptical orbits**.

According to Sommerfeld, an electron revolving around a central positively charged nucleus is so influenced by the nuclear charge that it is set into motion in *elliptical orbits* with the nucleus situated at one of the foci (Fig. 3). Thus, while according to Bohr's theory, electrons move in circular orbits, according to Sommerfeld's modification, electrons move in elliptical orbits. In the latter case, there will be a major axis and a minor axis having different lengths. As the orbit broadens, the lengths of the two axes become closer and they become equal when the orbit becomes circular, as shown in Fig. 3. Thus, the circular orbit is only a special case of elliptical orbits.

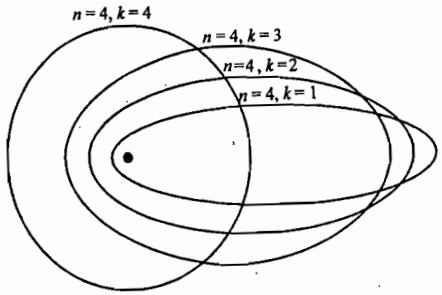

Fig. 3. Sommerfeld's elliptical orbits for $n = 4$.

The electron moving in an elliptical orbit will have its angular momentum. This momentum, according to the quantum theory, must also be quantised and thus can have only a limited number of values given by the factor $kh/2\pi$ where k is an integer known as the ***azimuthal quantum number***. It can be shown that n, the *principal quantum number* used by Bohr and k, the *azimuthal quantum number* ~~used by Sommerfeld, are related to each other as~~

$$\frac{n}{k} = \frac{\text{length of major axis}}{\text{length of minor axis}} \qquad ...(24)$$

Thus, for any given value of n (except 1), k can have more than a single value. When $k = n$, the orbit becomes circular. But, as k becomes smaller, the orbits become elliptical with greater and greater eccentricity. These facts are illustrated in Fig. 3. It may be noted that k cannot be zero because in that case minor axis would be zero which would imply linear motion of the electron passing through the nucleus.

As can be seen on reference to Fig. 3, the number of possible values of k is equal to the principal

quantum number n. Thus, if n is 4, k can have values varying from 4 to 1. It may have values of 4, 3, 2 and 1. When n is 1, k can have only one value.

According to Sommerfeld's extension of Bohr theory, referred to, sometimes, as Bohr-Sommerfeld theory, the energy depends not only on n, the principal quantum number but also, to some extent, on the azimuthal quantum number, k. Hence, the transition of an electron from one energy level n_2 to another energy level n_1 will be slightly different as it would also depend upon the various possible values of k in the two states. This explains the occurrence of groups of closely spaced lines observed in the hydrogen spectrum by using highly refined spectroscopes. The frequencies of these closely spaced lines were found to be in agreement with the values calculated from Bohr-Sommerfeld theory.

Alternative Explanation for the Emission of Multiple-line Spectrum of Hydrogen. The emission of groups of closely spaced spectral lines in the spectrum of hydrogen can be explained more effectively by taking into consideration the role of angular momentum of the electron, as illustrated below.

Electron moving around the nucleus in a particular orbit has a particular angular momentum called the *orbital angular momentum*. A portion of the energy of the electron is associated with its angular momentum which is described by the quantum number l called the **angular momentum quantum number**. This is related to the principal quantum number n as $l = n - 1$, the value of l will be 0, 1, 2, ... according as the value of n is 1, 2, 3, ..., respectively. The sublevels or subshells corresponding to $l = 0, 1, 2, 3,$ ..... are designated as *s, p, d, f,* ..... sublevels, respectively. Thus, if $n = 1$, l will have only one value, *i.e.*, 0 and there will be only one sub-shell, *viz.*, *s* subshell. For $n = 2$, l will have two values, *i.e.*, 0 and 1. There would thus be two subshells, *i.e.*, *s* and *p* subshells. If $l = 0$, the electron will be located in the *s* subshell of second major energy shell and if $l = 1$, the electron will be located in the *p* subshell of the second major energy shell. For $n = 3$, l will have three values, *i.e.*, 0, 1 and 2. There would thus be three subshells, *viz.*, *s, p* and *d* subshells according as the value of l is 0, 1 and 2 respectively, in which the electron can be located and so on.

The existence of various subshells in a given major energy shell, accounts for the appearance of groups of closely spaced lines in the spectrum of hydrogen observed using spectroscopes of high resolving power since the electronic transitions take place not only between the major energy shells but also between the various energy subshells.

According to Heisenberg's uncertainty principle (to be discussed shortly), it is impossible to determine simultaneously the exact position and exact velocity (momentum) of a small moving particle like an electron. The postulate of Bohr's theory that electrons revolve around the nucleus in *well defined orbits with well defined velocities* is thus not tenable. In order to overcome this shortcoming, the use of the term orbit in electronic motion has been dispensed with. In its place, we exclusively make use of the term **energy level** or **energy shell**. This is because the velocity of the electron can be measured with certainty but not its position.

Particle and Wave Character (Dual Character) of Electron. Einstein had suggested in 1905 that light has a *dual character* : as *wave* and also as '*particle*'. de Broglie proposed that *matter also has a dual character* : as wave and also as particle.

In Bohr's theory, electron is treated as a particle. But, according to de Broglie's theory, *electron has a dual character*, both as a material particle and as a wave. He derived (see below) an expression for calculating the wave length λ associated with the motion of a particle of mass m moving with velocity u, according to which $\lambda = h/mu$ where h is Planck's constant.

Derivation of de Broglie's equation. The de Broglie's equation for the wave-particle duality of electron can be easily derived by using Einstein's mass-energy relationship, *viz.*, $E = mc^2$. Equating this energy with the energy of a photon, we have

$$h\nu = mc^2 \qquad ...(25)$$

Since $\nu = c/\lambda$, hence

$$hc/\lambda = mc^2 \qquad ...(26)$$

or

$$\lambda = h/mc \qquad ...(27)$$

Replacing c by the velocity u of the particle, we have

$$\lambda = h/mu = h/p \qquad ...(28)$$

where p is the momentum of the particle. Eq. 28 is known as **de Broglie's equation**.

Distinction between matter waves and electromagnetic waves. It should be carefully noted that matter waves are *distinctly different* from electromagnetic waves. The speed of these waves is not the same as that of light. These waves cannot be radiated in empty space. They are certainly not emitted by the particle under consideration; they are simply associated with its motion. The wave lengths of matter waves are generally very small as compared with the wave lengths of electromagnetic waves.

Experimental Verification of de Broglie's Equation. The verification of de Broglie's equation is possible only by deriving from it certain consequences which may then be tested experimentally.

Let an electron of charge e be accelerated by a potential V. Then its kinetic energy would be Ve. The kinetic energy is also written as $1/2\, mu^2$ where u is the velocity of the electron.

$$1/2\, mu^2 = Ve \qquad ...(29)$$

$\therefore$ Inserting this value of u in de Broglie's equation, we have

$$\lambda = h / (2Vem)^{1/2} \qquad ...(30)$$

Substituting numerical values of various quantities, we have

$$\lambda = \frac{6{\cdot}626\times10^{-34}\,\text{J s}}{[(2)(V)(1{\cdot}602\times10^{-19}\,\text{C})(9{\cdot}109\times10^{-31}\,\text{kg})]^{1/2}} \qquad ...(31)$$

$$= 12{\cdot}26\times10^{-10}\,V^{-1/2}\ \text{metre}$$

where V is the numerical value of potential in volts.

If an electron is accelerated through a potential of 100 volts, its wave length should be $1{\cdot}226\times10^{-10}$ m, *i.e.*, 1·226 Å. If potentials are varied between 10 and 10,000 volts, λ should vary between 3·877 and 0·1266 Å. It is well known that X-rays have wave lengths of this order. It is also well known that crystalline solids can act as diffraction gratings for X-rays having wave lengths of the above order. Therefore, if de Broglie's view regarding wave-particle duality of electron is correct, the crystalline solids should act as diffraction gratings for a beam of electrons as well. This has been found to be so experimentally.

The Davisson and Germer Experiment. The de Broglie's bold hypothesis regarding wave character of electron received first experimental support from Davisson and Germer in 1927. In their experiment, electrons were emitted from a hot filament and were accelerated by a potential ranging between 40 and 68 volts before striking a nickel plate, as shown in Fig. 4.

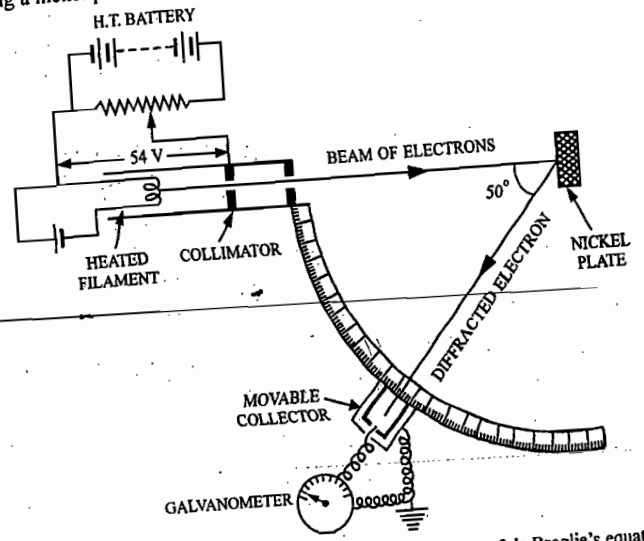

Fig. 4. The Davisson and Germer experiment for verification of de Broglie's equation.

They found that the impact of electrons resulted in the *production of diffraction patterns which were similar to those given by X-rays under similar conditions.* Since X-rays possess wave character, *the electrons must also have wave character associated with them.* Thus, this experiment gave *direct evidence for the wave character of electron.*

The intensities of electron waves scattered by the nickel plate at different angles were measured. It was found that the reflection was most intense and took place at an angle of 50° when electrons were accelerated through 54 volts. Substituting the value of V as 54 volts in Eq. 31, it can be shown that the value of λ, the wave length of the electron wave comes out to be 1·668Å. This wave length also lies in the X-ray range. This is another point of similarity between electron waves and X-rays. It should be possible, therefore, to apply Bragg's equation, derived for X-ray diffraction, to electron diffraction as well. According to this equation

$$2\,d\sin\theta = n\lambda \qquad ...(32)$$

where n is an integral multiple (1, 2, 3, etc.) of wave length λ for a reflection of maximum intensity, d is the distance between successive lattice planes of the crystal (nickel plate in the present case) and θ is the grazing angle of the wave. Davisson and Germer found the value of λ to be very close to that obtained by de Broglie's equation. Davisson and Germer's experiment thus offered full support to de Broglie's views and his equation.

The de Broglie's concept about dual character of matter is significant only for microscopic particles such as electrons, protons, atoms and molecules. It loses its significance when applied to macroscopic bodies. This is because the wave lengths of matter waves associated with macroscopic bodies are too small to be measured by any conceivable technique. Therefore, we can safely comment that "macroscopic bodies have no de Broglie wave lengths."

The wave length associated with an electron of mass $9{\cdot}11\times10^{-31}$ kg moving with a velocity of 10^6 m s^{-1} is 7·27Å, as shown below :

$$\lambda = \frac{h}{mu} = \frac{6{\cdot}626\times10^{-34}\,\text{J s}}{9{\cdot}11\times10^{-31}\,\text{kg}\times10^{6}\,\text{m s}^{-1}} = 0{\cdot}727\times10^{-9}\,\text{m} = 7{\cdot}27\text{Å} \qquad (\text{J} = \text{kg m}^2\,\text{s}^{-2})$$

On the other hand, the wave length associated with a ball weighing 0·01 kg and moving with the same velocity as that of electron (10^6 m s^{-1}) is $6{\cdot}626\times10^{-28}$ Å, as shown below :

$$\lambda = \frac{h}{mu} = \frac{6{\cdot}626\times10^{-34}\,\text{J s}}{0{\cdot}01\,\text{kg}\times10^{6}\,\text{m s}^{-1}} = 6{\cdot}626\times10^{-38}\,\text{m} = 6{\cdot}626\times10^{-28}\,\text{Å}$$

This wave length is far far shorter than the wave length of any electromagnetic radiation.

Example 2. The kinetic energy of an electron has been found to be $5{\cdot}76\times10^{-15}$ J. Calculate the wave length associated with the electron. (Mass of electron = $9{\cdot}1\times10^{-31}$ kg, $h = 6{\cdot}626\times10^{-34}$ J s).

Solution : Kinetic energy of the electron $= 1/2\, mu^2 = 5{\cdot}76\times10^{-15}$ J (given)

$\therefore$ $mu^2 = 5{\cdot}76\times10^{-15}\times2$ J

or $$u^2 = \frac{5{\cdot}76\times10^{-15}\times2\,\text{J}}{9{\cdot}1\times10^{-31}\,\text{kg}} = 1{\cdot}266\times10^{16}\,\text{m}^2\,\text{s}^{-2} \qquad (\text{J} = \text{kg m}^2\,\text{s}^{-2})$$

or $u = 1{\cdot}12\times10^{8}$ m s^{-1}

Using de Broglie equation, $$\lambda = h/mu = \frac{6{\cdot}626\times10^{-34}\,\text{J s}}{(9{\cdot}1\times10^{-31}\,\text{kg})(1{\cdot}12\times10^{8}\,\text{m s}^{-1})} = 6{\cdot}50\times10^{-12}\,\text{m}$$

$$= 0{\cdot}0650\ \text{Å}$$

Wave nature of electron and quantisation of angular momentum. Consider an electron moving in a circular orbit around a nucleus. The associated wave train would be as shown in Fig. 5. Evidently, if the wave is to remain continually in phase (Fig. 5*a*), the circumference of the circle must be an integral multiple of wave length λ, that is,

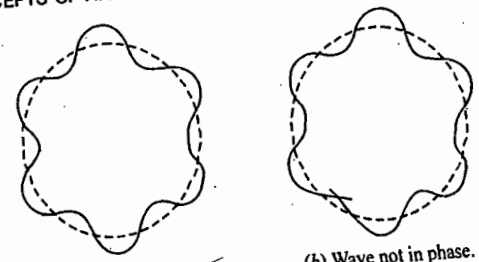
$$\text{circumference} = n\lambda$$

$$2\pi r = n\lambda = nh/mu$$

$$\therefore \quad mur = n\,h/2\pi$$

Evidently, if the circumference is bigger or smaller than the value $nh/2\pi$ given in Eq. 33, the wave will no longer remain in phase (Fig. 5*b*).

Since mur represents the angular momentum of the electron, it follows from Eq. 33 that the electron can move only in those orbits for which the angular momentum is an integral multiple of $h/2\pi$. In other words, *the angular momentum is quantised.* This is nothing but Bohr's postulate which was put forth by him without any theoretical basis.



(*a*) Wave continually in phase. (*b*) Wave not in phase.

Fig. 5. The wave trains associated with an electron moving in a circular path around a nucleus.

Heisenberg's Uncertainty Principle. According to this principle, *it is not possible to determine precisely both the position and the momentum (or velocity) of a moving minute particle.* This principle is mathematically expressed as :

$$(\Delta x) \times (\Delta p) = h/4\pi \qquad ...(34)$$

where Δx is uncertainty with regard to the position and Δp is uncertainty with regard to the momentum of the particle. Evidently, if Δx *is very small, i.e.,* the position of the particle is known more or less exactly, Δp would be *large, i.e.,* uncertainty with regard to momentum will be large. Similarly, if an attempt is made to measure exactly the velocity (momentum) of the particle, the uncertainty with regard to position will become large.

The physical concept of the uncertainty principle may become clear when it is realised that all observations have to be made by the impact of light radiations (photons). If the object is of reasonable size, its position or velocity will not be altered by the impact of light photons. Hence, it will be possible to know precisely both the position and the velocity of the object. In other words, the uncertainty Δx or Δp would be negligible. But this cannot be so when the object is extremely minute, such as an electron moving, say, in a circular path. *It will suffer a change in its velocity and path due to the impact of even a single photon of light used to observe it.*

In view of the uncertainty principle, Bohr's model, in which electrons are considered as particles revolving in *definite orbits with definite velocities* becomes untenable. It is not possible to know exactly the position of an electron moving with *a particular velocity* as is implied in Bohr's model. Instead, *it is possible only to state or predict the* **probability** *of locating an electron moving with a particular velocity in a given region of space around the nucleus at a given time.*

Example 3. An electron has a speed of 300 m s^{-1} accurate upto 0·001%. What is the uncertainty in locating its position ? Mass of an electron = 9·1×10^{-31} kg

Solution : According to uncertainty principle, $(\because p = mu)$

$$\Delta x \times m\,\Delta u = h/4\pi$$

$$\Delta u = \frac{0{\cdot}001}{100} \times 300 \text{ m s}^{-1} = 0{\cdot}003 \text{ m s}^{-1}$$

$$\therefore \quad \Delta x \times 9{\cdot}1\times10^{-31} \text{ kg} \times 0{\cdot}003 \text{ m s}^{-1} = 6{\cdot}626 \times 10^{-34} \text{ J s}/4\pi \qquad (\text{J} = \text{kg m}^2 \text{ s}^{-2})$$

$$\Delta x = 1{\cdot}93 \times 10^{-2} \text{ m}$$

or

Example 4. A microscope using suitable photons is employed to locate an electron in an atom within a distance of 0·1 Å. What is the uncertainty involved in the measurement of its velocity ? Mass of electron = 9·1 × 10^{-31} kg and Planck's constant (h) = 6·626 × 10^{-34} J s.

Solution : According to uncertainty principle,

$$\Delta x \times \Delta p = h/4\pi$$

$$\Delta x \times m\Delta u = h/4\pi$$

or

$$\Delta x = 0{\cdot}1 \times 10^{-10} \text{ m}$$

$$\therefore \quad 0{\cdot}1\times10^{-10} \text{ m} \times 9{\cdot}1\times10^{-31} \text{ kg} \times \Delta u = 6{\cdot}626 \times 10^{-34} \text{ J s}/4\pi$$

$$\Delta u = 5{\cdot}79 \times 10^{6} \text{ m s}^{-1} \qquad (\text{J} = \text{kg m}^2 \text{ s}^{-2})$$

Example 5. A cricket ball weighing 100 g *is to be located within* 0·1Å. What is the uncertainty in its velocity ? Comment on your result.

Solution : According to uncertainty principle,

$$\Delta x \times \Delta p = h/4\pi$$

or

$$\Delta p = h/(4\pi\,\Delta x)$$

$$\Delta x = 0{\cdot}1 \text{ Å} = 1 \times 10^{-11} \text{ m}$$

$$\therefore \quad \Delta u = \Delta p/m = \frac{h}{4\pi\Delta x \times m} = \frac{6{\cdot}626\times10^{-34} \text{ J s}}{4\pi(10^{-11} \text{ m})\ (0{\cdot}1 \text{ kg})}$$

$$= 5{\cdot}27 \times 10^{-23} \text{ m s}^{-1} \qquad (\text{J} = \text{kg m}^2 \text{ s}^{-2})$$

Comparing this value with the usual velocity of a cricket ball, we find that this uncertainty in velocity is negligible. This means that we can disregard the uncertainty principle for the motion of macroscopic bodies. In such cases, both the position and velocity can be simultaneously determined to a reasonable degree of precision.

Example 6. According to Bohr's theory of hydrogen atom, the velocity of electron in the first orbit is 10^6 m s^{-1}. Suppose the electron can be located in the orbit within 0·1Å. What will be the uncertainty in its velocity ? Comment on your result.

Solution : According to uncertainty principle,

$$\Delta p \times \Delta x = h/4\pi$$

or

$$m\,\Delta u \times \Delta x = h/4\pi$$

$$\Delta x = 0{\cdot}1\text{Å} = 1 \times 10^{-11} \text{ m}$$

$$\Delta u = \frac{h}{4\pi m\,\Delta x} = \frac{6{\cdot}626\times10^{-34} \text{ J s}}{4\pi(9{\cdot}1\times10^{-31}\text{kg})(10^{-11}\text{m})} = 5{\cdot}79 \times 10^{6} \text{ m s}^{-1}$$

But $\quad u = 10^6 \text{ ms}^{-1}$ (given)

This means that the uncertainty in velocity is greater than the velocity itself ! This appears to be ridiculous. One can avoid making such a statement by bearing in mind that when the position of the electron is specified with sufficient accuracy, it is meaningless to talk about its velocity at the same time.

The Compton Effect. Compton found that if monochromatic X-rays, *(i.e.,* X-rays having one particular wave length), are allowed to fall on carbon or some other light element, the scattered X-rays have wave lengths longer than the wave length of the incident rays. In other words, the scattered X-rays have lower frequency, *i.e.,* lower energy than the incident X-rays. Since scattering is caused by electrons present in the atoms of the elements, it is evident that some interaction between X-rays and electrons has taken place and this has resulted in decrease in the energy of the former. This decrease in energy or increase in wave length of X-rays after scattering from the surface of an object is known as **Compton effect.**

By applying the law of conservation of energy and the law of conservation of momentum and assuming X-rays to consist of 'particles' (photons), each possessing energy equal to $h\nu$, Compton derived the following equation :

$$\Delta\lambda = (2h/mc)\sin^2\theta/2 \qquad ...(35)$$

where $\Delta\lambda$ is the increase in wave length (termed as **Compton shift**) produced as a result of the collision, m is the rest mass of the electron, c is the velocity of light and θ is the angle between the incident and the scattered X-rays.

According to this equation, Compton shift should be independent of the wave length of the incident X-rays. This has been found to be so experimentally. Further, the values of Compton shift, as obtained

from the above equation by substituting the known values of h, c, m and θ, have been found to be in close agreement with the experimental values.

Compton effect provides a good illustration of the uncertainty principle. Suppose, X-rays are employed to determine the position and momentum of an electron. As a result of mutual interaction of X-rays and the electrons, the wave length of X-rays increases, *i.e.*, the frequency or energy of the X-rays decreases. This energy must have been transferred to the electron and, therefore, the momentum of the electron must have changed during the process. Consequently, the momentum (and hence velocity) of the electron cannot be determined with certainty.

Compton effect also provides evidence for the corpuscular or photon nature of radiation.

The Compton equation (35) can also be written as

$$\Delta\lambda = \lambda' - \lambda = \frac{2h}{mc} \times \frac{1}{2}\left[1 - \cos 2\theta/2\right] = \left(\frac{h}{mc}\right)(1 - \cos\theta) \qquad ...(36)$$

We see that the wave length λ' of scattered X-rays is always greater than the wave length λ of incident X-rays. The quantity $\Delta\lambda$ is also called the **wave length shift.** The wave length shift is independent of the nature of the substance and the wave length of incident X-rays. It depends only on the scattering angle θ. The following three cases may be considered :

Case 1. $\theta = 0°$, *i.e.*, the scattered radiation is parallel to the incident radiation. In this case, $\cos\theta = 1$ so that $\Delta\lambda = 0$, *i.e.*, there is no wave length shift.

Case 2. $\theta = 90°$, *i.e.*, the scattered radiation is perpendicular to the incident radiation. In this case, $\cos\theta = 0$ so that

$$\Delta\lambda = \frac{h}{mc} = \frac{6{\cdot}626 \times 10^{-34}\ \text{J s}}{(9{\cdot}109 \times 10^{-31}\ \text{kg})(3 \times 10^{8}\ \text{m s}^{-1})} \qquad (\text{J} = \text{kg m}^2\,\text{s}^{-2})$$

$$= 0{\cdot}02422 \times 10^{-10}\ \text{m} = 0{\cdot}0242\ \text{Å}$$

Case 3. $\theta = 180°$, *i.e.*, the radiation is scattered in a direction opposite to the incident radiation. In this case, $\cos\theta = -1$ so that

$$\Delta\lambda = 2h/mc = 2 \times 0{\cdot}0242\ \text{Å} = 0{\cdot}0484\ \text{Å}$$

QUANTUM MECHANICS OR WAVE MECHANICS

Classical mechanics, formulated by Isaac Newton, is obeyed by *macroscopic* particles such as planets and rigid bodies. Since the *microscopic* particles such as electrons, protons, atoms and molecules exhibit wave-particle duality, they do not obey Newtonian dynamics. On the other hand, they obey quantum mechanics or wave mechanics, the laws of which were formulated by Born, Heisenberg and Jordan in 1925 and by Schrodinger in 1926. The Schrodinger formulation is more familiar to chemists than the Born-Jordan-Heisenberg formulation. In classical mechanics, the state of a system is defined by specifying the forces acting on the particle and the exact position and velocity acquired by the particle as a result of these forces. It is impossible, however, to specify simultaneously the exact position as well as exact velocity in the case of a microscopic particle (Heisenberg uncertainty principle). Therefore, while classical mechanics allows us to predict the exact paths (or trajectories) taken by the particles of a macroscopic system, quantum mechanics gives the **probabilities** of the location of the particles of a microscopic system at various places in space.

As we shall see shortly, in quantum mechanics, the state of a system is defined by the *state function* or **wave function** ψ, which is a function of the coordinates of the particles of the system and is also a function of time (since the state may change with time). Thus, for a two-particle system, the wave function can be written as

$$\psi = f(x_1, y_1, z_1, x_2, y_2, z_2, t)$$

where x_1, y_1, z_1 are the coordinates of particle 1, etc. For an n-particle system, the equation governing the time-dependence of ψ is given by

$$\sum_{i=1}^{n} -\frac{\hbar^2}{2m_i}\left(\frac{\partial^2\psi}{\partial x_i^2} + \frac{\partial^2\psi}{\partial y_i^2} + \frac{\partial^2\psi}{\partial z_i^2}\right) + V(x_i, y_i, z_i, t)\psi = i\hbar\frac{\partial\psi}{\partial t}$$

where m_i is the mass and V is the potential energy of the particle.

The above equation is the celebrated time-dependent second-order differential equation, known as the Schrodinger wave equation.

It may be noted that if the velocity of a microscopic particle is far less than the velocity of light, then quantum mechanics gives the same results as Newton's classical mechanics. Also when the systems are in highly excited quantum states, classical mechanics and quantum mechanics tend to yield the same results.

The Postulates of Quantum Mechanics or Wave Mechanics. The formulation of quantum mechanics or wave mechanics for the wave mechanical treatment of the structure of atom rests upon a few postulates which, for a system moving in one dimension, say, the x-coordinate, are given below.

First Postulate. The physical state of a system at time t is described by the wave function $\psi(x, t)$.

Second Postulate. The wave function $\psi(x, t)$ and its first and second derivatives $\partial\psi(x, t)/\partial x$ and $\partial^2\psi(x, t)/\partial x^2$ are continuous, finite and single-valued for all values of x. Also, the wave function $\psi(x, t)$ is *normalized, i.e.,*

$$\int_{-\infty}^{\infty} \psi^*(x,t)\psi(x,t)\,dx = 1 \qquad ...(37)$$

where ψ^* is the *complex conjugate* of ψ formed by replacing i with $-i$ wherever it occurs in the function ψ. $(i = \sqrt{-1})$

Third Postulate. A physically observable quantity can be represented by a *Hermitian operator.* An operator A is said to be Hermitian if it satisfies the following condition :

$$\int \psi_i^* \hat{A}\psi_j\,dx = \int \psi_j (\hat{A}\psi_i)^*\,dx \qquad ...(38)$$

where ψ_i and ψ_j are the wave functions representing the physical states of the quantum system, *i.e.*, a minute particle such as an electron, proton, an atom or a molecule.

Fourth Postulate. The allowed values of an observable A are the eigenvalues, a_i, in the operator equation

$$\hat{A}\psi_i = a_i\psi_i \qquad ....(39)$$

Eq. 39 is known as an *eigenvalue equation.* Here $\hat{A}$ is the operator for the observable (physical quantity) and ψ_i is an eigenfunction of $\hat{A}$ with eigenvalue a_i. In other words, measurement of the observable A yields the eigenvalue a_i.

Fifth Postulate. The average value (or, the expectation value), $\langle A \rangle$, of an observable A, corresponding to the operator $\hat{A}$, is obtained from the relation

$$\langle A \rangle = \int_{-\infty}^{+\infty} \psi^* \hat{A}\,\psi\,dx \qquad ....(40)$$

where the function ψ is assumed to be normalized in accordance with Eq. 37. Thus, the average value of, say, the x-coordinate is given by

$$<x> = \int_{-\infty}^{\infty} \psi^* \hat{x}\, \psi\, dx \qquad ...(41)$$

Sixth Postulate. The quantum mechanical operators corresponding to the observables are constructed by writing the classical expressions in terms of the variables and converting the expressions to the operators, as shown in Table 2.

TABLE 2

Wave Mechanical Operators for Evaluating Various Classical Variables

Classical variable	Quantum mechanical operator	Operator	Operation
x	$\hat{x}$	x	Multiplication by x
p_x	$\hat{p}_x$	$-i\hbar\frac{\partial}{\partial x}$	Taking derivative with respect to x and multiplying by $-i\hbar$
x^2	$\hat{x}^2$	x^2	Multiplication by x^2
p_x^2	$\hat{p}_x^2$	$-\hbar^2\frac{\partial^2}{\partial x^2}$	Taking second derivative with respect to x and multiplying by $-\hbar^2$
t	$\hat{t}$	t	Multiplying by t
E	$\hat{E}$	$i\hbar\frac{\partial}{\partial t}$	Taking derivative with respect to t and multiplying by $i\hbar$

Seventh Postulate. The wave function $\psi(x, t)$ is a solution of the time-dependent equation

$$\hat{H}\psi(x,t) = i\hbar\frac{\partial\psi(x,t)}{\partial t} \qquad ...(42)$$

where $\hat{H}$ is the *Hamiltonian operator* of the system.

The Schrodinger Wave Equation. It is evident from the earlier discussion that moving electrons behave both as particles and as a wave. If the electrons behave as a wave, there must be a wave equation to describe their behaviour. Erwin Schrodinger, in 1926, gave a wave equation to describe the wave behaviour of electrons in atoms and molecules. In Schrodinger wave model of an atom, the discrete energy levels or orbits proposed by Bohr are replaced by mathematical functions ψ which are related with the probability of finding electrons at various places around the nucleus.

The Schrodinger wave equation for an electron wave propagating in three dimensions in space, is written as follows :

$$\frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{\partial^2\psi}{\partial z^2} + \frac{8\pi^2 m}{h^2}(E - V)\psi = 0 \qquad ...(43)$$

or

$$\nabla^2\psi + \frac{8\pi^2 m}{h^2}(E - V)\psi = 0 \qquad ...(44)$$

where $\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$.

∇^2 is known as *Laplacian mathematical operator*. A mathematical operator such as $\int$, $\frac{d}{dx}$ or $\sqrt{\ }$ appears alongwith a mathematical quantity or a function upon which it operates. Thus, in $\sqrt{2}$, $\sqrt{\ }$ is a mathematical operator and 2 is the mathematical quantity on which it operates. Similarly, in x^2, the power 2 is a mathematical operator operating upon the quantity x. A mathematical operator without the accompanying quantity or function has no meaning. ∇^2 alone, therefore, has no meaning unless it is accompanied by ψ.

It may be noted that $\nabla^2\psi$ does not mean ∇^2 multiplied by ψ. It means that the mathematical operator ∇^2 operates upon the mathematical function ψ.

The concept of operators is very important in wave mechanics. We have already listed a few operators in the sixth postulate. Here we shall briefly deal with the algebra of operators. If $\hat{A}$ and $\hat{B}$ are two operators and f is a function upon which they operate, then

$$(\hat{A}+\hat{B})f = \hat{A}f + \hat{B}f \qquad ...(45)$$

and

$$(\hat{A}-\hat{B})f = \hat{A}f - \hat{B}f \qquad ...(46)$$

Thus, we can generate new operators $\hat{A}+\hat{B}$ and $\hat{A}-\hat{B}$ by adding and subtracting $\hat{A}$ and $\hat{B}$. Also

$$\hat{A}+\hat{B} = \hat{B}+\hat{A} \qquad ...(47)$$

and

$$\hat{A}-\hat{B} = -\hat{B}+\hat{A} \qquad ...(48)$$

The multiplication of operators can be carried out by doing successive operations with two or more operators on a function. If $\hat{A}$ and $\hat{B}$ are two operators and f is their *operand*, then we can obtain the quantity $\hat{A}\hat{B}f$ as follows :

We first operate on f with $\hat{B}$ to obtain f'.

$$\hat{B}f = f'$$

Then, f' is operated upon by $\hat{A}$ to obtain f''.

$$\hat{A}f' = f''$$

Thus, we have

$$\hat{A}\hat{B}f = f'' \qquad ...(49)$$

It should be remembered that the order of application of operators is always from right to left as they are written. Application of the same operator several times in succession is written with a power. Thus, we have

$$\hat{A}\hat{A}f = \hat{A}^2 f \qquad ...(50)$$

The algebra of operators should be distinguished from the algebra of ordinary numbers. If a and b are two numbers, then we know that

$$a \times b = b \times a \qquad ...(51)$$

However, if $\hat{A}$ and $\hat{B}$ are two operators, then their *product* $\hat{A}\hat{B}$ may or may not be equal to $\hat{B}\hat{A}$. If $\hat{A}\hat{B} = \hat{B}\hat{A}$, then the two operators are said to commute with each other or said to be commutable.

The mathematical function ψ is a function of the space coordinates or variables x, y, z and should be expressed as $\psi(x, y, z)$. For the sake of brevity, however, it is written as ψ only. A *real* mathematical

function of x, y, z can be plotted in Cartesian space (three-dimensional space). The function ψ signifies the *amplitude* of the electron wave and is called the *wave function.*

In Schrodinger wave equation, x, y, z are the three space coordinates, m is the mass of the electron, E is the total energy and V is the electrostatic potential energy associated with the electron. $\frac{\partial^2 \psi}{dx^2}$, $\frac{\partial^2 \psi}{\partial y^2}$ and $\frac{\partial^2 \psi}{\partial z^2}$ are the double differentials of ψ with respect to x only, y only and z only, respectively.

Formulation of Schrodinger Wave Equation. Schrodinger assumed the electron waves to be similar to the stationary waves, *i.e.*, the waves produced by the vibrations of a stretched string. Consider such a wave being propagated in x direction. Let w be the amplitude of the wave at any point whose coordinate is x at time t. The equation for such a wave motion may be expressed as

$$\frac{\partial^2 w}{\partial x^2} = \frac{1}{u^2} \times \frac{\partial^2 w}{\partial t^2} \qquad ...(52)$$

where u is the velocity with which the wave propagates. The amplitude w in differential Eq. 52 depends upon x and t.

Eq. 52. can be solved only if w can be written as a product of two mathematical functions, one of which depends on x only [*i.e.*, the function f (x)] and the other on t only [*i.e.*, the function g (t)], that is, if we can write w as

$$w = f(x)\, g(t) \qquad ...(53)$$

For stationary waves, the function g (t) is represented by the expression

$$g(t) = A \sin(2\pi\nu t) \qquad ...(54)$$

where ν is the frequency of vibration and A is the maximum amplitude of the wave. Double differentiation of Eq. 54 with respect to time gives

$$\frac{\partial^2 g(t)}{\partial t^2} = -4\pi^2\nu^2 A \sin(2\pi\nu t) = -4\pi^2\nu^2 g(t) \qquad ...(55)$$

Similarly, double differentiation of Eq. 53 with respect to time and with respect to coordinate x, yields respectively,

$$\frac{\partial^2 w}{\partial t^2} = f(x)\frac{\partial^2 g(t)}{\partial t^2} = -f(x)\, 4\pi^2\nu^2 g(t) \qquad ...(56)$$

and

$$\frac{\partial^2 w}{\partial x^2} = \frac{\partial^2 f(x)}{\partial x^2} g(t) \qquad ...(57)$$

Substituting the values of $\frac{\partial^2 w}{\partial t^2}$ and $\frac{\partial^2 w}{\partial x^2}$ in Eq. 52, we get

$$\frac{\partial^2 f(x)}{\partial x^2} g(t) = -\frac{1}{u^2} 4\pi^2\nu^2 g(t) f(x) \qquad ...(58)$$

or

$$\frac{\partial^2 f(x)}{\partial x^2} = -\frac{4\pi^2\nu^2}{u^2} f(x) \qquad ...(59)$$

But, we know that $u = \nu\lambda$ where λ is the wave length of the stationary wave. Hence,

$$\nu/u = 1/\lambda \qquad ...(60)$$

Replacing ν/u by $1/\lambda$ in Eq. 59, we get

$$\frac{\partial^2 f(x)}{\partial x^2} = -\frac{4\pi^2}{\lambda^2} f(x) \qquad ...(61)$$

Eq. 61 is the equation for a uni-dimensional stationary wave propagating in one direction (*i.e.*, x direction) only. We may now extend this equation to three dimensions by replacing f(x) [an amplitude function of variable x] by $\psi(x, y, z)$ [an amplitude function of the variables x, y, z]. Similarly, the factor $\frac{\partial^2 f(x)}{\partial x^2}$ of uni-dimensional Eq. 61 will now be replaced by $\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2}$ in a three-dimensional equation. The factor $\frac{\partial^2 \psi}{\partial x^2}$ is double differentiation of $\psi(x, y, z)$ with respect to x only keeping y and z constant ; $\frac{\partial^2 \psi}{\partial y^2}$ is double differentiation of $\psi(x, y, z)$ with respect to y only keeping x and z constant and $\frac{\partial^2 \psi}{\partial z^2}$ is double differentiation of $\psi(x, y, z)$ with respect to z only keeping x and y constant). Hence, Eq. 61 in three-dimensional space takes the form

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} = -\frac{4\pi^2}{\lambda^2}\psi \qquad ...(62)$$

The above equation is applicable to all minute particles including electrons. Substituting the value of $\lambda = h/mu$ (de Broglie's relation) in Eq. 62, we get

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} = -\frac{4\pi^2 m^2 u^2}{h^2}\psi \qquad ...(63)$$

where m is the mass and u is the velocity of the particle. The total energy E of the particle is the sum of its kinetic energy $(= 1/2\, mu^2)$ and the potential energy, V. Thus,

$$E = 1/2\, mu^2 + V \qquad ...(64)$$

or

$$mu^2 = 2(E - V) \qquad ...(65)$$

or

$$u^2 = 2(E - V)/m \qquad ...(66)$$

Substituting the above value of u^2 in Eq. 63, we get

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} = -\frac{4\pi^2 m^2}{h^2} \times \frac{2}{m}(E - V)\psi \qquad ...(67)$$

or

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} + \frac{8\pi^2 m}{h^2}(E - V)\psi = 0 \qquad ...(68)$$

Eq. 68 is the well known **Schrodinger wave equation** proposed by him in 1926. It is customarily written in the following form :

$$\left[-\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right) + V\right]\psi = E\psi \qquad ...(69)$$

or $$\left[-\frac{\hbar^2}{2m}\nabla^2 + V\right]\psi = E\psi \qquad ...(70)$$

where $\hbar$ is $h/2\pi$ and ∇^2 is the Laplacian operator defined as $\nabla^2 = \left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)$.

The complete mathematical operator of ψ in Eq. 69 is the Hamiltonian operator $\hat{H}$. Thus,

$$\hat{H} = -\frac{\hbar^2}{2m}\nabla^2 + V \qquad ...(71)$$

Eq. 70, therefore, becomes $$\hat{H}\psi = E\psi \qquad ...(72)$$

The Hamiltonian operator $\hat{H}$ consists of two parts, *viz.*, the kinetic energy part $\left(-\frac{\hbar^2}{2m}\nabla^2\right)$ and the electrostatic potential energy part (V). The solution of Schrodinger wave equation implies finding out appropriate ψ which satisfies the wave equation.

The Schrodinger wave equation, being a second order differential equation, has innumerable solutions, many of them having no significance at all. Out of these, only those solutions are significant which give certain definite and acceptable values of the total energy E. The acceptable value of total energy E given by a solution is called eigenvalue and the corresponding function ψ which gives eigenvalue of the energy, is called eigenfunction. Thus, every function is not an eigen (or acceptable) function.

Conditions to be satisfied by an eigen (or acceptable) wave function. An acceptable solution of the Schrodinger wave equation, *i.e.*, an eigen wave function, must satisfy the following conditions :

1. The function should be finite.
2. It should be single-valued (*i.e.*, it should not have more than one value at a point in space).
3. It should be continuous (*i.e.*, the function if plotted in space should not show a break).
4. $\partial^2\psi/\partial x^2$, $\partial^2\psi/\partial y^2$, etc., should also be continuous.
5. The function should be normalised, *i.e.*, $\int_{-\infty}^{+\infty}\psi d\tau = 1$

Probability Density and Significance of ψ. According to Heisenberg's uncertainty principle, we can never know the exact position of the electron moving around the nucleus with a particular velocity. Therefore, we talk in terms of the probability of its location in any given region. In other words, we define its position by a probability function. Such a probability function will vary with the position of the region in space in which we want to find the probability of the existence of the electron. If $\rho(x, y, z)$ is such a probability function, then the probability that the electron will be found in the small cubic volume element of dimension $dxdydz$, is given by the product of $\rho(x, y, z)$ and the volume of the small element, *i.e.*, by

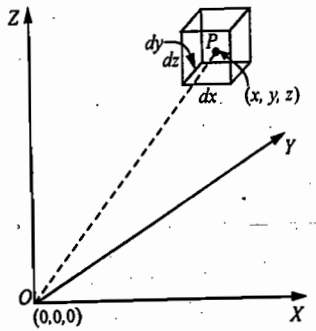


Fig.6. Representation of small volume elements $dxdydz$ (or $d\tau$) surrounding the point $P(x, y, z)$

$\rho(x, y, z)\,dxdydz$. The small volume element, represented by a cube of dimensions dx, dy, dz and surrounding the point $P(x, y, z)$ is shown in Fig. 6. The small volume element $dxdydz$ around the point x, y, z is also written as τ. The function ρ is also known as **probability density**. Imagine that the whole space is divided into a number of such volume elements. The total probability of finding the electron in the whole space will be given by the summation of all the terms of the type $\rho dxdydz$ or $\rho d\tau$. Since the electron has to be somewhere in space, the total probability must be equal to unity. Thus,

$$\int_{-\infty}^{+\infty}\rho\, d\tau = \int_{-\infty}^{+\infty}\rho\, dx\, dy\, dz = 1 \qquad ...(73)$$

The concept of probability accounts for the fundamental law of nature that our knowledge of the position of a small moving particle can never be absolute.

Suppose the solution of the wave equation for a single particle is a function $\psi(x, y, z)$, called the *wave function*. The factor ψ represents the amplitude of the wave, as already mentioned. It has no physical significance as such. In the case of waves, it is the square of the amplitude (*i.e.*, ψ^2) that has any significance rather than the amplitude (*i.e.*, ψ) itself. This is illustrated below :

Consider the dual nature of electromagnetic radiation. According to the wave theory, the intensity of radiation is measured by the square of the amplitude of the wave, a quantity obtained by solving the relevant wave equation. The photon theory relates intensity of radiation with the number of photons in a given volume, *i.e.*, photon density. Since photons are small particles, photon density will be related to the probability of their existence in the given volume, *i.e.*, the probability density. Thus, the probability density, *i.e.*, the probabilityof finding a photon in a given volume, gets related to the square of the amplitude of the associated wave. By analogy, therefore, ψ^2 (*i.e.*, the square of the amplitude) will be a measure of the probability of finding electron in the given volume. Accordingly,

$$\rho(x, y, z) \propto \psi^2(x, y, z) = k\,\psi^2(x, y, z) \qquad ...(74)$$

We choose the proportionality constant k in such a way that the proportionality is replaced by equality. If $\psi(x, y, z)$ is the solution of Schrodinger wave equation for any system, then ψ multiplied by any constant is also the solution of the same wave equation. This means we can take $(1/\sqrt{k})\psi$ instead of ψ in Eq. 74 so that Eq. 74 takes the form

$$\rho(x, y, z) = k \times \frac{1}{k}\psi^2(x, y, z) = \psi^2(x, y, z) \qquad ...(75)$$

$$\therefore \quad \int_{-\infty}^{+\infty}\rho\, d\tau = \int_{-\infty}^{+\infty}\psi^2 d\tau = 1 \qquad \left(\because \int_{-\infty}^{+\infty}\rho\, d\tau = 1, \text{ vide Eq. 73}\right) \qquad ...(76^*)$$

The factor $\psi^2 d\tau$ represents the probability of locating the electron in the small volume element $d\tau$.

*If ψ is a complex wave function, then the integrand ψ^2 in Eq. 76 is replaced by $\psi^*\psi$ (ψ^* is the complex component of ψ). This is so because the right hand side of Eq. 76 is real. Hence the left hand side has also to be real. For example, if ψ is a complex wave function $a + ib$ or $Ae^{im\phi}$, then ψ^2 will also be a complex wave function $(a + ib)^2$ or $A^2e^{2im\phi}$. But $\psi^*\psi$ would be $(a + ib)^*(a + ib)$ or $A^2e^{2im\phi}e^{-im\phi}$, that is, $\psi^*\psi$ would be real, being $(a^2 + b^2)$ or A^2e^0. (The complex component of $(a + ib)$ is $(a - ib)$.

Concept of Electron Charge Cloud. Let us consider hydrogen atom in its ground state. Suppose it is possible to see hydrogen nucleus and its lone electron. Let us assume that the nucleus remains at a fixed place whereas the electron keeps on moving. If it were possible for the electron to register its position by a dot, say, after every 1/1000th of a second for one thousand seconds, the maximum concentration of such dots would be closest to the nucleus and would go on decreasing as the distance of electron from the nucleus increases in all directions. This shows that the maximum probability of locating the electron is closest to the nucleus and goes on decreasing as the distance from the nucleus increases. It may be noted that it is not possible to specify the actual position of the electron. All that we can ever know is a definite region of space within which there is a probability for the existence of the electron. The electron probability distribution in three-dimensional space around the nucleus constitutes what is known as the **electron charge cloud.** The region where such an electron cloud is thickest, *i.e.*, where the number of dots registering the position of electron is maximum, is the region where the probability of locating the electron is maximum.

A model of hydrogen atom showing the electron charge cloud is shown in Fig. 7. Thus, the region within the sphere is a region of high probability. This means that the electron spends most of its time within this spherical region. In contrast to Bohr's concept, this region, according to wave mechanical model, does not have sharp boundaries.

Fig. 7. Electron charge cloud in hydrogen atom.

Solutions of Schrodinger Equation for Some Simple Systems

The Schrodinger equation can be solved exactly for the following simple systems :

1. *Particle in a One-dimensional Box.* 2. *Particle in a Three-dimensional Box.* 3. *Hydrogen atom.*

1. Particle in a One-dimensional Box. Consider a particle of mass m which is confined to move in a one-dimensional box of length a having infinitely high walls (Fig. 8). For the sake of simplicity, it is assumed that the potential energy of the particle is zero everywhere inside the box, that is,

$$V(x) = 0 \qquad ...(77)$$

Thus, inside the box, the Schrodinger equation in x dimension, *viz.*,

$$\left[-\frac{\hbar^2}{2m}\left(\frac{d^2}{dx^2}\right) + V(x)\right]\psi(x) = E\psi(x) \qquad ...(78)$$

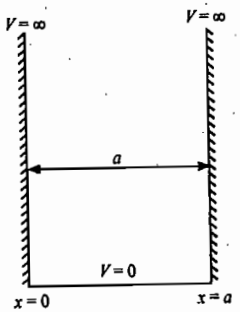

Fig. 8. Particle in a one-dimensional box.

takes the form

$$-\frac{\hbar^2}{2m}\left(\frac{d^2\psi}{dx^2}\right) = E\psi(x) \qquad ...(79)$$

Mathematically, Eq. 79 may be written as

$$\frac{d^2\psi}{dx^2} + \left[\frac{2mE}{\hbar^2}\right]\psi = 0 \qquad ...(80)$$

or as

$$\frac{d^2\psi}{dx^2} + k^2\psi = 0 \qquad ...(81)$$

where k^2 $(= 2mE/\hbar^2)$ is a constant independent of x.

Eq. 81 is an ordianry second-order differential equation which has solution of the form

$$\psi = A\cos kx + B\sin kx \qquad ...(82)$$

where A and B are constants.

For a particle moving *outside* the box where $V(x) = \infty$, the Schrodinger equation 78, is written as

$$\left[-\frac{\hbar^2}{2m}\left(\frac{d^2}{dx^2}\right) + \infty\right]\psi(x) = E\psi(x) \qquad ...(83)$$

which can be mathematically written as

$$\frac{d^2\psi}{dx^2} = \frac{2m}{\hbar^2}(E-\infty)\psi = 0 \qquad ...(84)$$

This equation is satisfied if ψ is zero everywhere *outside* the box which means that the particle cannot be found outside the box, *i.e.*, it is confined *within the box.* This implies that ψ must be zero at the walls of the box, *i.e.*, at $x = 0$ and $x = a$. Since ψ has to be a continuous function of x, it leads to the conclusion that in Eq. 82, A must be zero. Thus, the solution of Eq. 81 is of the form

$$\psi = B\sin kx \qquad ...(85)$$

Since $\psi = 0$ at $x = 0$ and at $x = a$, hence $B\sin ka = 0$ or $\sin ka = 0$ or $ka = n\pi$ so that

$$k = n\pi/a \qquad ...(86)$$

where n (= 1, 2, 3, 4...) is the principal quantum number. Hence, the allowed solutions of Eq. 81 are :

$$\psi = \psi_n = B\sin\left(\frac{n\pi x}{a}\right) \quad \text{where } n = 1, 2, 3..... \qquad ...(87)$$

The probability of finding the particle within the box in the small length segment dx is $\psi^2 dx$. Since the particle must be found within the box, therefore, $\int_0^a \psi^2 dx$ or $\int_0^a B^2\sin^2\frac{n\pi x}{a}dx = 1$. The solution of this equation gives B as $\left(\frac{2}{a}\right)^{1/2}$.

Hence,

$$\psi = \left(\frac{2}{a}\right)^{1/2}\sin\frac{n\pi x}{a}. \qquad ...(88)$$

This is the solution of Schrodinger equation for a particle in a one-dimensional box.

From Eqs. 80 and 86,

$$2mE/\hbar^2 = n^2\pi^2/a^2$$

or

$$E \equiv E_n = \frac{n^2\hbar^2\pi^2}{2ma^2} = \frac{n^2h^2}{8ma^2} \quad \text{where } n = 1, 2, 3... \qquad ...(89)$$

Eq. 89 is the expression for the **energy of the particle** in a one-dimensional box. Since the energy depends upon the quantum number n, which can have any integral value, the energy levels of the particle in the box are quantized.

Example 7. An electron is confined in a one-dimensional box of length 1 Å. Calculate its ground state energy in electron volts (eV).

Solution : *For the ground state, $n = 1$.*

∴ From Eq. 89, the ground state energy of the electron is given by

$$E_1 = \frac{(1)^2\,(6{\cdot}626\times10^{-34}\,\text{J s})^2}{(8)\,(9{\cdot}109\times10^{-31}\,\text{kg})\,(10^{-10}\,\text{m})^2\,(1{\cdot}602\times10^{-19}\,\text{J/eV})} = 37{\cdot}6\ \text{eV}$$

2. Particle in a Three-Dimensional Cubical Box. Let us now consider the motion of a particle of mass m confined to a three-dimensional cubical box with edges of length a and volume equal to a^3. The potential is zero within the box and is infinite outside the box and at its boundaries. The Schrodinger equation for the particle is

$$\left[\frac{-\hbar^2}{2m}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)\right]\psi(x,\ y,\ z) = E\,\psi(x,\ y, z) \qquad ...(90)$$

Eq. 90 may be rewritten as

$$\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}+\frac{\partial^2\psi}{\partial z^2}+\left(\frac{2mE}{\hbar^2}\right)\psi = 0 \qquad ...(91)$$

Assuming that the wave function ψ is a product of three parts $X_{(x)}$, $Y_{(y)}$ and $Z_{(z)}$ which separately depend on x only, y only and z only, respectively, we have

$$\psi(x,y,z) = X(x)\,Y(y)\,Z(z) \qquad ...(92)$$

Hence, $\dfrac{\partial^2\psi}{\partial x^2} = YZ\dfrac{\partial^2 X}{\partial x^2}$; $\dfrac{\partial^2\psi}{\partial y^2} = XZ\dfrac{\partial^2 Y}{\partial y^2}$; $\dfrac{\partial^2\psi}{\partial z^2} = XY\dfrac{\partial^2 Z}{\partial z^2}$

Substituting the above values in Eq. 91 and dividing throughout by $(2m/\hbar^2)\,XYZ$, we have

$$\frac{\hbar^2}{2m}\left(\frac{1}{X}\frac{\partial^2 X}{\partial y^2}+\frac{1}{Y}\frac{\partial^2 y}{\partial y^2}+\frac{1}{Z}\frac{\partial^2 Z}{\partial z^2}\right)+E=0 \qquad ...(93)$$

If engery E is written as the sum of three contributions E_x, E_y and E_z associated with the three coordinates, then Eq. 93 can be separated into the following three equations :

$$-\frac{\hbar^2}{2m}\left(\frac{1}{X}\frac{\partial^2 X}{\partial x^2}\right) = E_x \quad \text{for motion along } x\text{-axis. } (E_x \text{ is independent of } y \text{ and } z) \qquad ...(94)$$

$$-\frac{\hbar^2}{2m}\left(\frac{1}{Y}\frac{\partial^2 Y}{\partial y^2}\right) = E_y \quad \text{for motion along } y\text{-axis. } (E_y \text{ is independent of } x \text{ and } z) \qquad ...(95)$$

$$-\frac{\hbar^2}{2m}\left(\frac{1}{Z}\frac{\partial^2 Z}{\partial z^2}\right) = E_z \quad \text{for motion along } z\text{-axis. } (E_z \text{ is independent of } x \text{ and } y) \qquad ...(96)$$

It can be seen that Eq. 94 (which can be rewritten as $-\dfrac{\hbar^2}{2m}\dfrac{\partial X}{\partial x^2} = E_x X$) is similar to Eq. 79 and, hence leads to a similar solution given by the equation

$$E_x = n_x^2 h^2 / 8ma^2 \qquad ...(97)$$

Similar equations can be written for the solutions of Eqs. 95 and 96.

Thus,
$$E = E_x + E_y + E_z = \frac{(n_x^2+n_y^2+n_z^2)\,h^2}{8ma^2} \qquad ...(98)$$

where $n_x, n_y, n_z = 1, 2, 3, 4$ ..... .

Eq. 98 is the expression for the **energy of a particle in a three-dimensional cubical box.**

Schrodinger Wave Equation for Hydrogen and Hydrogen-like Systems

For a hydrogen-like atom, the nuclear charge is $+Ze$ and charge on the electron is $-e$.

∴ Potential energy of the electron, $V = -Ze^2/r$ ...(99)

For this system, therefore, the Schrodinger wave equation takes the form

$$\nabla^2\psi + \frac{8\pi^2 m}{h^2}\left(E - \frac{-Ze^2}{r}\right)\psi = 0 \qquad ...(100)$$

or
$$\left(\frac{\partial}{\partial x^2}+\frac{\partial}{\partial y^2}+\frac{\partial}{\partial z^2}\right)\psi + \frac{8\pi^2 m}{h^2}\left(E + \frac{Ze^2}{r}\right)\psi = 0 \qquad ...(101)$$

It is convenient to solve this equation if we substitute polar coordinates r, θ and ϕ in place of Cartesian coordinates x, y and z. The correlation between the two types of coordinates is illustrated in Fig. 9.

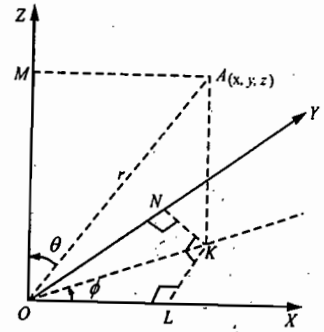

Fig. 9. Correlation between Cartesian coordinates (x, y, z) and polar coordinates $(r, \theta$ and $\phi)$.

The conversion of Cartesian coordinates into polar coordinates is given below.

Consider a point A with coordinates x, y, z, in space.

Let AK be the perpendicular from A on XY plane and KL, KN and AM be perpendiculars on the axes, X, Y and Z, from the points K, K and A, respectively.

Let $OA = r$ and let θ be the angle which the line OA makes with the Z-axis and let ϕ be the angle which the line OK makes with the X-axis (Fig. 9.)

Then,
$$z = OM = r\cos\theta \quad \text{and} \quad OK = AM = r\sin\theta$$
$$y = ON = KL = OK\sin\phi = r\sin\theta\sin\phi$$
$$x = OL = OK\cos\phi = r\sin\theta\cos\phi$$

Eq. 101 in terms of polar coordinates transforms as

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(\frac{r^2\partial\psi(r,\theta,\phi)}{\partial r}\right) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\frac{\sin\theta\ \partial\psi(r,\theta,\phi)}{\partial\theta}\right)$$

$$+\frac{1}{r^2\sin^2\theta}\times\frac{\partial^2\psi(r,\theta,\phi)}{\partial\phi^2} + \frac{8\pi^2 m}{h^2}\left(E + \frac{e^2}{r}\right)\psi(r,\theta,\phi) = 0 \quad ...(102)$$

Remember that ψ will now be a function of variables r, θ and ϕ instead of x, y and z ; that is why we have written $\psi(r,\theta,\phi)$ instead of $\psi(x,y,z)$ in Eq. 102.

The solution of Eq. 102, *i.e.*, evaluation of $\psi(r,\theta,\phi)$, is possible only if function ψ can be written in the form

$$\psi(r,\theta,\phi) = R(r)\,\Theta(\theta)\,\Phi(\phi) \quad ...(103)$$

where $R(r)$ is a function depending on r but is independent of the other two polar coordinates, θ and ϕ ; $\Theta(\theta)$ is a function dependent on θ and is independent of r and ϕ and $\Phi(\phi)$ is a function dependent on ϕ and is independent of r and θ.

The function $R(r)$ is known as the *radial wave function* while the functions $\Theta(\theta)$ and $\Phi(\phi)$ are called *angular wave functions*.

By expressing $\psi(r,\theta,\phi)$ as $R(r)\,\Theta(\theta)\,\Phi(\phi)$ in Eq. 102, we get a complicated equation (not written here) which can, however, be split into the following three simpler equations :

(1) $$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial R(r)}{\partial r}\right) - \frac{\beta}{r^2}R(r) + \frac{8\pi^2 m}{h^2}\left(E + \frac{Ze^2}{r}\right)R(r) = 0 \quad ...(104)$$

This equation is a function of r only and, on solution, yields the following expression for $R(r)$:

$$R(r)_{n,l} = \sqrt{\left(\frac{2Z}{na_0}\right)^3 \frac{\lfloor n-l-1}{2n\left(\lfloor n+l\right)^3}}\, e^{-\rho/2}\rho^l\, L_{n+l}^{2l+1}(\rho) \quad ...(105)$$

where $\rho = \left(\frac{2Z}{na_0}\right)r$ and $L_{n+l}^{2l+1}(\rho)$ is the associated Laguere polynomial. The numbers n and l are the two integral quantum numbers required for the solution of $R(r)_{n,l}$ and a_0 is Bohrs radius of H atom. It is obvious from the above expresion that l can, at the maximum, be equal to $(n-1)$ and not any higher value (why ?)

(2) $$\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\Theta(\theta)}{\partial\theta}\right) - \frac{m^2\Theta(\theta)}{\sin^2\theta} + \beta\Theta(\theta) = 0 \quad ...(106)$$

This equation is a function of θ only and, on solution, yields the following expression for $\Theta(\theta)$:

$$\Theta_{l,m}(\theta) = \sqrt{\frac{(2l+1)(l-|m|)}{2\lfloor l+m}}\, P_l^m(\cos\theta) \quad ...(107)$$

where $P_l^m(\cos\theta)$ is the associated Legendre polynomial. It is obvious from the expression for $\Theta(\theta)$ that

the maximum absolute value of the newly introduced quantum number m can be equal to l only and not any higher value (why ?). Hence, m can have values equal to $\pm l, \pm(l-1), \pm(l-2)$..... 0.

(3) $$\frac{\partial^2\Phi(\phi)}{\partial\phi^2} + m^2\Phi(\phi) = 0 \quad ...(108)$$

This equation is a function of ϕ only and, on solution, gives $\Phi(\phi)$:

$$\Phi(\phi) = \frac{1}{\sqrt{2\pi}}e^{\pm im\phi} \quad ...(109)$$

The total wave function $\psi(r,\theta,\phi)$ is then written as $R(r)\,\Theta(\theta)\,\Phi(\phi)$ (Eq. 103)

The total wave function is normalized so that

$$\int_0^r R_{n,l}^* R_{n,l}\, r^2 dr \int_0^\pi \Theta_{l,m}^*\Theta_{l,m}\sin\theta d\theta \int_0^{2\pi}\Phi_m^*\Phi_m\, d\phi = 1 \quad ...(110)$$

That is, $$\int_0^r R_{n,l}^* R_{n,l}\, r^2 dr = 1\ ;\ \int_0^\pi \Theta_{l,m}^*\Theta_{l,m}\sin\theta d\theta = 1 \text{ and } \int_0^{2\pi}\Phi_m^*\Phi_m\, d\phi = 1 \quad ...(111)$$

The radial wave function $R(r)$ *gives the energy and size of the orbitals* and the angular wave function, which is the product of $\Theta(\theta)$ and $\Phi(\phi)$, *gives the shapes of the orbitals*. These aspects have been discussed below in some details.

1. The Radial Wave Function, $R(r)$

The solution of Eq. 104 for hydrogen and hydrogen-like systems *yields two quantum numbers, n and l*. The quantum number n can have integral values of 1, 2, 3, etc. and is ***analogous to the principal quantum number of Bohr theory.*** The quantum number l can have integral values from $n-l$ to 0 and is ***similar to the azimuthal quantum number of Bohr-Sommerfeld theory.*** The various values of l are given special designations, *viz.*, *s*, *p*, *d* and *f* for $l = 0, 1, 2$ and 3, respectively. The radial wave function is, therefore, generally written as $R_{n,l}(r)$ or simply as $R_{n,l}$ for the sake of simplicity.

The radial wave functions for electron present in different *s* and *p* orbitals are given below :

$R_{1,0}$, *i.e.*, $R_{1s} = 2\left(\frac{Z}{a_0}\right)^{3/2} e^{-\sigma}$ [represents radial wave function of electron in 1*s* orbital

$R_{2,0}$, *i.e.*, $R_{2s} = 2^{-3/2}\left(\frac{Z}{a_0}\right)^{3/2}(2-\sigma)\,e^{-\sigma/2}$ [represents radial wave function of electron in 2*s* orbital

$R_{2,1}$, *i.e.*, $R_{2p} = 2^{-1}\left(\frac{Z}{a_0}\right)^{3/2}\sigma\, e^{-\sigma/2}$ [represents radial wave function of electron in 2*p* orbital

In the above functions, a_0 is Bohr's radius, Z is the atomic number and σ is Zr/a_0.

An mentioned above the radical wave function gives the size of the orbitals depending upon the value of $R_{n,l}$.

2. The Angular Wave Function

The angular wave function which is the product of $\Theta(\theta)$ and $\Theta(\phi)$, as already mentioned, is expressed in terms of spherical harmonics of the point A (x, y, z) of Fig. 9. These are defined as

$$Y_n^{m_A} = \Theta_{n,m_A} \Phi_{m_A} \qquad ...(112)$$

where

$$\Theta_{n,m_A} = \sqrt{\frac{(2n+1)}{2}\frac{\lfloor n-|m_A| \rfloor}{\lfloor n+|m_A| \rfloor}}\, P_n^{m_A}(\cos\theta) \qquad ...(113)$$

and

$$\Phi_{m_A} = \frac{1}{\sqrt{2\pi}} e^{i m_A \phi} \qquad ...(114)$$

In the above equations, $P_n^{m_A}$ is the associated Legendre polynomial function and both Θ_{n,m_A} and Φ_{m_A} are normalised.

The general form of associated Legendre polynomial $P_n^{m_A}(x)$ is :

$$P_n^{m_A}(x) = (1-x^2)^{|m_A|/2} \frac{d^{m_a} P_n(x)}{d_x^{m_a}} \qquad ...(115)$$

where $P_n(x)$ is Legendre polynomial which is given by

$$P_n(x) = \frac{1}{2^n \lfloor n} \frac{d^n (x^2-1)^n}{d^n} \qquad ...(116)$$

In the general expression (112) for spherical harmonics we do not assign any specific meaning to n and m_A. These are simply numbers. It is evident from Eq. 113 that the maximum value of $|m_A|$ can be n. In other words, $|m_A|$ can have values $= \pm n, \pm(n-1), \pm(n-2)$ .....0 only.

In order to evaluate the spherical harmonics of point A for different sets of n and $|m_A|$, we need the values of $P(x)$, and $P_n^{m_A}(x)$. The expression (116) for $P(x)$ yields the following results :

$$P_0(x) = 1 \qquad \therefore \quad P_0(\cos\theta) = 1$$

$$P_1(x) = x \qquad \therefore \quad P_1(\cos\theta) = \cos\theta$$

$$P_2(x) = \frac{1}{2}(3x^2-1) \qquad \therefore \quad P_2(\cos\theta) = \frac{1}{2}(3\cos^2\theta - 1)$$

$$P_3(x) = \frac{1}{2}(5x^3-3x) \qquad \therefore \quad P_3(\cos\theta) = \frac{1}{2}(5\cos^3\theta - 3\cos\theta)$$

$$P_4(x) = \frac{1}{8}(35x^4-30x^2+3) \qquad \therefore \quad P_4(\cos\theta) = \frac{1}{8}(35\cos^4\theta - 30\cos^2\theta + 3)$$

Similarly, the expression (115) for $P_n^{|m_A|}(x)$ yields the following results :

$$P_0^0(x) = 1 \qquad \therefore \quad P_0^0(\cos\theta) = 1$$

$$P_1^0(x) = x \qquad \therefore \quad P_1^0(\cos\theta) = \cos\theta$$

$$P_1^{|1|}(x),\ i.e.,\ P_1^{\pm1}(x) = (1-x^2)^{1/2} \qquad \therefore \quad P_1^{\pm1}(\cos\theta) = \sin\theta$$

$$P_2^0(x) = \frac{1}{2}(3x^2-1) \qquad \therefore \quad P_2^0(\cos\theta) = \frac{1}{2}(3\cos^2\theta - 1)$$

$$P_2^{|1|}(x),\ i.e.,\ P_2^{\pm1}(x) = 3x(1-x^2)^{1/2} \qquad \therefore \quad P_2^{\pm1}(\cos\theta) = 3\cos\theta\sin\theta$$

$$P_2^{|2|}(x),\ i.e.,\ P_2^{\pm2}(x) = 3(1-x^2) \qquad \therefore \quad P_2^{\pm2}(\cos\theta) = 3\sin^2\theta$$

$$P_3^0(x) = \frac{1}{2}(5x^2-3)x \qquad \therefore \quad P_3^0(\cos\theta) = \frac{1}{2}\cos\theta(5\cos^2\theta - 3)$$

$$P_3^{|1|}(x),\ i.e.,\ P_3^{\pm1}(x) = \frac{3}{2}(1-x^2)^{1/2}(5x^2-1) \qquad \therefore \quad P_3^{\pm1}(\cos\theta) = \frac{3}{2}\sin\theta(5\cos^2\theta - 1)$$

$$P_3^{|2|}(x),\ i.e.,\ P_3^{\pm2}(x) = 15x(1-x^2) \qquad \therefore \quad P_3^{\pm2}(\cos\theta) = 15\cos\theta\sin^2\theta$$

$$P_3^{|3|}(x),\ i.e.,\ P_3^{\pm3}(x) = 15x(1-x^2)^{3/2} \qquad \therefore \quad P_3^{\pm3}(\cos\theta) = 15\sin^3\theta$$

$$P_4^0(x) = \frac{1}{8}(35x^4-30x^2+3) \qquad \therefore \quad P_4^0(\cos\theta) = \frac{1}{8}(35\cos^4\theta - 30\cos^2\theta + 3)$$

$$P_4^{|1|}(x),\ i.e.,\ P_4^{\pm1}(x) = (1-x^2)^{1/2}(7x^3-3x)\frac{5}{2} \qquad \therefore \quad P_4^{\pm1}(\cos\theta) = \frac{5}{2}\sin\theta\cos\theta(7\cos^2\theta - 3)$$

$$P_4^{|2|}(x),\ i.e.,\ P_4^{\pm2}(x) = (1-x^2)(7x^2-1)\frac{15}{2} \qquad \therefore \quad P_4^{\pm2}(\cos\theta) = \frac{15}{2}\sin^2\theta(7\cos^2\theta - 1)$$

$$P_4^{|3|}(x),\ i.e.,\ P_4^{\pm3}(x) = 105x(1-x^2)^{3/2} \qquad \therefore \quad P_4^{\pm3}(\cos\theta) = 105\sin^3\theta\cos\theta$$

$$P_4^{|4|}(x),\ i.e.,\ P_4^{\pm4}(x) = (1-x^2)^2 \times 105 \qquad \therefore \quad P_4^{\pm4}(\cos\theta) = 105\sin^4\theta$$

With the help of the results reported above and making use of Eqs. 112—114, we can easily arrive at the following values for spherical harmonics, $Y_n^{m_A}$:

$$\Theta_{0,0} = \frac{1}{\sqrt{2}} \qquad Y_0^0 = \frac{1}{2\sqrt{\pi}}$$

$$\Theta_{1,0} = \sqrt{\frac{3}{2}}\cos\theta \qquad Y_1^0 = \sqrt{\frac{3}{2}}\frac{1}{\sqrt{2\pi}}\cos\theta$$

$$\Theta_{0,\pm1} = \sqrt{\frac{3}{4}}\sin\theta \qquad Y_1^{\pm1} = \sqrt{\frac{3}{4}}\sin\theta\frac{1}{\sqrt{2\pi}}e^{\pm i\phi}$$

$$\Theta_{2,0} = \sqrt{\frac{5}{8}}(3\cos^2\theta - 1) \qquad Y_2^0 = \sqrt{\frac{5}{8}}(3\cos^2\theta - 1)\frac{1}{\sqrt{2\pi}}$$

$$\Theta_{2,\pm1} = \sqrt{\frac{15}{4}}\sin\theta\cos\theta \qquad Y_2^{\pm1} = \sqrt{\frac{15}{4}}\sin\theta\cos\theta\frac{1}{\sqrt{2\pi}}e^{\pm i\phi}$$

$$\Theta_{2,\pm2} = \sqrt{\frac{15}{16}}\sin^2\theta \qquad Y_2^{\pm2} = \sqrt{\frac{15}{16}}\sin^2\theta\frac{1}{\sqrt{2\pi}}e^{\pm i2\phi}$$

$$\Theta_{3,0} = \sqrt{\frac{7}{8}}\cos\theta(5\cos^2\theta - 3) \qquad Y_3^0 = \sqrt{\frac{7}{8}}\cos\theta(5\cos^2\theta - 3)\frac{1}{\sqrt{2\pi}}$$

$$\Theta_{3,\pm1} = \sqrt{\frac{21}{32}}\sin\theta(5\cos^2\theta - 1) \qquad Y_3^{\pm1} = \sqrt{\frac{21}{32}}\sin\theta(5\cos^2\theta - 1)\frac{1}{\sqrt{2\pi}}e^{\pm i\phi}$$

$$\Theta_{3,\pm2} = \sqrt{\frac{105}{16}}\sin^2\theta\cos\theta \qquad Y_3^{\pm2} = \sqrt{\frac{105}{16}}\sin^2\theta\cos\theta\frac{1}{\sqrt{2\pi}}e^{\pm i2\phi}$$

$$\Theta_{3,\pm3} = \sqrt{\frac{35}{32}}\sin^3\theta \qquad Y_3^{\pm3} = \sqrt{\frac{35}{32}}\sin^3\theta\frac{1}{\sqrt{2\pi}}e^{\pm i3\phi}$$

$$\Theta_{4,0} = \sqrt{\frac{9}{128}}(35\cos^4\theta - 30\cos^2\theta + 3) \qquad Y_4^0 = \sqrt{\frac{9}{128}}(35\cos^4\theta - 30\cos^2\theta + 3)\frac{1}{\sqrt{2\pi}}$$

$$\Theta_{4,\pm1} = \sqrt{\frac{45}{32}}\sin\theta\cos\theta\,(7\cos^2\theta - 3) \qquad Y_4^{\pm1} = \sqrt{\frac{45}{32}}\sin\theta\cos\theta\,(7\cos^2\theta - 3)\frac{1}{\sqrt{2\pi}}e^{\pm i\phi}$$

$$\Theta_{4,\pm2} = \sqrt{\frac{45}{64}}\sin^2\theta\,(7\cos^2\theta - 1) \qquad Y_4^{\pm2} = \sqrt{\frac{45}{64}}\sin^2\theta\,(7\cos^2\theta - 1)\frac{1}{\sqrt{2\pi}}e^{\pm i2\phi}$$

$$\Theta_{4,\pm3} = \sqrt{\frac{315}{32}}\sin^3\theta\cos\theta \qquad Y_4^{\pm3} = \sqrt{\frac{315}{32}}\sin^3\theta\cos\theta\,\frac{1}{\sqrt{2\pi}}e^{\pm i3\phi}$$

$$\Theta_{4,\pm4} = \sqrt{\frac{315}{256}}\sin^4\theta \qquad Y_4^{\pm4} = \sqrt{\frac{315}{256}}\sin^4\theta\,\frac{1}{\sqrt{2\pi}}e^{\pm i4\phi}$$

While expressing angular wave functions of hydrogen-like systems in terms of spherical hormonics, we use symbols l and m in place of n and m_A, respectively, in Eqs. 112—114. Accordingly, we write :

$$Y_l^m = \Theta_{l,m}\Phi_m \qquad ...(117)$$

$$\Theta_{l,m} = \sqrt{\frac{(2l+1)}{2}\frac{|l-|m|}{|l+|m|}}\,P_l^m\cos\theta \qquad ...(118)$$

$$\Phi_m = \frac{1}{\sqrt{2\pi}}e^{im\phi} \qquad ...(119)$$

The symbols l and m used in Eqs. 117—119 for hydrogen-like system are referred to as orbital angular momentum quantum number and magnetic quantum number, respectively.

As already mentioned, while the radial wave function $[R(r)]$ gives the size of the orbitals, the angular wave function [the product of $\Theta_{l,m}(\theta)$ and $\Phi_m(\phi)$], now designated as spherical harmonics, gives the shape of the orbitals. $Y_l^m = \Theta_{l,m}(\theta)\,\Phi_m(\phi)$. Therefore, the **complete wave function**, which is obtained by the product of the radial wave function and the angular wave function, *i.e.*, the spherical harmonics, gives both the size and the shape of the orbitals.

Let us write complete wave functions for some of the orbitals and deduce their shapes.

Complete wave function for *s* orbitals and their shapes. For an *s* orbital, $l = 0$, therefore, $m = 0$. The complete wave function is, therefore, written as

$$R_{n,0}(r)\,Y_0^0 = R_{n,0}(r)\frac{1}{\sqrt{2}}\times\frac{1}{\sqrt{2\pi}} = R_{n,0}(r)\frac{1}{2\sqrt{\pi}} \qquad ...(120)$$

Since the complete wave function in this case is independent of the angles θ and ϕ, therefore, the orbital is *symmetrical* along all directions for a particular r, *i.e.*, it has a **spherical shape**. The 1*s* orbital has no radial node whereas 2*s* and 3*s* orbitals have one and two radial nodes, respectively, as shown in Fig. 10.

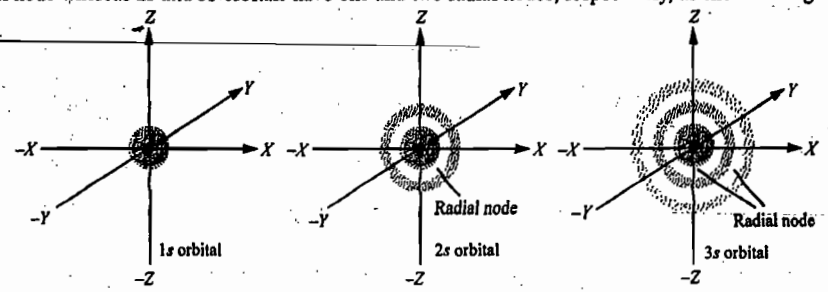

Fig. 10. The shapes of varius *s* orbitals

Complete wave function for *p* orbitals and their sphapes. For *p* orbitals $l = 1$, therefore, $m = 0, +1, -1$. The corresponding complete wave functions are written as (0), (+1) and (–1), respectively. The sets of single electronic wave functions having the same l and the same m but different m_s are written as (m_1), (m_2), etc. Thus,

$$(0) = R_{n,1}(r)\,Y_1^0 = R_{n,1}(r)\sqrt{3/2}\cos\theta\times1/\sqrt{2\pi} = R_{n,1}(r)\sqrt{3/4\pi}\cos\theta \qquad ...(121)$$

$$(+1) = R_{n,1}(r)\,Y_1^{+1} = R_{n,1}(r)\sqrt{3/4}\sin\theta\times1/\sqrt{2\pi}\,e^{+i\phi} \qquad ...(122)$$

$$(-1) = R_{n,1}(r)\,Y_1^{-1} = R_{n,1}(r)\sqrt{3/4}\sin\theta\times1/\sqrt{2\pi}\,e^{-i\phi} \qquad ...(123)$$

While the wave function represented by Eq. 121 is real, the wave functions represented by Eqs. 122 and 123 are not real as they contain the imaginary quantity i and as such cannot be visualised. An acceptable solution of wave equation is that which yields a real wave function. In order to obtain real wave functions for *p* orbitals, two linear combinations of angular wave functions represented by Eqs. 122 and 123 are taken into consideration. The two normalised linear combinations thus obtained are :

$1/\sqrt{2}\,[(+1)+(-1)]$, *i.e.*, $1/\sqrt{2}\,R_{n,1}(r)(\Theta_{1,+1}\Phi_{+1} + \Theta_{1,-1}\Phi_{-1})$ and

$1/\sqrt{2}\,[(+1)-(-1)]$, *i.e.*, $1/\sqrt{2}R_{n,1}(r)\,(\Theta_{1,+1}\Phi_{+1} - \Theta_{1,-1}\Phi_{-1})$

These wave functions yield the following results :

Combination $1/\sqrt{2}\,[(+1)+(-1)]$ for real *p* wave function $= R_{n,1}(r)\sqrt{3/4\pi}\,\sin\theta\,\cos\phi$ ...(124)

Combination $1/\sqrt{2}\,[(+1)-(-1)]$ for real *p* wave function $= R_{n,1}(r)\sqrt{3/4\pi}\,\sin\theta\,\sin\phi$ ...(125)

Thus, Eqs. 121, 124 and 125 now represent a set of *real* wave functions for *p* orbitals.

Let us now investigate the **shapes of the 2*p* orbitals** represented by the real wave functions as given by Eqs. 121, 124 and 125. Expressing these functions in terms of the Cartesian coordinates, the real *p* wave function, as given by Eq. 121 is

$$(0) = R_{2,1}(r)\sqrt{3/4\pi}\cos\theta \qquad ...(126)$$

$$= R_{2,1}(r)\sqrt{3/4\pi}\times z/r \quad [\because z = r\cos\theta \text{ (Fig. 9)}] \qquad ...(127)$$

This is, evidently, a function of z and is, therefore, known as p_z wave function.

The wave function p_z when plotted in three-dimensional space yields a dumb-bell shaped curve along the z-axis, as shown in Fig. 11.

It can be seen from Eq. 127 that the function p_z will be positive when z is positive and negative when z is negative. It may be noted that + and – signs are geometric signs of the plotted wave functions only and should not be confused with positive or negative charges.

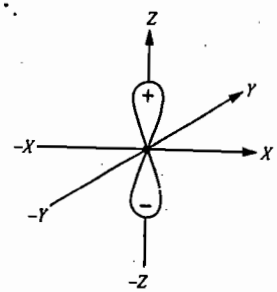

Fig. 11. The shape of p_z orbital

Let us now consider the real wave function given by Eq. 124. Expressing this wave function in terms of Cartesian coordinates, we get

$$1/\sqrt{2}\,[(+1)+(-1)] = R_{2,1}(r)\sqrt{3/4\pi}\,\sin\theta\cos\phi$$

$$= R_{2,1}(r)\,\sqrt{3/4\pi}\times x/r \quad [\because \sin\theta\cos\phi = x/r \text{ (Fig. 9)}] \qquad ...(128)$$

Evidently, the *p* wave function given by Eq. 128 varies with x only. It is, therefore, referred to as p_x wave function. A plot of p_x wave function in three-dimensional space gives a dumb-bell shaped curve along the x-axis, as shown in Fig. 12.

It can be easily seen from Eq. 128 that the function p_x would be positive when x is positive and negative when x is negative.

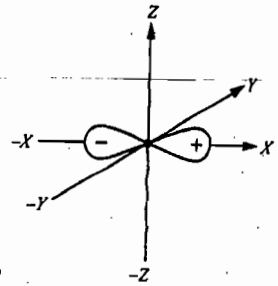

Fig. 12. The shape of p_x orbital

Similarly, the real wave function as given by Eq. 125 when expressed

in terms of Cartesian coordinates yields Eq. 129. Thus,

$$1/\sqrt{2}\,[(+1)-(-1)] = R_{2,1}(r)\ \sqrt{3/4\ \pi}\ \sin\theta\ \sin\phi$$

$$= R_{2,1}(r)\ \sqrt{3/4\pi}\times y/r\ \ [\because \sin\theta\sin\phi = y/r \text{ (Fig. 9)}] \qquad ...(129)$$

Thus, the p wave function in this case varies with y only. It is, therefore, called p_y wave function.

A plot of p_y wave function in three-dimensional space gives a dumb-bell shaped curve along the y-axis, as shown in Fig. 13.

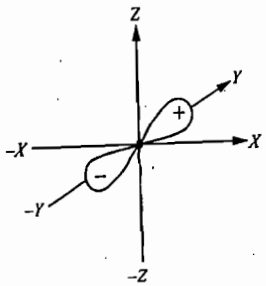

Fig. 13. The shape of p_y orbital

The complete wave functions of $2p$, $3p$, $4p$ orbitals would give rise to dumb-bell shaped curves except for the fact that the $4p$ orbital would occupy more space than $3p$ orbital and $3p$ orbital would occupy more space than $2p$ orbital (Fig. 14).

Also, the $4p$ orbital would have *two radial nodes*, the $3p$ orbital would have *one radial node* and $2p$ orbital would have *no radial node* (the number of radial nodes is given by $n-l-1$).

The shapes of $2p_x$, $3p_x$ and $4p_x$ orbitals with radial nodes are shown in Fig. 14.

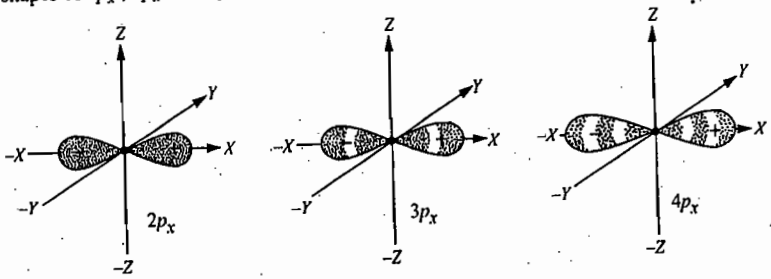

Fig. 14. The shapes of $2p_x$, $3p_x$ and $4p_x$ orbitals.

Complete wave functions for *d* orbitals and their shapes. For d orbitals, $l = 2$ so that $m = 0, +1, +2, -1, -2$. The complete wave functions for the d orbitals may be written as follows :

$$(0) = R_{n,2}(r)\ Y_2^0 = R_{n,2}(r)\sqrt{5/16\pi}\ (3\cos^2\theta - 1) \qquad ...(130)$$

$$(+1) = R_{n,2}(r)\ Y_2^{+1} = R_{n,2}(r)\sqrt{15/8\pi}\ (\sin\theta\ \cos\theta)\,e^{i\phi} \qquad ...(131)$$

$$(+2) = R_{n,2}(r)\ Y_2^{2+} = R_{n,2}(r)\sqrt{15/32\pi}\ (\sin^2\theta)\,e^{i2\phi} \qquad ...(132)$$

$$(-1) = R_{n,2}(r)\ Y_2^{-1} = R_{n,2}(r)\sqrt{15/8\pi}\ (\sin\theta\cos\theta)\,e^{-i\phi} \qquad ...(133)$$

$$(-2) = R_{n,2}(r)\ Y_2^{-2} = R_{n,2}(r)\sqrt{15/32\pi}\ (\sin^2\theta)\,e^{-i2\phi} \qquad ...(134)$$

Of the above five wave functions, only one wave function given by Eq. 130 is real. All other wave functions contain the imaginary quantity i for d orbitals. We obtain real d orbital wave functions by the procedure similar to the one we adopted for obtaining p orbital wave functions. The real d orbital wave functions obtained from linear combination of Eqs. 131 and 133 are : (*i*) $1/\sqrt{2}\,[(+1)+(-1)]$, *i.e.*, $1/\sqrt{2}\,R_{n,2}(r)\,(\Theta_{2,1}\Phi_1 + \Theta_{2,-1}\Phi_{-1})$ and (*ii*) $1/\sqrt{2}\,[(+1)-(-1)]$, *i.e.*, $1/\sqrt{2}\,R_{n,2}(r)(\Theta_{2,1}\Phi_1 - \Theta_{2,-1}\Phi_{-1})$ and the d orbital wave functions obtained from linear combination of Eqs. 132 and 134 are :

(*i*) $1/\sqrt{2}\,[(+2)+(-2)]$, *i.e.*, $1/\sqrt{2}\ R_{n,2}(r)\,(\Theta_{2,2}\,\Phi_2 - \Theta_{2,-2}\Phi_{-2})$ and (*ii*) $1/\sqrt{2}\,[(+2)-(-2)]$, *i.e.*, $1/\sqrt{2}\ R_{n,2}(r)\,(\Theta_{2,2}\,\Phi_2 - \Theta_{2,-2}\Phi_{-2})$.

From these wave functions, the five real d orbital wave functions obtained are as follows :

$$\text{Real } d \text{ wave function } (0) = R_{n,2}(r)\ \sqrt{5/16\pi}\ (3\cos^2\theta - 1) \qquad ...(135)$$

$$\text{Real } d \text{ wave function } 1/\sqrt{2}\,[(+1)+(-1)] = R_{n,2}(r)\ \sqrt{15/4\pi}\ \sin\theta\cos\theta\cos\phi \qquad ...(136)$$

$$\text{Real } d \text{ wave function } 1/\sqrt{2}\,[(+1)-(-1)] = R_{n,2}(r)\ \sqrt{15/4\pi}\ \sin\theta\cos\theta\sin\phi \qquad ...(137)$$

$$\text{Real } d \text{ wave function } 1/\sqrt{2}\,[(+2)+(-2)] = R_{n,2}(r)\ \sqrt{15/16\pi}\ \sin^2\theta\cos 2\phi \qquad ...(138)$$

$$\text{Real } d \text{ wave function } 1/\sqrt{2}\,[(+2)-(-2)] = R_{n,2}(r)\ \sqrt{15/16\pi}\ \sin^2\theta\ \sin 2\phi \qquad ...(139)$$

Expressing the above wave functions in terms of Cartesian co-ordinates with the help of Fig. 9, we get

(*i*)
$$(0) = R_{n,2}(r)\ \sqrt{15/16\pi}\ (3\cos^2\theta - 1)$$

$$= R_{n,2}(r)\ \sqrt{15/16\pi}\ (3z^2 - r^2)\times 1/r^2 \qquad ....(140)$$

As can be seen, the above d wave function *varies as* z^2. Hence, it is called d_z^2 wave function.

(*ii*)
$$1/\sqrt{2}\,[(+1)+(-1)] = R_{n,2}(r)\ \sqrt{15/4\pi}\ \sin\theta\ \cos\theta\ \cos\phi$$

$$= R_{n,2}(r)\ \sqrt{15/4\pi}\ \times xz/r^2 \qquad ...(141)$$

Since the d wave function *varies as* xz, it is called d_{xz} wave function.

(*iii*)
$$1/\sqrt{2}\,[(+1)-(-1)] = R_{n,2}(r)\ \sqrt{15/4\pi}\ \sin\theta\ \cos\theta\ \sin\phi$$

$$= R_{n,2}(r)\ \sqrt{15/4\pi}\times yz/r^2 \qquad ...(142)$$

Since the d wave function *varies as* yz, it is called d_{yz} wave function.

(*iv*)
$$1/\sqrt{2}\,[(+2)+(-2)] = R_{n,2}(r)\sqrt{15/16\pi}\ \sin^2\theta\ \cos 2\phi$$

$$= R_{n,2}(r)\sqrt{15/16\pi}\sin^2\theta(\cos^2\phi - \sin^2\phi)$$

$$= R_{n,2}(r)\sqrt{15/16\pi}\ (\sin^2\theta\ \cos^2\phi - \sin^2\theta\ \sin^2\phi)$$

$$= R_{n,2}(r)\ \sqrt{15/16\pi}\ (x^2 - y^2)/r^2 \qquad ...(143)$$

Since the d wave function *varies as* $x^2 - y^2$, it is called $d_{x^2-y^2}$ wave function.

(*v*)
$$1/\sqrt{2}\,[(+2)-(-2)] = R_{n,2}(r)\ \sqrt{15/16\pi}\ \sin^2\theta\ \sin 2\phi$$

$$= R_{n,2}(r)\ \sqrt{15/16\pi}\sin^2\theta\ 2\sin\phi\ \cos\phi$$

$$= R_{n,2}(r)\sqrt{15/4\pi}\,\sin\theta\sin\phi\sin\theta\cos\phi$$

$$= R_{n,2}(r)\sqrt{15/4\pi}\;xy/r^2 \qquad ...(144)$$

Since the d wave function *varies as xy*, it is called d_{xy} wave function.

Thus, the five real wave functions of d orbitals are d_{z^2}, d_{xz}, d_{yz}, $d_{z^2-y^2}$ and d_{xy}. These wave functions when plotted in three-dimensional space yield curves as shown in Fig. 15. It may be remembered that all these are solid curves, *i.e., these are three-dimensional* because of their dependence on $r\,(=\sqrt{x^2+y^2+z^2})$.

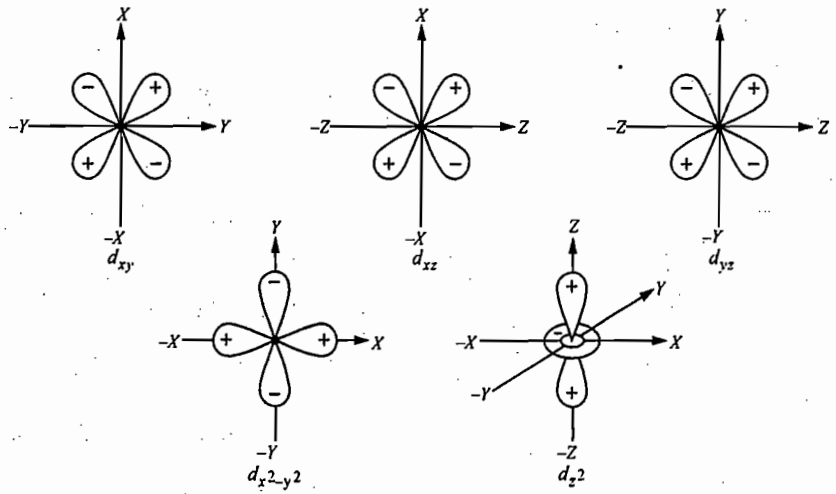

Fig. 15. Shapes of d orbitals

The orbital d_{z^2} has a dumb-bell shaped curve symmetric about the Z-axis, having a ring-like collar in XY plane. The dumb-bell shaped part of the curve has a *positive geometric sign* (because whatever be the sign of z, positive or negative, its square is always positive) whereas the collar in the XY plane has a *negative geometric sign.*

The orbital d_{xy} has a double dumb-bell shape. The quantity xy will be positive when both x and y are positive or when both are negative. However, xy will be negative when either of x or y is negative. Thus, the sign of the curve is positive in first and third quadrants while it is negative in second and fourth quadrants. The shapes of d_{xz}, d_{yz} orbitals can be explained in a similar manner.

The orbital $d_{x^2-y^2}$ is also double dumb-bell shaped but its lobes lie on X and Y axes. The signs of the lobes on X axis will always be positive (because whatever be the sign of x, x^2 will always be positive) whereas the signs of the lobes on Y axis will always be negative (because whatever be the sign of y, $-y^2$ will always be negative). The *exact shapes* of d orbitals are obtained by taking into consideration the total wave function. Accordingly, $3d_{x^2-y^2}$ orbital would be similar in shape to $4d_{x^2-y^2}$ orbital or $5d_{x^2-y^2}$ orbital except for the fact that

1. A $5d$ orbital would have *two*, a $4d$ orbital would have *one* and a $3d$ orbital would have *no* radial node.

2. A $5d$ orbital would occupy more space than a $4d$ orbital and a $4d$ orbital would occupy more space than a $3d$ orbital, as shown in Fig. 16.

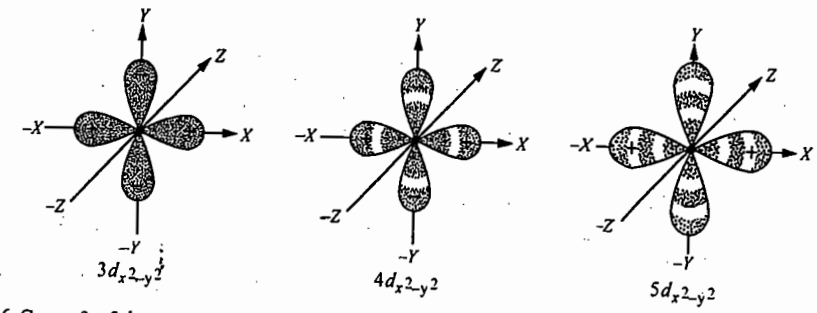

Fig. 16. Curves for $3d_{x^2-y^2}$, $4d_{x^2-y^2}$ and $5d_{x^2-y^2}$ orbitals in three-dimensional space. The curves for the other $3d$, $4d$, $5d$ orbitals can be drawn on similar lines.

In a similar manner, we can determine the shapes of f orbitals

The set of complete wave functions for f orbitals is given below :

$$(0) = R_{n,3}(r)\,Y_3^0$$

$$(\pm1) = R_{n,3}(r)\,Y_3^{\pm1}$$

$$(\pm2) = R_{n,3}(r)\,Y_3^{\pm2}$$

$$(\pm3) = R_{n,3}(r)\,Y_3^{\pm3}$$

The spherical harmonics for the f orbital wave functions have been given earlier. In the set given above, only (0) is real. The rest of the six f orbital wave functions are imaginary. We can derive the real set of f orbital wave functions by following the same procedure as was adopted by obtaining sets of real p and d orbital wave functions. The real f orbital wave functions thus obtained would be desinated as follows :

$f_{z(x^2-y^2)}$, $f_{y(z^2-x^2)}$, $f_{x(y^2-z^2)}$, $f_{z(5z^2-3r^2)}$, $f_{x(5x^2-3r^2)}$, $f_{y(5y^2-3r^2)}$ and $f_{(x,y,z)}$

Energy of Electron in Hydrogen and Hydrogen-like Systems

The solution of Schrodinger wave equation given in standard books in quantum mechanics yields the following expression for the energy of electron in hydrogen or hydrogen-like systems :

$$E_n = \frac{2\pi^2 Z^2 \mu e^4}{(4\pi\varepsilon_0)^2 n^2 h^2} \qquad ...(145)$$

where μ is the reduced mass of the electron and the nucleus defined as $\mu = (m_e \times m_n)/(m_e + m_n)$ where m_e is the mass of electron and m_n is the mass of the nucleus. Since $m_n \gg m_e$, hence $\mu = m_e$. Replacing m by m_e in Eq. 145, we find that Eq. 145 is exactly the same as obtained by Bohr (Eq. 20).

Quantum Numbers (n, l, m). As discussed earlier, the three quantum numbers n, l and m are the direct consequence of the solutions of the Schrodinger wave equation put forth to describe the behaviour of electron as a wave. The principal quantum number n and the angular momentum quantum number l have already been discussed in details. It may be recalled that the principal quantum number n represents the main energy level or energy shell in which the electron is present. It determines to a large extent the energy of an electron moving in a particular energy level. It also determines the average distance of an electron from the nucleus. As the value of n increases, the electron gets farther away from the nucleus and its energy increases. The angular momentum quantum number, l gives a description of the angular

momentum of the electron and the existence of energy subshells which accounts for the appearance of groups of closely spaced lines in the spectrum of hydrogen. The quantum numbers n and l are related as $l = n - 1$.

Magnetic Quantum Number, m. The motion of an electron in an orbit may be likened to the flow of electricity in a coil of wire. Such a flow produces magnetic field (electromagnetic effect). The magnitude of the magnetic field thus generated is proportional to the magnitude of the orbital angular momentum. Since orbital angular momentum is a vector quantity, it can have a number of orientations in space as a result of which the magnetic field and the accompanying magnetic moment can also have a number of orientations in space. The number of these orientations is given by the magnetic quantum number, m. The value of m ranges from $-l$ through zero to $+l$, thus totalling $2l+1$ values. Each value of m represents a particular **orbital** which is defined as the space in which threre is maximum probability of the existence of electron.

Thus, if $l = 0$ (*i.e.*, the subshell is s), m will have only one value, *i.e.*, 0. There will, therefore, be only one orientation of the magnetic moment which means that the s subshell will have only *one orbital*, called the *s orbital*.

If $l = 1$ (*i.e.*, the subshell is p), m will have three values, -1, 0, $+1$. There would thus be three orientations of the magnetic moment. This means that the p subshell will have three orbitals. These are designated as p_x, p_y and p_z orbitals.

If $l = 2$ (*i.e.*, the subshell is d), m will have five values, -2, -1, 0, $+1$, $+2$. Accordingly, magnetic moment will have five orientations in space. This means that d subshell will have five orbitals. These are designated as d_{xy}, d_{yz}, d_{zx}, $d_{x^2y^2}$ *and* d_{z^2}.

Similarly, it can be shown that the f subshell will have seven orbitals.

Electron Spin and Magnetic Spin Quantum Numbers (s, m_s). In order to explain the nature of atomic spectra, G. Uhlenback and S. Gouldsmit postulated that an electron spins about its own axis and thus generates spin angular momentum which is a vector quantity and is collinear with the axis of spin of the electron. The magnitude of the spin angular momentum of the electron is given by $\sqrt{s(s+1)}\ h/2\pi$ where s is known as the **spin quantum number** of the electron.

The spin angular momentum is quantised in space. That is, it can have only a fixed number of orientations in space about any chosen direction generally referred to as Z direction. The number of orientations in space is given by $2s + 1$. Since for a single electron, s is 1/2, hence only two orientations ($2\times1/2 + 1 = 2$) of spin angular momentum vector are allowed about the Z-axis, one of which has the Z-component equal to $+1/2$ and the other has the Z-component equal to $-1/2$ in units of $h/2\pi$, as shown in Fig 17. The Z-components $+1/2$ and $-1/2$ (excluding the unit $h/2\pi$) are known as **magnetic spin quantum numbers, m_s.**

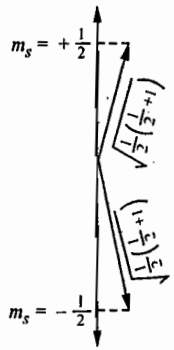

Fig. 17. The space-orientation of spin angular momentum of an electron.

The spin angular momentum of the negatively charged electron also generates magnetic moment which is collinear with the spin angular momentum. Therefore, the allowed orientations of angular momentum and of the magnetic moment, both of which are generated due to the spin of the electron, are the same.

In the case of atoms with single electrons, both the orientations of spin angular momentum (specified by their m_s values) are of equal energy. But in the presence of external magnetic field, their energies become different from each other.

The Zeeman Effect. Zeeman, in 1896, found that when a strong magnetic field is applied to a system whose spectrum is being recorded, *each spectral line gets split up into a number of separate lines.* This

phenomenon is known as the **Zeeman effect.**

As already stated, there are $(2l + 1)$ components of orbital angular momentum vector along any chosen direction, say, the Z-direction. The magnitudes of these components are given by $mh/2\pi$. Since the magnetic field generated due to the motion of electron in an orbital has also $(2l + 1)$ orientations of orbital angular momentum vector and since the magnetic field generated depends upon the magnitude of orbital angular momentum, it will also have $(2l + 1)$ components along the Z-axis whose magnitudes depend on the magnitudes of the Z-components of the orbital angular momentum (*i.e.*, $mh/2\pi$).

In the absence of any external magnetic field, all the orientations of the orbital angular momentum (and hence of the magnetic field generated due to the motion of the electron in the orbital) have equal probability to occur. But, if an external magnetic field is applied along the Z-axis, the orientation with maximum positive value of m will have maximum magnetic field component *parallel* to the direction of the external field applied. Such an orientation of orbital angular momentum will, therefore, be of lowest energy. Similarly, the orientation with maximum negative value of m will have maximum magnetic field component *antiparallel* to the direction of the external magnetic field applied. Such an orientation will, therefore, be of highest energy. Likewise, the energies of all other orientations of orbital angular momenta having different values of m will be different, ranging between the two extremes mentioned above, in the presence of external magnetic field.

Let us consider the example of a d orbital whose orbital angular momentum is $\sqrt{2(2+1)}\,h/2\pi$. It has five orientations of different energies in the presence of external magnetic field. Each orientation has a different Z-component whose value ranges from $+2h/2\pi$ to $-2h/2\pi$, as shown in Fig. 18. Thus, a spectral line obtained in the absence of external magnetic field due to the shift of electron from a higher to a lower d orbital of an atom will be split up into five lines in the presence of the external magnetic field.

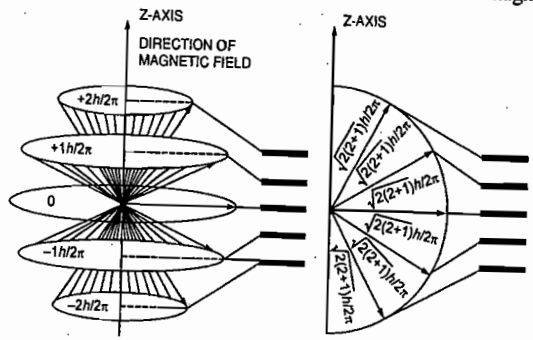

Fig. 18. Five different space orientations corresponding to $l = 2$.

Pauli's Exclusion Principle

This is an important generalisation put forth by Wolfgang Pauli, in 1925, which determines the maximum number of electrons that an energy level can accommodate. Pauli's exclusion principle states that *it is impossible for any two electrons in the same atom to have all the four quantum numbers identical.* Thus, in the same atom, any two electrons may have three quantum numbers identical but not the fourth which must be different. This principle is very useful *in determining the maximum number of electrons that can occur in any quantum group.* For K shell, for instance, since $n=1$, l can have only one value (*viz.*, 0) and m can also have only one value (*viz.*, 0). Hence, m_s can be either $+1/2$ or $-1/2$. Thus, there are **two combinations** of the quantum numbers, as shown :

$$n=1 \quad l=0 \quad m=0 \quad m_s = +1/2$$
$$n=1 \quad l=0 \quad m=0 \quad m_s = -1/2$$

This shows that in the K shell, there is only one subshell $l = 0$ and in this only ***two*** **electrons** of opposite spins can be accommodated.

For L shell, since $n = 2$, l can have two values (0 and 1), m can have only one value for $l = 0$ and three values for $l = 1$, *viz.*, -1, 0 and $+1$ and m_s can have two values, *viz.*, $+1/2$ and $-1/2$, for each value of m. These possibilities would give rise to **eight combinations** of the four quantum numbers, keeping in view the *exclusion principle*. Thus, L shell can accommodate **8 electrons**, 2 in the $l = 0$ subshell (s subshell) and 6 in the $l = 1$ subshell (p subshell).

Similarly, it can be shown that the M shell can have **18 electrons**, 2 in the $l = 0$ subshell (s subshell), 6 in the $l = 1$ subshell (p subshell) and 10 in the $l = 2$ subshell (d subshell) and so on.

The *maximum number* of electrons that can be accommodated in the first four principal energy shells as distributed in the various subshells (l values) are given in Table 3.

TABLE 3

Distribution of Electrons in Various Energy Shells and Subshells

Principal energy shell (n)	Subshells (l)	Orbitals (m)	Number of electrons in : Subshell	Number of electrons in : Principal energy shell
1	0 (1s subshell)	0 (one orbital)	2	2
2	0 (2s subshell)	0 (one orbital)	2	8
	1 (2p subshell)	$-1, 0, +1$ (three orbitals)	6	
3	0 (3s subshell)	0 (one orbital)	2	18
	1 (3p subshell)	$-1, 0, +1$ (three orbitals)	6	
	2 (3d subshell)	$-2, -1, 0, +1, +2$ (five orbitals)	10	
4	0 (4s subshell)	0 (one orbital)	2	32
	1 (4p subshell)	$-1, 0, +1$ (three orbitals)	6	
	2 (4d subshell)	$-2, -1, 0, +1, +2$ (five orbitals)	10	
	3 (4f subshell)	$-3, -2, -1, 0, +1, +2, +3$ (seven orbitals)	14	

Pauli's Exclusion Principle – Wave Mechanical Approach

Consider an orbital ψ_A containing two electrons (1) and (2). Ignoring the interelectronic repulsion betweeen the two electrons, we can write the orbital wave function for the system as :

$$\psi = \psi_{A(1)}\,\psi_{A(2)}$$

In writing ψ, the spins of the two electrons have not been taken into account. The possible electron spin wave functions for the two-electron system are $\alpha_1\alpha_2$, $\beta_1\beta_2$, $\alpha_1\beta_2 + \alpha_2\beta_1$ and $\alpha_1\beta_2 - \alpha_2\beta_1$ where α and β are, respectively, the spin wave functions corresponding to $+\frac{1}{2}$ and $-\frac{1}{2}$ spin states of the electrons. Assuming that there is no spin–orbital interaction, the complete wave functions for the system, comprising

of both the spin and the orbital part, can be written as :

$$\psi_{complete} = \psi_{A(1)}\psi_{A(2)}\alpha_1\alpha_2$$

$$\psi_{complete} = \psi_{A(1)}\psi_{A(2)}\beta_1\beta_2$$

$$\psi_{complete} = \psi_{A(1)}\psi_{A(2)}(\alpha_1\beta_2 + \alpha_2\beta_1)$$

$$\psi_{complete} = \psi_{A(1)}\psi_{A(2)}(\alpha_1\beta_2 - \alpha_2\beta_1)$$

According to the wave mechanical statement of Pauli's exclusion principle, the complete wave function of the system must be **asymmetric**. That is, it must change sign when we exchange the coordinates of electrons (1) and (2).

Let us consider the last complete wave function, *viz.*, $\psi_{complete} = \psi_{A(1)}\psi_{A(2)}(\alpha_1\beta_2 - \alpha_2\beta_1)$. The exchange of positions of electrons leads to $\psi_{A(2)}\psi_{A(1)}(\alpha_2\beta_1 - \alpha_1\beta_2)$ which is, evidently, equal to $-\psi_{complete}$. This complete wave function is thus assymmetric and hence acceptable. The first three complete wave functions, however, retain the same sign on exchanging the positions of electrons and are, therefore, symmetric. These are, therefore, not acceptable.

The acceptable complete wave function can be expanded and written as follows :

$$\psi_{complete} = \psi_{A(1)}\psi_{A(2)}\,\alpha_1\beta_2 - \psi_{A(1)}\psi_{A(2)}\,\alpha_2\beta_1 = \begin{vmatrix} \psi_{A(1)}\beta_1 & \psi_{A(1)}\beta_1 \\ \psi_{A(2)}\beta_2 & \psi_{A(2)}\beta_2 \end{vmatrix}$$

Imagine now that both the electrons in the same orbital ψ_A have the same spin. In that case, the above expression can be written as :

$$\psi_{complete} = \begin{vmatrix} \psi_{A(1)}\alpha_1 & \psi_{A(1)}\alpha_1 \\ \psi_{A(2)}\alpha_2 & \psi_{A(2)}\alpha_2 \end{vmatrix} \text{ or } \begin{vmatrix} \psi_{A(1)}\beta_1 & \psi_{A(1)}\beta_1 \\ \psi_{A(2)}\beta_2 & \psi_{A(2)}\beta_2 \end{vmatrix}$$

Since the two columns of the determinant are identical, it becomes equal to zero. Therefore, even though the quantum numbers n, l and m are the same for the two electrons in the same orbital ψ_A, the spins of the two electrons cannot be the same and have to be opposite in order that $\psi_{complete}$ is non-zero.

Suppose that we add one more electron to the ψ_A orbital which already contains two electrons having opposite spins with spin wave functions α and β. The third electron would have either α spin wave function or β spin wave function. The complete wave function can be written as the following 3×3 determinant :

$$\psi_{complete} = \begin{vmatrix} \psi_{A(1)}\alpha_1 & \psi_{A(1)}\beta_1 & \psi_{A(1)}\alpha_1 \\ \psi_{A(2)}\alpha_2 & \psi_{A(2)}\beta_2 & \psi_{A(2)}\alpha_2 \\ \psi_{A(3)}\alpha_3 & \psi_{A(3)}\beta_3 & \psi_{A(3)}\alpha_3 \end{vmatrix} \text{ if the spin wave function of the third electron is } \alpha.$$

and

$$\psi'_{complete} = \begin{vmatrix} \psi_{A(1)}\alpha_1 & \psi_{A(1)}\beta_1 & \psi_{A(1)}\beta_1 \\ \psi_{A(2)}\alpha_2 & \psi_{A(2)}\beta_2 & \psi_{A(2)}\beta_2 \\ \psi_{A(3)}\alpha_3 & \psi_{A(3)}\beta_3 & \psi_{A(3)}\beta_3 \end{vmatrix} \text{ if the spin wave function of the third electron is } \beta.$$

In each of the abvoe two determinants, the two columns are identical. Therefore, both these determinants would vanish.

We conclude from the above discussion that it is impossible for us to *accommodate more than two electrons in the same orbital and that it is impossible for the two electrons in the same orbital to have the same spin*. This leads to the statement of Pauli's exclusion principle that *no two electrons in an orbital can have all the four quantum numbers identical.*

However, it can be shown from the determinantal forms of $\psi_{complete}$ that if the two electrons having the same n, l and m values are present in different orbitals ψ_A, ψ_B, ψ_C, etc., in a system, the spins of the two electrons may or may not be the same.

Number of Various Atomic Orbitals. We have seen above that for *s* subshell (*i.e.*, when $l = 0$), there is only one possible orientation (*i.e.*, *m* has only one value). This means that there is only **one *s* orbital** whatever be the value of the principal quantum number *n*. For *p* subshell (*i.e.*, when $l = 1$), *m* has *three* values. In other words, a *p* subshell can have *three* possible orientations. Thus, there can be **three *p* orbitals** whatever be the value of the principal quantum number *n*. The three *p* orbitals are designated as p_x, p_y and p_z. For *d* subshell (*i.e.*, when $l = 2$), *m* has *five* values, *i.e.*, there are *five* possible orientations. This means that there can be **five *d* orbitals** whatever be the value of the principal quantum number *n*. The five *d* orbitals are designated as d_{xy}, d_{yz}, d_{xz}, d_{z^2}, $d_{x^2-y^2}$. For *f* subshell (*i.e.*, when $l = 3$), *m* has *seven* values, *i.e.*, there are *seven* possible orientations. This means that there can be **seven *f* orbitals** whatever be the value of the principal quantum number *n*. The *f* orbitals have complicated designations, the discussion of which is beyond the scope of the book.

To sum up : There can be *only one s orbital, three p orbitals, five d orbitals* and *seven f orbitals whatever be the major energy shell.*

Example 8. What subshells are possible in $n = 4$ energy level ? How many orbitals are possible for this level ?

Solution : For $n = 4$, the possible values of l are 0, 1, 2 and 3. The corresponding subshells are *s, p, d* and *f*.

For $n = 4$, there is one *s*, three *p*, five *d* and seven *f* orbitals. Therefore, the total number of orbitals for $n = 4$ is 16.

Example 9. An electron is in 3*d* orbital. What possible values for the quantum numbers *n, l, m* and m_s can it have ?

Solution : For 3*d* orbital, $n = 3$, $l = 2$ so that $m = -2, -1, 0, +1, +2$ and $m_s = +1/2$ and $-1/2$ for each value of *m*.

Example 10. Can we have 5*g* subshell ? How many orbitals are possible for this subshell?

Solution : For $n = 5$, l can have values = 0, 1, 2, 3 and 4. The corresponding subshells are 5*s*, 5*p*, 5*d*, 5*f* and 5*g*. Thus, **we can have 5*g* subshell.**

For 5*g* subshell ($l = 4$), the values of *m* are $-4, -3, -2, -1, 0, +1, +2, +3, +4$. There are thus **nine orbitals** in 5*g* subshell.

Energy Level Diagram of a Multi-electron Atom. The energy values of various orbitals belonging to different principal energy levels in a multi-electron atom are depicted in the energy level diagram shown in Fig. 19.

It is seen that in a multi-electron atom, different types of orbitals even in the same principal energy level have different energy values. This is because the energies of these orbitals depend not only on the value of *n* but also on the values of *l*. Thus, the 2*p* orbital (n=2, l=1) has higher energy than the 2*s* orbital ($n = 2$, $l = 0$). Similarly, the energy of the 3*d* orbital ($n = 3$, $l = 2$) is greater than that of the 3*p* orbital ($n = 3$, $l = 1$) which, in turn, is greater than that of the 3*s* orbital ($n = 3$, $l = 0$).

Further, it is seen that there is also a crossing of energies, particularly in the higher energy shells. For example, the energy of 4*s* orbital is lower than that of 3*d* orbital although the former belongs to the higher principal energy shell. Similarly, the energy of 5*s* orbital is lower than that of 4*d* orbital and that of 6*s* orbital is lower than that of 5*d* orbital. Thus, in multi-electron atoms, the energies are determined not only by principal quantum number *n* but also by subsidiary quantum number *l*.

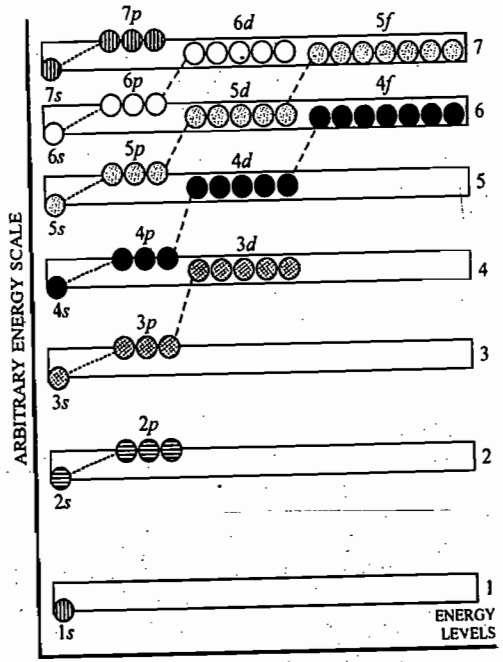

Fig. 19. Energy level diagram of multi-electron atoms.

It may be mentioned, however, that the **energy level diagram of hydrogen or a hydrogen-like atom,** *i.e.*, an atom having only one electron, is *distinctly different* from the energy level diagram of a multi-electron atom. In the former case, *all the orbitals belonging to any particular principal energy level have the same energy.* For example, the 2*s* and the three 2*p* orbitals of second energy level have the same energy. Similarly, the 3*s*, the three 3*p* and the five 3*d* orbitals of the third energy level have the same energy.

The energy of an orbital depends upon (*i*) *nuclear charge* (*ii*) *principal quantum number* and (*iii*) *the presence of other electrons* in the lower energy orbitals having different *l* values. Since in hydrogen or hydrogen-like atoms, there is *only one electron* and the attractive effect of the nuclear charge on the electron remains undisturbed, the energy of any orbital which this solitary electron occupies at any instant is determined by the principal quantum number only. In multi-electron atoms, however, there are a number of electrons. Some of them, occupying lower energy orbitals, *tend to reduce the effect of nuclear charge on the electrons present in higher energy orbitals.* This is due to the fact that these orbitals intervene between the nucleus and the electrons in the higher energy orbitals. This effect is known as **screening effect.** Since the electrons present in *different types of orbitals* (*s, p, d* or *f*) *are screened differently, they are attracted to different extents by the nucleus.* As a result, various orbitals are held at different distances from the nucleus and have different energies. This explains the difference in the energies of *s, p, d* and *f* orbitals even though belonging to the same principal energy shell in a multi-electron atom. The extent of screening of an electron by other electrons in the atom is calculated with the help of some *empirical rules* known as **Slater's rules.**

The Slater's Rules, The Concept of Effective Nuclear Charge

Consider an electron in one of the atomic orbitals of a multi-electron atom. Because of the electrostatic repulsion by other electrons in the same or other orbitals, the nuclear charge felt by this electron will be less than the actual nuclear charge. This electron is said to be screened from the influence of the nuclear charge and *the reduced charge felt by the electron is known as the* **effective nuclear charge.** The intervening electrons screen the electrons present in the peripheral *s, p, d* or *f* orbitals of even the same principal shell to different extents.

The effective nuclear charge for any electron in the configuration of an atom may be calculated with the help of the following correlation :

$$Z_{ef} = Z_{actual} - S \qquad ...(144)$$

where *S* is the **screening constant** or the **shielding constant** whose magnitude determines the extent to which the electron is screened or shielded by other electrons in the atom from the nuclear charge.

The screening constant is evaluated by the following empirical rules known as the **Slater's rules :**

1. The various orbitals are grouped as follows and written in the order given below, starting from the side of the nucleus :

(1*s*) (2*s* 2*p*) (3*s* 3*p*) (3*d*) (4*s* 4*p*) (4*d*) (4*f*) (5*s* 5*p*), etc.

2. For an electron in a group of *s, p* electrons, the value of the screening constant *S* is the sum of the following contributions :

(*i*) No contribution from any electron present in groups of orbitals lying on the right side of the group in which the electron (for which *S* is to be determined) is present.

(*ii*) A contribution of 0·35 from every other electron present in the group of orbitals (say, ns np) under consideration. A contribution of 0·30 from the other electron in 1*s* orbital if the electron for which *S* is to be calculated belongs to 1*s* orbital.

(*iii*) A contribution of 0·85 per electron from all electrons with quantum number $n - 1$, *i.e.*, electrons present in $(n - 1)$th shell.

(*iv*) A contribution of 1·0 per electron from all electrons present in the $(n - 2)$th and the next inner shell.

3. For an electron in a group of *d* or *f* electrons, the rules 2(*i*) and 2(*ii*) apply as such. However, the rules 2(*iii*) and 2(*iv*) are replaced by the rule that the contribution per electron from *all electrons* in the inner shells is 1·0.

We shall now apply these rules to calculate the effective nuclear charges for various electronic systems.

Example 11. What is the effective nuclear charge felt by 1*s* electron of helium atom ?

Solution : The electronic configuration of helium atom is $1s^2$

There is one more 1*s* electron, apart from the electron for which Z_{eff} is to be calculated.

∴ The screening constant, $S = 1 \times 0{\cdot}30 = 0{\cdot}30$

Hence, Z_{eff} felt by 1*s* electron of helium atom $= 2 - 0{\cdot}30 = \mathbf{1{\cdot}70}$

Example 12. What is the effective nuclear charge felt by a 2*p* electron of a nitrogen atom ? What will be the effective nuclear charge felt by its 1*s* electron ?

Solution : Z_{eff} for 2*p* electron :

Electronic configuration of N atom is $1s^2\,2s^2\,2p^3$.

∴ There are four other electrons in (2*s* 2*p*) group.

Screening constant *S* for 2*p* electron $= 4 \times 0{\cdot}35 + 2 \times 0{\cdot}85 = 1{\cdot}40 + 1{\cdot}70 = 3{\cdot}10$

Z_{eff} felt by 2*p* electron $= Z_{actual} - S = 7 - 3{\cdot}10 = \mathbf{3{\cdot}90}$

Z_{eff} for 1*s* electron :

Z_{eff} felt by 1*s* electron $= Z_{actual} - S = 7 - 1 \times 0{\cdot}30 = \mathbf{6{\cdot}70}$

(There will be no contribution from (2*s* 2*p*) electrons in this case as per Slater's rule 2(*i*))

Example 13. Calculate the effective nuclear charge felt by a 3*d* electron of chromium atom (Z = 24).

Solution : The grouping of electrons in Cr atom according to Slater's rules is

$$(1s^2)\,(2s^2\,2p^6)\,(3s^2\,3p^6)\,(3d^5)\,(4s^1)$$

There will be no contribution from 4*s* electron.

There are 4 other 3*d* electrons.

∴ Z_{eff} felt by the 3*d* electron of Cr atom $= 24 - (0{\cdot}35 \times 4 + 1{\cdot}0 \times 18) = \mathbf{4{\cdot}60}$

The Effective Nuclear Charge at the Periphery of An Atom or An Ion. The effective nuclear charge felt at the periphery of an atom or an ion is calculated by considering the screening of the nuclear charge by *all the electrons* present in the electronic configuration of the atom or the ion.

The calculation of the effective nuclear charge at the periphery of an atom or an ion is illustrated below.

Example 14. Calculate the effective nuclear charge at the periphery of nitrogen atom ?

Solution : Imagine an 'extra electron' in the last filled orbital of nitrogen atom.

The screening constant *S* for this extra electron $= 5 \times 0{\cdot}35 + 2 \times 0{\cdot}85 = 3{\cdot}45$

∴ Z_{eff} at the periphery of N atom $= 7 - 3{\cdot}45 = \mathbf{3{\cdot}55}$

Example 15. Calculate the effective nuclear charge at the periphery of chromium atom ?

Solution : Imagine an extra electron in the last filled orbital, *i.e.*, the 4*s* orbital of the Cr atom.

The screening constant *S* for this extra electron $= 1 \times 0{\cdot}35 + (8 + 5) \times 0{\cdot}85 + 1{\cdot}0 \times 10 = 21{\cdot}40$

Z_{eff} at the periphery of Cr atom $= 24 - 21{\cdot}40 = \mathbf{2{\cdot}60}$

Example 16. Calculate Z_{eff} for 3*d* electron, 4*s* electron and at the periphery of a Cu atom.

Solution : Electronic configuration of Cu atom is $(1s^2)\,(2s^2\,2p^6)\,(3s^2\,3p^6)\,(3d^{10})\,(4s^1)$

Z_{eff} felt by 3*d* electron $= 29 - [\,9 \times 0{\cdot}35 + 1{\cdot}0 \times 18\,] = 29 - (3{\cdot}15 + 18) = \mathbf{7{\cdot}85}$

(there is no contribution from 4*s* electron)

Z_{eff} felt by 4*s* electron $= 29 - (0{\cdot}35 \times 0 + 0{\cdot}85 \times 18 + 1{\cdot}0 \times 10)$

$= 29 - 25{\cdot}30 = \mathbf{3{\cdot}70}$

Z_{eff} at the periphery of the atom $= 29 - (\,0{\cdot}35 \times 1 + 0{\cdot}85 \times 18 + 1{\cdot}0 \times 10)$

$= 29 - (\,0{\cdot}35 + 15{\cdot}30 + 10{\cdot}00\,) = \mathbf{3{\cdot}35}$

Other Applications of Slater's Rules. The Slater's rules are also applied to explain the following facts.

1. A 4*s* orbital is filled earlier than a 3*d* orbital. Consider a potassium atom ($Z = 19$). In this case, 18 of 19 electrons occupy orbitals as in argon $(1s^2\,2s^2\,2p^6\,3s^2\,3p^6)$. The 19th electron may enter a 4*s* or a 3*d* orbital.

Let us calculate the Z_{eff} for the 19th electron when it enters the 4*s* orbital.

$$Z_{eff} = 19 - 0 \times 0{\cdot}35 - 8 \times 0{\cdot}85 - 10 \times 1{\cdot}0 = 19 - 16{\cdot}80 = 2{\cdot}20$$

Z_{eff} felt by the 19th electron when it enters the 3*d* orbital

$$= 19 - 0 \times 0{\cdot}35 - 18 \times 1{\cdot}0 = 19 - 18 = 1{\cdot}00$$

Thus, a 4*s* electron would be subjected to a greater electrostatic attraction (due to a higher effective nuclear charge of 2·20) than a 3*d* electron. Consequently, potassium atom with outer electronic configuration $3s^2p^6\,4s^1$ would be associated with lower energy than with outer electronic configuration $3s^2p^6\,3d^1$. As a result, the configuration $3s^2p^6\,4s^1$ would be more stable than the configuration $3s^2p^6\,3d^1$. Thus, a 4*s* orbital is filled earlier than a 3*d* orbital.

2. The transition metal atoms lose n*s* electrons first during Ionization. Consider Mn atom with atomic number 25. It has a configuration $1s^2\,2s^2\,2p^6\,3s^2\,3p^6\,3d^5\,4s^2$ (arranged as per Slater's rules).

Let us calculate Z_{eff} felt by the 3*d* as well as the 4*s* electron.

Z_{eff} felt by the 3*d* electron $= 25 - (0{\cdot}35 \times 4 + 1{\cdot}0 \times 18) = \mathbf{5{\cdot}60}$

Z_{eff} felt by the 4*s* electron $= 25 - (1 \times 0{\cdot}35 + 13 \times 0{\cdot}85 + 1{\cdot}0 \times 10) = \mathbf{3{\cdot}60}$

Evidently, the attraction between the 4*s* electron and the nucleus is less than the attraction between the 3*d* electron and the nucleus of Mn atom. Hence, the removal of the 4*s* electron from an isolated gaseous atom of Mn would be easier than the removal of the 3*d* electron from it.

3. Trends in successive ionization energies. The first ionization energy is always lower than the second ionization energy and second ionization energy is always lower than the third ionization energy and so on. This is because the effective nuclear charge goes on increasing with each removal of electron from an atom. (The student may verify this fact by taking a suitable example and calculating the effective nuclear charge for the unipositive, dipositive and tripositive ions).

4. An anion is always bigger and a cation is always smaller in size than the parent atom. Consider a chlorine atom with electronic configuration $1s^2\,2s^2\,p^6\,3s^2\,3p^5$.

Z_{eff} felt by the last electron of chlorine *atom* $= 17 - (6 \times 0{\cdot}35 + 8 \times 0{\cdot}85 + 2 \times 1{\cdot}0) = \mathbf{6{\cdot}10}$

Z_{eff} felt by the last electron of chloride *ion* $= 17 - (7 \times 0{\cdot}35 + 8 \times 0{\cdot}85 + 2 \times 1{\cdot}0) = \mathbf{5{\cdot}75}$

As can be seen, Z_{eff} in the case of Cl^- ion is less than in the case of Cl atom. Therefore, the electrostatic attraction between the electrons and the nucleus is more in chlorine atom than in chloride ion. As a result, the nucleus would have lesser hold on electrons in the chloride ion than in chlorine atom. Consequently, the size of chloride ion will be larger than the size of chlorine atom.

Now consider a sodium atom with electronic configuration $1s^2\,2s^2\,2p^6\,3s^1$.

Z_{eff} felt by the last electron of Na atom $= 11 - (0{\cdot}35 \times 0 + 8 \times 0{\cdot}85 + 2 \times 1{\cdot}0) = \mathbf{2{\cdot}20}$

Z_{eff} felt by the last electron of Na^+ ion $= 11 - (0{\cdot}35 \times 7 + 2 \times 0{\cdot}85) = \mathbf{6{\cdot}85}$

As can be seen, Z_{eff} in the case of Na atom is less than in the case of the Na^+ ion. Therefore, the hold of the nucleus on the electrons is less in the case of Na atom than in the case of Na^+ ion. Consequently, Na atom is bigger in size than the Na^+ ion.

5. The atomic size within a period goes on decreasing with increase in atomic number. Consider the elements of the First transition series from Sc to Zn. The Z_{eff} goes on increasing with increase in atomic number. Therefore, the hold of the nucleus on the electrons also goes on increasing as we move from Sc to Zn. Hence, the atomic size goes on decreasing with increase in atomic number as we move along the series.

The Slater's rules are also applied for **calculating electronegativities** of atoms by Allred-Rochow method. This aspect would be discussed in the next chapter.

Limitations of Slater's Rules. The Slater's rules have some serious limitations as well.

1. According to Slater's rules, the outer shell electrons do not shield the inner electrons. This may not be true. For example, even the outer *s* electrons penetrate quite close to the nucleus and would thus exercise a shielding effect.

2. We have already discussed that *s* electrons are more penetrating than the *p* electrons of the same shell so that the screening by the *s* electrons will be more than the screening by the *p* electrons. According to Slater's rules, however, the screening by the *s* and *p* electrons of the same shell is the same.

3. According to Slater's rules, the *s*, *p*, *d* and *f* electrons of the same shell screen the higher shell electrons to the same extent. This is, however, not correct. The electrons in *s*, *p*, *d* and *f* orbitals differ so much in their penetrating power. An *ns* electron has greater probability of being present near the nucleus than an n*p* electron. Similarly, an n*p* electron has greater probability of being present near the nucleus than an *nd* electron. The electrons present in these orbitals would not screen the outer shell electrons to the same extent.

Filling of Orbitals in Atoms. *The distribution of electrons in various orbitals in known as* **electronic configuration.** The atom is built up by filling electrons in various orbitals one at a time and by placing each new electron in the next lowest energy orbital. An atom in its lowest energy state is said to be in the normal state or the ground state. This state is the most stable state for the atom.

The filling of orbitals in the ground state is determined by the following rules.

1. Aufbau principle. The aufbau principle states that in the ground state of an atom, the orbital with a lower energy is filled up first before the filling of the orbital with a higher energy commences. In other words, the electrons enter the various orbitals in the order of increasing energy.

The increasing order of energy of various orbitals is :

1*s*, 2*s*, 2*p*, 3*s*, 3*p*, 4*s*, 3*d*, 4*p*, 5*s*, 4*d*, 5*p*, 6*s*, 4*f*, 5*d*, 6*p*, 7*s*, 5*f*, 6*d*...

The above sequence of energy levels can be easily remembered with the help of the graphical representation shown in Fig. 20.

2. Pauli's exclusion principle. According to this principle, an orbital can contain a maximum of two electrons and these two electrons must be of opposite spin.

3. Hund's rule of maximum multiplicity. This rule states that in the ground state electronic configuration of an atom, electron pairing in orbitals of the same energy will not take place unless all such available orbitals of a given subshell contain one electron each with parallel spin. For example, we know that there are three *p* orbitals (p_x, p_y and p_z) of the *p* subshell in a principal energy level. According to Hund's rule, each of the three *p* orbitals must get one electron each of parallel spin before any one of them gets the second electron of opposite spin.

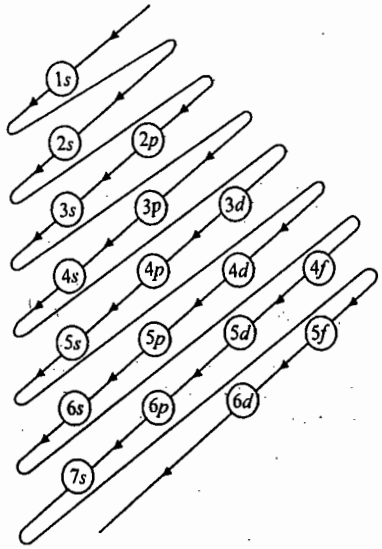

Fig. 20. Sequence of the filling of the various orbitals

Electronic Configurations of Atoms

Based on the sequence given in Fig. 20, the ground state electronic configurations of atoms of various elements of the periodic table are given below. (*Hund's rule is applicable for ground state only*).

Hydrogen has only one electron (Z = 1). This electron will enter the lowest energy orbital which is 1*s*. Thus, the solitary electron of hydrogen atom will occupy 1*s* orbital. The electronic configuration of hydrogen atom is, therefore, represented as $\mathbf{1s^1}$.

The next element, **helium**, has two electrons (Z = 2). One of these electrons occupies the 1*s* orbital as in the case of the hydrogen atom. The second electron can also enter this orbital so as to fill it completely. The electronic configuration of helium is, therefore, represented as $\mathbf{1s^2}$. The two electrons occupying this orbital will have opposite spins.

The next element is **lithium**. It has three electrons (Z = 3). Since there is only one orbital in the first principal energy shell and this has been filled up by the occupancy of two electrons, the third electron in lithium enters the *s* orbital of the second principal energy shell. The electronic configuration of lithium, therefore, is represented as $\mathbf{1s^2\ 2s^1}$.

Arguing in the same way, the electronic configuration of **beryllium** (Z = 4) would be $\mathbf{1s^2\ 2s^2}$.

The next element, **boron** (Z = 5), has five electrons. The 2*s* orbital has already been filled. But, as the principal quantum number is now 2, there are three *p* orbitals still available. The fifth electron, therefore, enters one of these *p* orbitals. The electronic configuration of boron, therefore, is $\mathbf{1s^2\ 2s^2\ 2p^1}$.

The next five elements, namely, carbon (Z = 6), nitrogen (Z = 7), oxygen (Z = 8), fluorine (Z = 9) and neon (Z = 10) of this period get their *p* orbitals successively filled. Their electronic configurations are given in Table 4.

TABLE 4

Electronic Configurations of the First 20 Elements

At. No.	Element	Electronic Configuration			
1	Hydrogen	$1s^2$			
2	Helium	$1s^2$			
3	Lithium	$1s^2$	$2s^1$		
4	Beryllium	$1s^2$	$2s^2$		
5	Boron	$1s^2$	$2s^2\ 2p_x^1$		
6	Carbon	$1s^2$	$2s^2\ 2p_x^1\ 2p_y^1$		
7	Nitrogen	$1s^2$	$2s^2\ 2p_x^1\ 2p_y^1\ 2p_z^1$		
8	Oxygen	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^1\ 2p_z^1$		
9	Fluorine	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^1$		
10	Neon	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$		
11	Sodium	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$	$3s^1$	
12	Magnesium	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$	$3s^2$	
13	Aluminium	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$	$3s^2\ 3p_x^1$	
14	Silicon	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$	$3s^2\ 3p_x^1\ 3p_y^1$	
15	Phosphorus	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$	$3s^2\ 3p_x^1\ 3p_y^1\ 3p_z^1$	
16	Sulphur	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$	$3s^2\ 3p_x^2\ 3p_y^1\ 3p_z^1$	
17	Chlorine	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$	$3s^2\ 3p_x^2\ 3p_y^2\ 3p_z^1$	
18	Argon	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$	$3s^2\ 3p_x^2\ 3p_y^2\ 3p_z^2$	
19	Potassium	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$	$3s^2\ 3p_x^2\ 3p_y^2\ 3p_z^2$	$4s^1$
20	Calcium	$1s^2$	$2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$	$3s^2\ 3p_x^2\ 3p_y^2\ 3p_z^2$	$4s^2$

It may be noted that in carbon, the arrangement of electrons in p orbitals is $2p_x^1\ 2p_y^1$ and not $2p_x^2$. Similarly, in nitrogen, the arrangement is $2p_x^1\ 2p_y^1\ 2p_z^1$ and not $2p_x^2\ 2p_y^1$. This is in accordance with Hund's rule of maximum multiplicity. According to this rule, electrons occupy all the available orbitals of a given subshell *singly* with parallel spins before they pair up in any orbital.

It will be seen that in neon all the four orbitals of principal energy shell 2 are completely filled, its electronic configuration being $1s^2\ 2s^2\ 2p^6$.

The principal energy shell 3 begins with **sodium** ($Z = 11$). The eleventh electron will, evidently, enter the $3s$ orbital, the configuration being $1s^2\ 2s^2 2p^6\ 3s^1$.

The next seven elements, namely, magnesium (Z = 12), aluminium (Z = 13), silicon (Z = 14), phosphorus (Z = 15), sulphur (Z = 16), chlorine (Z = 17) and argon (Z = 18) follow the sequence described above. Their electronic configurations are also included in Table 4.

Consider now the electronic configuration of the next element which is **potassium** ($Z = 19$). The additional electron (*i.e.*, nineteenth electron) instead of entering $3d$ orbitals, all of which are lying unoccupied so far, goes into the $4s$ orbital. This is because $4s$ orbital is at a lower energy level than $3d$ orbitals (Fig. 20). The electronic configuration of potassium, therefore, may be represented as $1s^2\ 2s^2\ p^6\ 3s^2\ p^6\ 4s^1$. The additional electron in **calcium** ($Z = 20$) follows the same course and goes into the same, *i.e.*, $4s$ orbital, to fill it completely. Therefore, the electronic configuration of calcium is $1s^2\ 2s^2 p^6\ 3s^2 p^6\ 4s^2$.

The next ten elements (Z = 21 to 30) which follow calcium are scandium (Sc), titanium (Ti), vanadium (V), chromium(Cr), manganese (Mn), iron (Fe), cobalt (Co), nickel (Ni), copper (Cu) and zinc (Zn). In these elements, addition of electrons takes place in the inner $3d$ orbitals while the outer $4s$ orbital remains fully occupied. All these elements are known as the **transition elements.** The electronic configuration of scandium ($Z = 21$), the first transition element, for example, is $1s^2\ 2s^2 p^6\ 3s^2 p^6\ 4s^2\ 3d^1$ while that of zinc ($Z = 30$), the last element of the series, is $1s^2\ 2s^2 p^6\ 4s^2\ 3d^{10}$. Thus, while the filling of $3d$ orbitals begins with scandium, it ends with zinc. The electronic configurations of all the 10 transition elements are represented in Table 5.

TABLE 5

Electronic Configurations of Transition Elements

Scandium ($Z = 21$) to Zinc ($Z = 30$)

Atomic number	Element	Electronic Configuration	Outer Configuration 3d	4s
21	Sc	[Ar] $3d^1\ 4s^2$	↑ ○ ○ ○ ○	↑↓
22	Ti	[Ar] $3d^2\ 4s^2$	↑ ↑ ○ ○ ○	↑↓
23	V	[Ar] $3d^3\ 4s^2$	↑ ↑ ↑ ○ ○	↑↓
24	Cr	[Ar] $3d^5\ 4s^1$	↑ ↑ ↑ ↑ ↑	↑
25	Mn	[Ar] $3d^5\ 4s^2$	↑ ↑ ↑ ↑ ↑	↑↓
26	Fe	[Ar] $3d^6\ 4s^2$	↑↓ ↑ ↑ ↑ ↑	↑↓
27	Co	[Ar] $3d^7\ 4s^2$	↑↓ ↑↓ ↑ ↑ ↑	↑↓
28	Ni	[Ar] $3d^8\ 4s^2$	↑↓ ↑↓ ↑↓ ↑ ↑	↑↓
29	Cu	[Ar] $3d^{10}\ 4s^1$	↑↓ ↑↓ ↑↓ ↑↓ ↑↓	↑
30	Zn	[Ar] $3d^{10}\ 4s^2$	↑↓ ↑↓ ↑↓ ↑↓ ↑↓	↑↓

Anomalous Configurations of Chromium and Copper. It may be noted that the configurations of chromium ($Z = 24$) and copper ($Z = 29$) do not follow the general trend. The electronic configurations of Cr and Cu are expected to be as follows :

$$\text{Cr} : 1s^2\ 2s^2 2p^6\ 3s^2 3p^6\ 3d^4\ 4s^2 \quad \text{and} \quad \text{Cu} : 1s^2\ 2s^2 2p^6\ 3s^2 3p^6 3d^9\ 4s^2$$

But actually their configurations are :

$$\text{Cr} : 1s^2\ 2s^2 2p^6\ 3s^2 3p^6 3d^5\ 4s^1 \quad \text{and} \quad \text{Cu} : 1s^2\ 2s^2 2p^6\ 3s^2 3p^6 3d^{10}\ 4s^1$$

These anomalies are attributed to the fact that exactly half-filled and completely filled orbitals, *i.e.*, d^5, d^{10}, f^7 and f^{14} have lower energy and hence possess extra stability. The cause of this extra stability has been discussed in details in a subsequent section. Thus, to acquire increased stability, one of the electrons from $4s$ orbital goes into the nearby $3d$ orbital so that the $3d$ orbitals become exactly half-filled in the case of chromium and completely filled in the case of copper.

For the sake of simplicity, we do not always write the complete electronic configuration. Instead, the configuration of the noble gas preceding the valence shell is not given ; it is represented by its symbol in square bracket. For example, for Na ($Z = 11$), we may write [Ne]$3s^1$ and for Ca ($Z = 20$), we may write [Ar]$4s^2$.

Electronic Configurations of Lanthanides and Actinides. It may be mentioned that the sequence of filling of the various orbitals in the case of lanthanides and actinides, as revealed by spectroscopic analysis, shows a little deviation from the arrangement shown in Fig. 20. After the filling of $6s$ subshell with barium (Z = 56), the next electron in lanthanum (Z = 57), goes to $5d$ subshell and *not to* $4f$ *subshell.* The subsequent electrons in the succeeding elements of the lanthanide series (from Ce to Lu, $Z = 58$ to 71), however, enter the $4f$ subshell as required by the representation in Fig. 20. The filling of $5d$ subshell recommences only after the $4f$ subshell is completely filled with Lu ($Z = 71$). Thus, the configurations of La, Ce, Pr and Gd would be as follows :

La ($Z = 57$) : [Xe] $6s^2 5d^1$

Ce ($Z = 58$) : [Xe] $6s^2 5d^1 4f^1$

Pr ($Z = 59$) : [Xe] $6s^2 5d^1 4f^2$

Gd ($Z = 64$) : [Xe] $6s^2 5d^1 4f^7$

Similarly, after the filling of $7s$ subshell with radium (Z = 88), the next electron in actinium (Z = 89) goes to $6d$ subshell and *not to* $5f$ subshell. The subsequent electrons in the succeeding elements of the actinides (from Th to Lr, $Z = 90$ to 103), however, enter the $5f$ subshell as required by the representation shown in Fig. 20. Thus, the configurations of Ac, Th and Pa would be as follows :

Ac (Z = 89) : [Rn] $7s^2\ 6d^1$

Th (Z = 90) : [Rn] $7s^2\ 6d^1\ 5f^1$

Pa (Z = 91) : [Rn] $7s^2\ 6d^1\ 5f^2$

Electronic configurations of elements upto atomic number 103 are given in Table 6.

Elements Beyond Atomic Number 103

The electrons in elements with atomic numbers 103 to 112 (elements upto atomic number 108 have already been prepared artificially through nuclear reactions) enter the inner $6d$ orbitals continuing the process initiated by actinium. The d subshell gets completely filled with the element with atomic number 112. The common names of elements with atomic numbers 101 to 105 are mendelevium (101), nobelium (102), lawrencium (103), kurchatovium (104) and hahnium (105). However, all the elements with atomic numbers beyond 100 are now named in accordance with IUPAC system as, for example, un-nil-unium (101), un-nil-bium (102), un-nil-trium (103), un-nil-quadium (104), un-nil-pentium (105), un-nil-hexium (106), un-nil-septium (107), un-nil-octium (108), etc. (see Chapter 2 and the periodic table annexed in that chapter).

**Anomalous configurations of Nb, Ru, Rh and Pt, can be explained on the basis of nucleus-electron and electron-electron forces, the discussion of which is beyond the scope of the book.

The electronic configurations of elements with atomic numbers 104 to 112 would be as shown below :

$$Z = 104: \ [Rn]5f^{14}6d^{2}7s^{2}$$

$$Z = 105: \ [Rn]5f^{14}6d^{3}7s^{2}$$

$$Z = 106: \ [Rn]5f^{14}6d^{4}7s^{2}$$

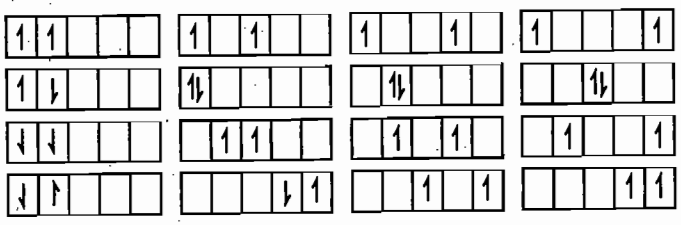
$$Z = 112: \ [Rn]5f^{14}6d^{10}7s^{2}$$

Elements beyond atomic number 112, if discovered, will be normal or representative elements in which $7p$ subshell will be increasingly filled, ending with a noble gas having an atomic number 118. In this way, the seventh period will also have 32 elements.

Extra Stability of Half-filled and Completely-filled Orbitals

Before we discuss the relative stabilities of various electronic configurations, we should clearly understand the ***difference between electronic configuration and electronic arrangement.*** For this, let us consider Ti^{2+} ion. Its outer electronic configuration is $3d^2$. From this we get the information that two electrons are present in a set of five $3d$ orbitals. This configuration gives no information about the manner in which these two electrons are placed in the five $3d$ orbitals.

It can be easily shown through permutations and combinations that there are as many as 45 different ways of placing these two electrons in the five $3d$ orbitals. In other words, *the electronic configuration $3d^2$ can have 45 different electronic arrangements.* Some of these *arrangements* are shown below :



Let us consider two of these arrangements, *viz.*, $(3d_z^2)^1(3d_{x^2-y^2})^1$ and $(3d_{xy})^1(3d_{x^2-y^2})^1$. If we recall the shapes of the d orbitals, we would immediately realise that the *mutual* repulsion of the two electrons would be different in these two arrangements. As a result, *the two electronic arrangements would have different energies.* This is true of many other electronic arrangements of the $3d^2$ configuration. We may thus conclude that any given electronic configuration would give rise to a large number of electronic arrangements which would have *different energies** in spite of the fact that they belong to the same electronic configuration. Therefore, *when we talk of the stability of an electronic configuration, we are ipso facto concerned with the stability of the electronic arrangement of that configuration.* Of all the electronic arrangements permitted by a given configuration, the most stable arrangement can be predicted by Hund's rule of maximum multiplicity, as discussed below.

Hund's Rule – Its Basis and Application. We would first discuss the basis of Hund's rule of maximum multiplicity and would see how it can predict the most stable electronic arrangement of a given electronic configuration.

According to Pauli's exclusion principle, if two electrons have the same spin, *i.e.*, the same m_s quantum number, they would occupy different orbitals since they *cannot have* the same values of n, l and m. On the other hand, if the two electrons have opposite spin, they *can occupy* the same orbital, *i.e.*, they *can have* the same values of n, l and m.

*Some of the electronic arrangements may have the same inter-electronic repulsions and hence may have the same energy. Such electronic arrangements are known as degenerate arrangements.

In the case of *degenerate orbitals, i.e.*, orbitals with the same energy, if two electrons are placed in the same orbital, the electrostatic repulsion would be greater than when they are placed in different orbitals. Hence, *for least repulsion, the electrons in degenerate orbitals should be placed* **singly** *until it becomes necessary to place two of them in the same orbital* (*i.e.*, when the number of electrons exceeds the number of degenerate orbitals.) Thus, *the most stable arrangement is one in which there is maximum number of unpaired electrons. This is the first part of* **Hund's rule.**

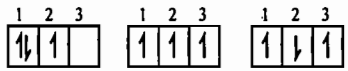
For illustration, let us find out the most stable electronic arrangement for a p^2 configuration. It can be easily shown that there are 15 ways of arranging two electrons in the three p orbitals. Three of these arrangements are shown below :

(1) (2) (3)

According to the first part of Hund's rule stated above, the arrangement (1) is *least stable.* Of the remaining two, which one is more stable can be decided by involving the contribution of **exchange energy,** as discussed below.

By advanced mathematical treatment, it can be shown that if *on exchanging the position in space of two electrons with parallel spins, there is no change in the electronic arrangement, it would lead to decrease in energy.* Such a pair of electrons is called the **exchange pair.** The larger the number of exchange pairs of electrons, the greater would be the decrease of energy. *The energy decrease per exchange pair of electrons is termed as* **exchange energy.** It would, evidently, carry a negative sign. As can be seen, there is one exchange pair of electrons in arrangement (2) but none in arrangement (3). Consequently, there would be a loss of energy in the form of exchange energy in arrangement (2) but there would be no such loss in arrangement (3). The arrangement (2) associated with lower energy would thus be more stable than arrangement (3).

Let us now consider the case of a p^3 configuration. This configuration can give rise to 20 electronic arrangements, three of which are shown below :



(4) (5) (6)

According to the first part of Hund's rule, arrangement (4) is *least stable.* Arrangement (5) has *three* exchange pairs of electrons, *viz.*, 1, 2, ; 1, 3 and 2, 3 while arrangement (6) has only *one* such pair, *viz.*, 1, 3. If E is the exchange energy (per exchange pair), then the energy of arrangement (5) would *decrease* by $3E$ and that of arrangement (6) would *decrease* by E. Thus, of the three arrangements shown above, arrangement (5) associated with minimum energy is *most stable.* It follows from the above discussion that *the electronic arrangement with maximum number of parallel electronic spins would be the most stable arrangement of a given configuration since such an arrangement would have maximum number of exchange pairs of electrons and thus would have maximum exchange energy. This is the second part of* **Hund's rule.**

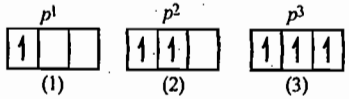
Pairing Energy. As already mentioned, placing of two electrons together in the same orbital results in considerable repulsion. *The energy required for placing two electrons together in the same orbital,* i.e., for pairing of electrons, is called **pairing energy.** Pairing energy, having a positive sign, would tend to increase the energy of the system and hence would tend to destabilise it. Thus, the overall stability of a system would be decided by the aggregate of exchange energy (E) and pairing energy (P).

Referring again to the three electronic arrangements (4), (5) and (6) of p^3 configuration, we notice that the aggregates of exchange energy and pairing energy in the three arrangements are : $-E + P, -3E + 0$

and $-E+0$, respectively. The order of stability of the electronic arrangements would, thus, be (5) > (6) > (4).

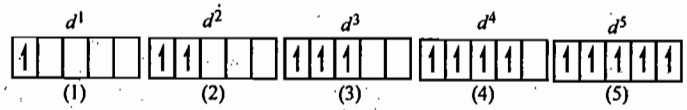
Relative Stabilities of Most Stable Electronic Arrangements of Different Electronic Configurations. So far we have considered the relative stabilities of different electronic arrangements of the same electronic configuration. We shall now take into consideration *the most stable electronic arrangements of different configurations and discuss their relative stabilities.*

The solitary electronic arrangement of p^1 configuration and the most stable electronic arrangements of p^2 and p^3 configurations, in accordance with Hund's rule, are as shown below :



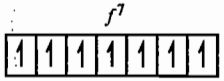
The number of exchange pairs of electrons in (1), (2) and (3) are 0, 1 and 3 (*viz.*, 1, 2, ; 1, 3 ; 2, 3), respectively. Therefore, the exchange energy for (1), (2) and (3) would be 0, $-E$ and $-3E$, respectively. Since no pairing of electrons is required in any of these arrangements, no pairing energy is involved in any of them. Thus, *we see that arrangement* (3) *of p^3 configuration, associated with maximum exchange energy $= -3E$, is the most stable and this is also the arrangement in which all the three degenerate p orbitals are exactly half-filled.*

Similarly, the solitary electronic arrangement of d^1 configuration and the most stable electronic arrangements of d^2, d^3, d^4 and d^5 configurations, are as shown below :



It can be easily shown that the number of exchange pairs of electrons in these arrangements are 0, 1, 3, 6 and 10, respectively. Hence, exchange energy associated with these arrangements would be 0, $-E$, $-3E$, $-6E$ and $-10E$, respectively. Since no pairing of electrons is required in any of these arrangements, hence no pairing energy is involved in any of them. Thus, in this case also, *we see that arrangement* (5) *of d^5 configuration, associated with the maximum exchange energy $= -10E$, is the most stable and this is also the arrangement in which all the five degenerate d orbitals are exactly half-filled.*

In a similar manner it can be shown that of all the electronic arrangements of f^1 to f^7 configurations, the electronic arrangement shown below is the most stable :

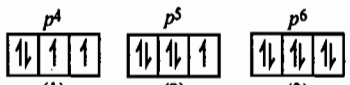


This is also the arrangement in which all the seven degenerate f orbitals are exactly half-filled.

It is evident from the above discussion that *an electronic arrangement containing a set of exactly half-filled degenerate orbitals is more stable than any other arrangement of any configuration.*

Let us now consider the relative stabilities of most stable electronic arrangements of different electronic configurations in which the number of electrons is more than the number of degenerate orbitals, *i.e.*, in which some of the electrons are paired. ~~The configurations p^4 to p^6 and d^6 to d^{10} fall in this category.~~

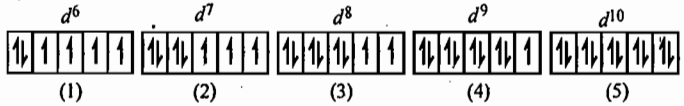
The most stable electronic arrangements of p^4, p^5 and p^6 configurations, in accordance with Hund's rule, are shown below :



The number of electrons with upward spin is 3 in each arrangement giving rise to 3 exchange pairs in each case. The number of electrons with downward spin is 1, 2, and 3, respectively, in arrangements (1), (2) and (3). The corresponding number of exchange pairs would be 0, 1 and 3, respectively. The number of electron pairs occupying the same orbital, as can be seen, is 1, 2, and 3 in arrangements (1), (2) and (3), respectively. It may again be emphasised that while the exchange pairs give rise to exchange energy, the pairing of electrons gives rise to pairing energy.

As a consequence of exchange energy and pairing energy, the net energy change in the case of electronic arrangements (1), (2) and (3) would be $(-3E+P)$, $(-4E+2P)$ and $(-6E+3P)$, respectively. It may be recalled that while exchange energy tends to decrease, the pairing energy tends to increase the energy of the arrangement. This means that the relative stabilities of the three arrangements cannot be predicted on the basis of the aggregates of exchange energy and pairing energy *alone*. Experimentally, the arrangement (3) is found to be more stable than arrangements (1) and (2). This shows that there must be some other stabilising factor in favour of (3).

The most stable electronic arrangements of d^6, d^7, d^8, d^9 and d^{10} configurations, in accordance with Hund's rule, are given below :



Based on the number of exchange pairs and the electron pairs, the aggregates of exchange energy and pairing energy in the above electronic arrangements would be $[-10E+P]$, $[-(10+1)E+2P]$, $[-(10+3)E+3P]$, $[-(10+6)E+4P]$ and $[-(10+10)E+5P]$, as we move from configuration d^6 to d^{10}. On the basis of the same considerations as mentioned above, it can be argued that in this case also, it is not possible to predict as to which of the above arrangements would be most stable. According to experiments, electronic arrangement (5) is more stable than the rest of the arrangements which cannot be accounted for on the basis of exchange energy and pairing energy *alone*.

This shows that *as in the case of arrangement* (3) of p^6 configuration, *there must be some other stabilising factor in favour of arrangement* (5) of d^{10} configuration. This factor is the ***effect of the symmetrical distribution of charge***, as illustrated below.

Symmetrical Distribution of Charge. In order to understand the effect of the symmetrical distribution of charge in orbitals on the stability of electronic arrangements, let us recall the shapes of the various sets of orbitals, one by one. The *s orbital* is *spherical* in shape which implies that the electronic charge would be distributed uniformly in all directions whether there is one or two electrons present in the orbital.

Of the three *p* orbitals, the orbital p_x is symmetrical along the *x*-axis while the orbitals p_y and p_z are symmetrical along the *y*-axis and *z*-axis, respectively. If we place an electron in p_x orbital, *i.e.*, we take into consideration p_x^1 configuration, the electronic charge would be mainly concentrated in the *x*-direction only. Likewise, in p_y configuration, the electronic charge would be mainly concentrated in the *y*-direction. Similarly, in $p_x^2 p_y^1$ configuration, the electronic charge would be mainly concentrated in the *xy* plane. Likewise, the electronic charge would be concentrated more along the *x*-direction in the configuration $p_x^2 p_y^1 p_z^1$ and ~~more in the plane *xy* in the configuration $p_x^2 p_y^1 p_z^1$. It is evident that in~~ all the *p* configurations mentioned above, *the charge is not evenly spread along all the directions.* In other words, *the distribution of charge is non-uniform or unsymmetrical.* On the other hand, *the distribution of charge in the configurations p_x^1 p_y^1 p_z^1* and *p_x^2 p_y^2 p_z^2 would be uniform or symmetrical in all directions.*

Configurations with even or uniform or symmetrical distribution of charge in all directions would evidently be associated with lower energy and hence higher stability than the configurations with unsymmetrical distribution of electronic charge.

To sum up : *A symmetrical distribution of electronic charge leads to a decrease in energy and hence an increase in the stability of the system.*

It follows from the above discussion that of all the d configurations, the configurations d^1_{xy} d^1_{yz} d^1_{zx} $d^1_{x^2-y^2}$ $d^1_{z^2}$ and d^2_{xy} d^2_{yz} d^2_{zx} $d^2_{x^2-y^2}$ $d^2_{z^2}$ would have a *uniform or symmetrical distribution of charge in space*. Therefore, these configurations would be more stable than all other d configurations.

- It can thus be concluded *that electronic arrangements with exactly half-filled or completely filled degenerate orbitals would be more stable than any other electronic arrangement.*

Promotional Energies. Stability of Configurations having Non-degenerate Orbitals

The energy required to promote an electron from a lower energy orbital to a higher energy orbital is known as **promotional energy.** This may be designated as ΔE. Both ΔE and pairing energy (P) are positive.

Let us consider a case in which the lower energy orbital contains two electrons while the higher energy orbital is empty. The energy difference between the two orbitals, *viz.*, ΔE, is the promotional energy, as already stated. This is shown in Fig. 21. In arrangement (a), the two electrons are present in the lower energy orbital. Such an arrangement would be stable if the pairing energy, *i.e.*, the energy required to pair the two electrons in the same orbital is less than the promotional energy, *i.e.*, $P < \Delta E$. If, however, the promotional energy is less than the pairing energy, the two electrons would get unpaired and one of these would get promoted to the higher energy orbital, as shown in arrangements (b) and (c). This shows that if $\Delta E < P$, the arrangements (b) and (c) would be more stable than the arrangement (a).

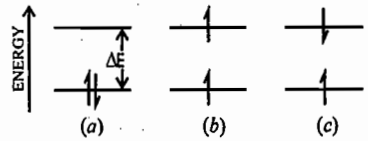


Fig. 21. Possible electron distributions in the two energy levels for a two-electron system :
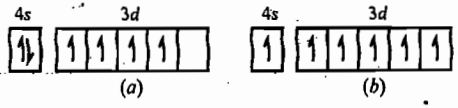
(a) Both the electrons are present in ground state.
(b) Electrons are evenly distributed with parallel spins
(c) Electrons are evenly distributed but with antiparallel spins.

Out of arrangements (b) and (c), the arrangement (b) would be more stable due to parallel spins of both the electrons. The arrangement (b) has one exchange pair of electrons whereas arrangement (c) has none. The presence of an exchange pair lowers the energy of the arrangement, as already illustrated. Thus, Hund's rule of maximum multiplicity is also applicable to non-degenerate orbitals *provided they have comparable energies, i.e.*, $\Delta E \leq P$. In such cases, the arrangement containing electrons having maximum number of parallel spins and thereby maximum number of exchange pairs would be most stable.

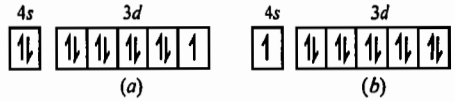
Let us apply the above considerations to some specific cases.

1. Configuration of chromium atom. The two possible outer electronic configurations of Cr atom ($Z = 24$) are (a) $4s^2\,3d^4$ and (b) $4s^1\,3d^5$. The electronic arrangements for these configurations are shown below :



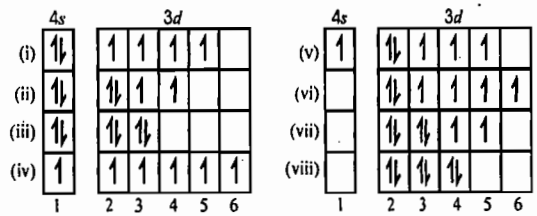
The electronic arrangement (b) is obtained from arrangement (a) by promoting one electron from $4s$ to $3d$ orbital. Since the energy difference between $4s$ and $3d$ orbitals is small, Hund's rule of maximum multiplicity would largely determine the relative stability of the arrangements. The energy of arrangement (a) is $-10E + P$ while that of arrangement (b) is $-15E + \Delta E$. Since ΔE is small, hence arrangement (b) is more stable than arrangement (a). The symmetrical electronic charge distribution in $4s$ and $3d$ orbitals in arrangement (b) further adds to its stability.

2. Configuration of copper atom. The two possible outer electronic configurations for Cu atom ($Z = 29$) are (a) $4s^2\,3d^2$ and (b) $4s^1\,3d^5$. The electronic arrangements for these configurations are shown below :



The electronic arrangement (b) is obtained by promoting electron from $4s$ to $3d$ orbital. Since the energy difference between $4s$ and $3d$ is small, Hund's rule of maximum multiplicity shall largely determine the stability of the arrangement. The energy of arrangement (a) is $-25E + 5P$ while that of arrangement (b) is $-25E + 5P + \Delta E$. On energy considerations, arrangement (b) should be slightly less stable than arrangement (a). But actually arrangement (b) is more stable than (a). Why is it so ? For the answer, we have to take into consideration the type of the electronic charge distribution in arrangements (a) and (b). The electronic charge distribution in the $4s$ orbitals would be *symmetrical* in both the arrangement (a) and (b). In the $3d$ orbitals, however, while the electronic charge distribution is symmetrical in all directions in arrangement (b), it is unsymmetrical in arrangement (a), as has been discussed earlier. The symmetrical charge distribution in arrangement (b) increases the stability of this arrangement to such an extent that it more than overcomes the de-stabilisation due to ΔE. Thus, arrangement (b) is more stable than arrangement (a).

Example 17. Assuming the energy difference between $4s$ and $3d$ orbitals to be small, the following 8 electronic arrangements have been listed for the outer electronic configuration of chromium :



(a) Find out the number of exchange pairs of electrons in each of these arrangements.

(b) Which of these arrangements are not possible according to Aufbau principle.

(c) Which of these arrangements is the most stable ?

Solution : (a) An exchange pair is one which contains electrons *with parallel spins*. The electronic arrangement remains unaltered if the electrons in the said pair exchange their positions. Number of exchange pairs is equal to the number of ways of selecting two electrons out of the electrons having parallel spins in a given arrangement.

In arrangement (i), there are 5 electrons (one $4s$ and four $3d$) with parallel spins. There are **10 exchange pairs**, viz., 1, 2 ; 1, 3 ; 1, 4, ; 1, 5 ; 2, 3 ; 2, 4, 2, 5, ; 3, 4 ; 3, 5 and 4, 5. Mathematically, the number of exchange pairs is given by

$$^5C_2 = \frac{5!}{2!\,3!} = 10$$

In arrangement (ii), there are 6 **exchange pairs** ($= {}^4C_2$) for electrons with upward spins and **1 exchange pair** for electrons with downward spins

The numbers of exchange pairs in the remaining arrangements are as follows :

(iii) **3+3** (iv) **15** (v) **10** (vi) **10** (vii) **6+1** ($viii$) **3+3**

(*b*) According to aufbau principle, the lower energy 4*s* orbital must contain at least one electron before 3*d* orbital starts filling up. Accordingly, **the arrangements (*v*), (*vii*) and (*viii*) are not possible.**

(*c*) **Arrangement (iv) is the most stable** because

(*i*) it has maximum electron exchange energy ($= -15\,E$) and

(*ii*) the electronic charge distribution is *symmetrical in all directions* since the set contains degenerate half-filled orbitals.

Example 18. Some of the possible outer electronic arrangements for sulphur atom are as shown:

Taking into consideration, the exchange energy and pairing energy, work out the most stable electronic arrangement for the sulphur atom.

Solution : The number of exchange pairs for the various arrangements are as follows :

Arrangement (1) : There are 6 exchange pairs for electrons with upward spin and 1 exchange pair for electrons with downward spin.

Arrangement (2) : 3 + 3 Arrangement (3) : 6 + 1

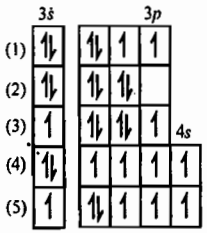
Arrangement (4) : 10 + 0 Arrangement (5) : 10 + 0

Hence, the aggregates of exchange energy, pairing energy and promotional energy in various arrangements are as follows :

Arrangement (1) $-(6+1)\,E+2P$ Arrangement (2) $-(3+3)\,E+3P$

Arrangement (3) $-(6+1)\,E+2P+\Delta E$ Arrangement (4) $-10\,E+P+\Delta E$

Arrangement (5) $-10\,E+P+\Delta E$



E is the magnitude of exchange energy, P is the magnitude of pairing energy and ΔE is the magnitude of promotional energy.

The energy difference, ΔE, between 3*s* and 3*p* and between 3*p* and 4*s* is much greater than the aggregate of exchange energy and pairing energy in any of the arrangements. Hence, electron excitation from 3*s* to 3*p* or from 3*p* to 4*s* is energetically unfavourable.

This rules out the possibility of arrangements (3), (4) and (5).

Exchange energy (stabilising energy) is more and pairing energy (destabilising energy) is less in arrangement (1) as compared to (2). Hence, **arrangement (1) is the most stable.**

QUESTIONS

1. Describe briefly the limitations of Bohr's theory of atomic structure.
2. (*a*) What do you understand by dual character of matter ? Derive de Broglie relation. How was it verified experimentally ?

   (*b*) How are matter waves different from electromagnetic waves ?

   (*c*) Why is the wave nature of matter not apparent in our daily observations ?
3. What do you understand by Heisenberg's uncertainty principle and concept of probability ? Explain that the concept of probability follows from Heisenberg's uncertainty principle.
4. Write down the Schrodinger equation for the wave mechanical model of an atom. Name the three quantum numbers of an electron which are yielded by the solution of this equation. Explain the significance of each quantum number.
5. (*a*) Explain the terms : principal quantum number, angular momentum quantum number, magnetic quantum number and electron spin and magnetic spin quantum number. Explain the significance of each of these numbers.

   (*b*) Discuss in details the Pauli's exclusion principle. Explain how with the help of this principle it is possible to determine the maximum number of electrons that can occur in any energy level.
6. Derive Schrodinger wave equation. Discuss the significance of the wave function ψ in this equation.
7. Write down the equations for the solutions of Schrodinger equation in terms of polar coordinates.
8. What are radial and angular wave functions. What information can we get from these functions ?
9. Derive an expression for the angular wave function in terms of the spherical harmonics.

10. Show from the complete wave function for an *s* orbital that the distribution of electronic charge in an *s* orbital is spherically symmetrical.
11. Write down the complete wave functions for *p* orbitals. From these derive real angular wave functions for these orbitals. Illustrate which real angular wave function corresponds to which *p* orbital.
12. Show from the complete wave function for *p* orbitals that the distribution of charge in *p* orbitals is dumb-bell sphaped.
13. Derive expressions for complete wave functions of *d* orbitals. Explain how these expressions account for the various shapes of the *d* orbitals.
14. Justify + and – signs in various parts of d_{xy}, $d_{x^2-y^2}$, p_x, p_y and p_z orbitals. Do these signs have any relation with charge ?
15. What is meant by screening effect ? Describe Slater's rules. How are these rules useful in determining the effective nuclear charge for any electron in an atom ? What are the limitations of these rules ?
16. Describe in details the Slater's rules. Discuss their important applications.
17. (*a*) What are the main rules for filling of orbitals ? Illustrate your answer with suitable examples.

    (*b*) What values of *n* will permit (*i*) only *s* type of orbital (*ii*) *s*, *p* and *d* types of orbitals ?
18. (*a*) What do you understand by Hund's rule of maximum multiplicity. Apply this rule to show the electronic configurations of oxygen and nitrogen.

    (*b*) Which of the following electronic configurations is correct for the copper atom : $[Ar]3d^{10}4s^1$ or $[Ar]3s^9 4s^2$? Given reason. **[Ans. $[Ar]3d^{10}4s^1$]**

    (*c*) Write the possible values of *l* and *m* for an electron in 3*p* orbital. **[Ans. $l = 1, m = -1, 0, +1$]**
19. (*a*) What is the difference between the energy level diagram of the hydrogen atom and that of a multi-electron atom ? How would you account for this difference ?

    (*b*) Arrange the following orbitals in order of increasing energy for a multi-electron atom :

    1*s*, 3*s*, 5*s*, 2*p*, 4*p*, 5*p*, 3*d*, 4*d*, and 4*f*.
20. Discuss the basis of Hund's rule.
21. Explain the terms : exchange pair, exchange energy, pairing energy and promotional energy.
22. Illustrate the difference between electronic configuration and electronic arrangement.
23. Explain carefully why exactly half-filled and completely filled orbitals are more stable than other orbitals. Illustrate your answer giving suitable examples.
24. Electrons prefer to fill those orbitals which thereby get either exactly half-filled or fully filled. Why is it so. Explain the configurations of Cu and Cr.

2 PERIODIC TABLE AND ATOMIC PROPERTIES

The eighteenth and nineteenth centuries witnessed rapid development of chemistry in all directions. During this period, several new elements were discovered. These elements were found to have numerous properties. It was realised that instead of studying the properties of all these elements *individually*, it would be more convenient to divide them into a few groups or families such that each group contains a number of elements with similar properties.

The first important attempt to divide elements on the basis of their physical and chemical properties was made by Mendeleeff, a Russian chemist, who observed that *when elements are arranged in the order of increasing atomic weights, elements with similar properties appear at regular intervals.* In 1869, he enunciated a law, known as the **periodic law**, which states :

The physical and chemical properties of elements are periodic functions of their atomic weights.

Henry Moseley, a brilliant young British physicist, in 1912, discovered a new property of elements, called **atomic number**, which provided a better basis for the periodic arrangement of the elements. As is well known, atomic number of an element is equal to the number of protons present in the nucleus (or the number of electrons present outside the nucleus) of the atom of the element. The periodic law was, therefore, modified. The **modern periodic law** may thus be stated as :

The properties of elements are periodic functions of their atomic numbers.

Periodic Table. A table in which elements are arranged in the order of increasing atomic number in the manner that the elements with similar properties fall in the same vertical column is known as the **periodic table.** The elements which fall in the same column and resemble one another in their properties are said to belong to the same **group** or **family** of elements. Thus, elements belonging to one particular group or family resemble one another quite closely but differ from the elements belonging to the other groups quite appreciably.

Various forms of periodic table have been put forth from time to time. The fundamental principle in each case, however, has been the same as enunciated in the modern periodic law.

We shall consider only the **modern form,** known as the **long form** of the periodic table.

LONG FORM PERIODIC TABLE

The objective of the periodic table is to *organise and systematise the chemistry of the elements.* The long form periodic table serves this objective very well. It may be recalled that the number of elements known at present is more than 100 including those prepared artificially through nuclear reactions in recent times. A broad study of the characteristics of various groups gives us a fairly good insight into the general behaviour and important properties of most of the elements.

The long form periodic table also helps us to understand the reason why certain elements resemble one another and why they differ from other elements in their properties. The arrangement of elements in this table is also in keeping with their electronic configurations.

Another significant feature of the long form periodic table is that it *helps us to understand the cause of periodicity of properties* and *the reason why similar properties recur at certain regular intervals, i.e.,* after 2, 8, 8, 18, 18 and 32 elements. The numbers, 2, 8, 18 and 32 are, sometimes, referred to as *magic numbers.*

The **long form** periodic table is given at the end of the book. This is constructed by arranging elements in the order of increasing atomic number. The *horizontal rows constitute* **periods** while the *vertical rows constitute* **groups.**

Periods. There are seven periods or horizontal rows in the table. The **first period** is made up of only **2 elements**, namely, *hydrogen* and the noble gas *helium*. The properties of hydrogen are somewhat similar to those of alkali metals (Group 1) and also similar to those of the halogens (Group 17) in some respects. However, it is more reasonable, though not entirely logical, to place it in Group 1. Helium is a typical noble gas and belongs to Group 18.

The second period contains **8 elements.** It starts with *lithium,* an alkali metal of Group 1. The other elements placed in succeeding groups are : *beryllium, boron, carbon, nitrogen, oxygen, fluorine* and lastly, *neon*, a noble gas. Thus, this period also ends with a noble gas placed in Group 18.

The **third period** which begins with *sodium* also contains **8 elements.** These are : *sodium, magnesium, aluminium, silicon, phosphorus, sulphur, chlorine* and the noble gas *argon*. The first seven elements are placed in Groups 1, 2, 13–17 while argon is placed in Group 18. This period, like the first two periods, also ends with a noble gas.

The **fourth period** begins, again, with an alkali metal, potassium. We have to pass now seventeen other elements before we come across a noble gas (krypton). This period, therefore, consists of **18 elements** from potassium ($Z = 19$) to the noble gas, krypton ($Z = 36$). The first two elements, potassium and calcium, show recurrence of properties. Thus, potassium resembles lithium and sodium of Group 1 in which it falls while calcium resembles beryllium and magnesium of Group 2 in which it falls. The difficulty arises after calcium because the next element, scandium, has very little in common with aluminium. We have to pass through 10 elements, from scandium to zinc, before we get an element, gallium, which shows resemblance with aluminium of Group 13. Gallium, therefore, is placed under aluminium in Group 13. The succeeding five elements, namely, germanium, arsenic, selenium, bromine and krypton, are placed, correctly, in Groups 14, 15, 16, 17 and 18, respectively. Of the 18 elements belonging to the fourth period, 8 elements, namely, potassium, calcium, gallium, germanium, arsenic, selenium, bromine and krypton ($Z = 19$, 20 and 31 to 36) are said to be **normal** or **main group** or **representative elements** as they resemble elements of the first two periods under which they are placed. The remaining 10 elements, from scandium to zinc ($Z = 21$ to 30) are called **transition elements.** The difference between the normal and the transition elements lies in the manner of the entrance of electrons. Since chemical properties are determined largely by the number of electrons in the outermost shell, the properties of transition elements, in which the outermost shell (4*s*) continues to have the same number of electrons, do not change radically. In the case of normal elements, on the other hand, the gradation of properties on moving across a period, is well pronounced. The transition elements differ from the normal elements in several other respects also, for example, in showing variable valency, forming coloured ions and being *paramagnetic.* ~~The fourth period is said to be the first long period.~~

The **fifth period**, like the fourth period, also consists of **18 elements** ($Z = 37$ to 54). It begins with rubidium ($Z = 37$) and ends with xenon ($Z = 54$) which, again, is a noble gas. Of the 18 elements, eight ($Z = 37$, 38 and 49 to 54) are normal elements and the remaining ten ($Z = 39$ to 48) are transition elements.

The **sixth period** is also a long period. It consists of **32 elements** ($Z = 55$ to 86). They include 8 normal elements ($Z = 55$, 56 and 81 to 86), 10 transition elements ($Z = 57$ and 72 to 80) and 14 **rare earth elements** ($Z = 58$ to 71). The *rare earth elements* begin with cerium ($Z = 58$) and continue upto lutetium ($Z = 71$). They are so called because they occur very *rarely*. The rare earths are so similar to

one another and also to *lanthanum* that they are called collectively as **lanthanides**. If these elements are placed horizontally in the same group, there will be undue expansion of the table. To avoid this, they are placed as a separate series below the periodic table, as shown.

The **seventh period**, as shown, consists of radioactive elements with atomic numbers 87 and beyond. So far, elements upto atomic number 108 only have been discovered. As mentioned above, elements beyond atomic number 92 have been prepared artificially through nuclear reactions. Just as the elements after lanthanum are called lanthanides, similarly, the elements after **actinium**, *i.e.*, from thorium to lawrencium ($Z = 90$ to 103) are called **actinides**. These elements, too, are placed as a separate series below the periodic table, as shown. The elements beyond uranium which have been prepared artificially by nuclear reactions are called **transuranic elements**. The common names of elements with atomic numbers 93 to 105 are : *neptunium, plutonium, americium, curium, berkeylium, californium, einsteinium, fermium, mendelevium, nobelium, lawrencium, kurchatovium* and *hahnium*. The IUPAC convention of 1977 has suggested new names for elements having atomic numbers beyond 100. These names are un-nil-unium (Unu, 101), un-nil-bium (Unb, 102), un-nil-trium (Unt, 103), un-nil-quadium (Unq, 104), un-nil-pentium (Unp, 105), un-nil-hexium (Unh, 106), un-nil-septium (Uns, 107), un-nil-octium (Uno, 108), un-nil-ennium (Une, 109), un-un-nilium (Uun, 110), un-un-unium (Uuu, 111), un-un-bium (Uub, 112).

Groups. The elements arranged in vertical columns of the periodic table are called **groups**. In the recent long form periodic table, the transition elements are also taken into account while numbering the groups. All the groups are numbered in Arabic numberals. The groups headed by H and He are numbered as Groups 1 and 2, respectively. The groups headed by Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu and Zn are numbered as Groups 3, 4, 5, 6, 7, 8, 9, 10, 11 and 12, resectively. The groups headed by B, C, N, O, F and Ne are numbered as Groups 13, 14, 15, 16, 17 and 18. If the transition elements are taken out, the rest of the elements (the normal elements), excluding hydrogen and helium, arrange themselves in various groups as shown below :

1	2	13	14	15	16	17	18
Li	Be	B	C	N	O	F	Ne
Na	Mg	Al	Si	P	S	Cl	Ar
K	Ca	Ga	Ge	As	Se	Br	Kr
Rb	Sr	In	Sn	Sb	Te	I	Xe
Cs	Ba	Tl	Pb	Bi	Po	At	Rn
Fr	Ra						

The elements of each group are now analogous to one another. For example, lithium and sodium of Group 1 resemble the elements potassium, rubidium, cesium and francium while beryllium and magnesium of Group 2 resemble the elements calcium, strontium, barium and radium. Likewise, fluorine and chlorine of Group 17 have properties in common with bromine, iodine and astatine, and so on. The elements of Group 18 (noble gases) lie in between the most electronegative halogens and the most electropositive alkali metals.

Cause of Periodicity

We have seen already that elements with similar properties occur at regular intervals in the periodic table. Such elements fall in the same vertical column, *i.e.*, the same group. *The recurrence of similar properties of elements after certain regular intervals when they are arranged in the order of increasing atomic numbers is called* **periodicity**. A question arises : What is the cause of this periodicity ?

To answer this question, we may consider elements of Groups 1, 17 and 18. The electronic configurations of these elements are given in Table 1.

TABLE 1

Electronic Configurations of Elements of Groups 1, 17 and 18

Elements of Group 1	Elements of Group 17	Elements of Group 18
Li : $1s^2\,2s^1$		He : $1s^2$
Na : $1s^2\,2s^2p^6\,3s^1$	F : $1s^2\,2s^2p^5$	Ne : $1s^2\,2s^2p^6$
K : $1s^2\,2s^2\,p^6\,3s^2p^6\,4s^1$	Cl : $1s^2\,2s^2p^6 3s^2p^5$	Ar : $1s^2\,2s^2p^6\,3s^2p^6$
Rb : $1s^2\,2s^2p^6\,3s^2p^6\,d^{10}\,4s^2p^6\,5s^1$	Br : $1s^2\,2s^2p^6\,3s^2\,p^6d^{10}\,4s^2p^5$	Kr : $1s^2\,2s^2p^6\,3s^2p^6d^{10}\,4s^2p^6$
Cs : 2, 8, 18, 18, $5s^2p^6\,6s^1$	I : 2, 8, 18, 18, $5s^2p^5$	Xe : 2, 8, 18, 18, $5s^2p^6$
Fr : 2, 8, 18, 32, 18, $6s^2p^6\,7s^1$	At : 2, 8, 18, 32, 18, $6s^2p^5$	Rn : 2, 8, 18, 32, 18, $6s^2p^6$

The elements belonging to each group have similar properties but they differ from the elements belonging to the other groups. For example, all the alkali metals belonging to Group 1 are *strongly metallic* and *electropositive* as they form cations (*e.g.*, Li^+, Na^+) very readily. The halogens belonging to Group 17 are *strongly non-metallic* and *electronegative* as they form anions (*e.g.*, F^-, Cl^-) very readily. The elements of Group 18 which connect the two extreme types of elements are *chemically least reactive.*

We may now look at their electronic configurations (Table 1). Since electrons in the inner shells do not, ordinarily, take part in any chemical combination, we have to examine only the *outermost electronic configurations* of these elements. We find that *all the elements belonging to a particular family (or group) have similar outer electronic configuration*. Thus,

(*i*) All the elements of Group 1 have *one* electron in the outermost *s* orbitals preceded by the noble gas configuration (ns^2p^6 ; for Li, $1s^2$). Their outer electronic configuration may thus be written as ns^1.

(*ii*) All the elements of Group 17 have *seven* electrons in the outermost level. Two of these electrons are present in the *s* orbitals while the remaining five are present in the *p* orbitals. Their outer electronic configuration is ns^2p^5.

(*iii*) All the elements of Group 18, except helium, have *eight* electrons in the outer level, two of which are accommodated in the *s* orbitals and the remaining six fill the *p* orbitals *completely*. In helium, there are only two electrons both of which are present in 1*s* orbital which is, therefore, completely filled. Thus, all the orbitals are fully occupied in these elements, which, as already mentioned, are chemically inert. Their outer electronic configuration is ns^2p^6 except for helium which is $1s^2$.

The **cause of periodicity** in properties of elements appears to lie, therefore, in the *recurrence of similar outer electronic configurations of their toms at certain regular intervals.*

Cause of Recurrence of Properties at Regular Intervals of Atomic Numbers. We have seen already that elements with similar properties recur at certain regular atomic number intervals in the periodic table. These intervals are : 2, 8, 8, 18, 18, 32 and 32. In other words, we have to pass 2, 8, 18 and 32 elements as the case may be before we come across an element with similar properties. A question arises : Why do we have these particular numbers called *magic numbers* ? The answer is as follows :

As has been discussed in the previous pages and as has been shown clearly in the periodic table affixed at the end of the book, *each period begins with a new major energy level*. The energy level

diagram of various orbitals belonging to different major energy levels is shown in Fig. 1.

As can be seen, for $n = 1$, there is only one orbital (1*s* orbital). We may recall that each orbital can have a maximum of two electrons. We may also recall that one electron is added at a time as we move from one element to the next in the periodic table. It is evident, therefore, that since there is only one orbital associated with $n = 1$, there can be only 2 *elements in the first period.*

When $n = 2$, there are *four* orbitals (one 2*s* and three 2*p* orbitals) as shown in Fig. 1. Hence, *the number of elements in the second period will be* 8.

When $n = 3$, there are *nine* orbitals (one 3*s*, three 3*p* and five 3*d* orbitals). However, the 3*d* orbitals are associated with higher energies than even the 4*s* orbitals. These orbitals, therefore, cannot be occupied before the complete filling of the 4*s* orbitals. The result is that corresponding to $n = 3$, *only four orbitals* (one *s* and three *p* orbitals) *can be occupied.* Hence, *the number of elements in the third period is also* **8.**

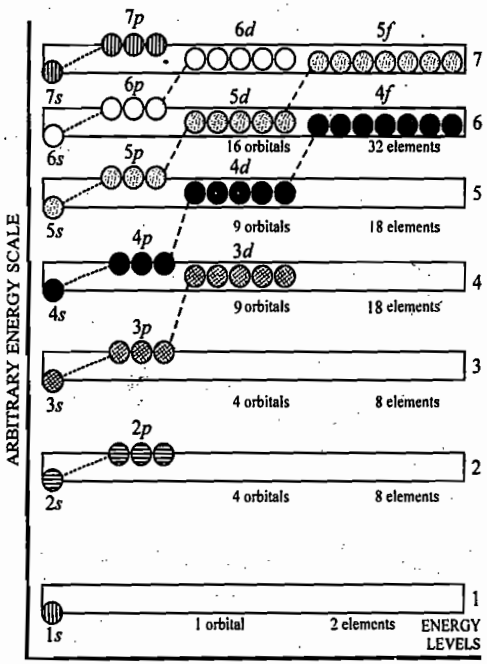


Fig. 1. The energy level diagram depicting energies of various orbitals belonging to different major energy levels.

Following the same line of argument, it can be seen on reference to Fig. 1, that when $n = 4$, there are *nine* orbitals (one 4*s*, five 3*d* and three 4*p* orbitals) to be filled up and hence *the number of elements in the fourth period is* **18.** This is the first long period.

Similarly, when $n = 5$, there are, again, only *nine* orbitals (one 5*s*, five 4*d* and three 5*p* orbitals) to be filled up and hence *the number of elements in the fifth period is also* **18.**

Finally, when $n = 6$ and $n = 7$, there are *sixteen* orbitals to be filled in each case (Fig. 1). Therefore, *there are* **32** *elements in the sixth period and there will also be* **32** *elements in the seventh period* when all of them are discovered. At present, the seventh period is incomplete and contains only 22 elements.

The above discussion clearly explains why the number of elements in the successive periods of the periodic table happens to be 2, 8, 8, 18, 18, 32 and 32. The elements with similar properties, therefore, also appear after intervals of 2, 8, 8, 18, 18, 32 and 32, as we move along the periodic table in the order of increasing atomic numbers.

Division of Elements into *s, p, d* and *f* Blocks

The elements, as arranged in the long form periodic table, can also be divided into **four blocks** known as *s, p, d* and *f* blocks. This classification depends upon the type of the orbitals (*s, p, d* or *f*) into which the last electron of the atoms of the elements enters.

s Block Elements. *The elements whose atoms receive the last electron in the s orbital of their outermost energy shell* are called ***s* block elements.** This block consists of elements of Groups 1 and 2 in which the *s* orbitals are being progressively filled. The elements of Group 1 have the general ground state electronic configuration ns^1. These are called **alkali metals.** The elements of Group 2 have the general ground state electronic configuration ns^2. These are called **alkaline earth metals.**

***p* Block Elements.** *The elements whose atoms receive the last electron in their p orbitals are called* ***p* block elements.** The atoms of elements of Groups 13, 14, 15, 16, 17 and 18 having one, two, three, four, five and six electrons, respectively, in *p* orbitals (while *s* orbitals are already filled) in the outermost shells, constitute *p block.* The general electronic configuration for the atoms of the elements of this block may be written as $ns^2\ np^{1-6}$.

***d* Block Elements.** The atoms of elements of Groups 3 to 12 lying between *s* and *p* blocks have the *s* and *p* orbitals (of their outermost principal energy shell) completely filled. The *d* orbitals in the penultimate (inner to the outermost) shell, however, are still empty (cf. periodic table). The last electron in these elements, therefore, enters the *d* orbitals which, thereby, get progressively filled as we move across a period. Thus, *the elements in which the last electron enters the d orbitals of their last but one (penultimate) energy shells are called* ***d* block elements.** The general electronic configurations of *d* block elements may be written as $(n-1)d^{1-10}\ ns^{1-2}$. These elements are also called **transition elements.** This block consists of three rows called *First, Second* and *Third transition series* which involve the filling of 3*d*, 4*d* and 5*d* orbitals, respectively. The elements from scandium ($Z = 21$) to zinc ($Z = 30$) in the fourth period constitute the *First transition series* ; from yttrium ($Z = 39$) to cadmium ($Z = 48$) in the fifth period constitute the *Second transition series* and from hafnium ($Z = 72$) to mercury ($Z = 80$) in the sixth period constitute the *Third transition series.*

***f* Block Elements.** The elements in which the last electron enters the *f* orbitals of their atoms are called ***f* block elements.** In these elements, the last electron enters the third to the outermost (ante penultimate), *i.e.*, $(n-2)f$ energy shell. It consists of two series of 14 elements each placed at the bottom of the periodic table. The first series follows lanthanum, La ($Z = 57$) and the second series follows actinium, Ac ($Z = 89$) in the order of increasing atomic numbers. These series are called **lanthanides** (from cerium to lutetium) and **actinides** (from thorium to lawrencium), respectively. In lanthanides, 4*f* orbitals and in actinides, 5*f* orbitals are being progressively filled.

These four blocks are distinctly shown in the periodic table.

ATOMIC PROPERTIES

Before we are in a position to understand such topics as chemical bonding between atoms and geometry and shapes of molecules, it is necessary to have adequate knowledge of certain atomic properties. These properties are : (*i*) *Sizes of Atoms and Ions* (*ii*) *Ionisation Energy* (*iii*) *Electron Affinity* and (*iv*) *Electronegativity.*

SIZES OF ATOMS AND IONS

The sizes of atoms and ions are generally reflected in the magnitude of their respective radii. The **radius of an atom** or **an ion** may be taken, in the ordinary sense, as *the distance between the centre of the nucleus and the outermost shell of electrons.* If the atom or the ion is assumed to be spherical, the atomic or ionic radius corresponds to the radius of the sphere. However, the absolute size of an atom is difficult to define because of the following reasons :

(*i*) According to quantum mechanics, *there is no certainty* with regard to the *exact position* occupied by electrons at any time. Theoretically, an electron, at times, may be very close to the nucleus while at other times it may be far away from the nucleus. In other words, it is not possible to define any boundary for an atom or an ion. The electron probability is never zero even at very large distances from the nucleus.

(*ii*) It is not possible to have isolated atoms and the probability distribution of electrons in an atom is appreciably influenced by the presence of other atoms in its environment. As a result, the size of an atom or an ion would change with change in the environment.

Despite these limitations, we need to have some *operational definition* of the radius of an atom or an ion. This is necessary in order to get comparative values for atoms and ions of different elements and also to explain a number of chemical phenomena.

There are three **operational concepts** of these radii. These are :

(1) *Covalent Radius* (2) *Van der Waals Radius* and (3) *Ionic Radius.*

1. Covalent Radius

One half of the distance between the nuclei of two covalently bonded atoms of the same element in a molecule, is taken as the **covalent radius** *of the atom of that element.* While defining the covalent radius as above, it is assumed that atoms are hard, incompressible spheres which are touching each other in normal covalent bond formation. However, atoms are neither fully incompressible nor do they touch each other in a covalent molecule. Therefore, the covalent radii calculated on the basis of the above definition cannot be regarded as exact.

The distance between the centres of any two neighbouring atoms (*viz.*, the internuclear distance) can be measured by X-ray diffraction or spectroscopic studies. For instance, we know from spectroscopic data that the distance between the nuclei of two hydrogen atoms in a H_2 molecule is 0·74 Å. Half of this distance, *viz.*, 0·37 Å, gives the covalent radius of the hydrogen atom.

Similarly, the internuclear distances in Cl_2 and Br_2 molecules are 1·98 Å and 2·28 Å, respectively. Accordingly, the covalent radii of chlorine and bromine atoms would be 0·99 Å and 1·14 Å, respectively.

Once we know the covalent radii of some of the elements, we can calculate the covalent radii of other elements from the internuclear distances between the elements whose covalent radii are known and those whose covalent radii are to be determined. For this purpose, the covalent radii are taken to be **additive**. For instance, the covalent radius of carbon is known to be 0·77 Å and the internuclear distance between C and H atoms in CH_4 is found to be 1·14 Å. Therefore, the covalent radius of H atom is 1·14 – 0·77 = 0·37 Å. This value is the same as obtained spectroscopically.

However, the length of a bond between two unlike atoms, *i.e.*, atoms differing appreciably in their electronegativities, is shorter than the sum of their covalent radii. The shortening of bond length is due to the polarity developed in the bond because of difference in electronegativities of the two atoms forming the covalent bond. Consider a covalent bond A – B. If A is more electronegative than B, the electronic charge between A and B which is responsible for bond formation, would be shifted nearer to A resulting in the accumulation of excess negative charge on A and a corresponding excess positive charge on B. *This would result in additional electrostatic attraction between* A and B which would bring A and B further nearer to each other. In other words, the *bond between* A *and* B *gets shortened.* The greater the electronegativity difference between A and B, the shorter would be the bond distance and the smaller would be the covalent radii of A and B as obtained from the bond length, *i.e.*, the internuclear distance.

According to Shoemaker and Stevenson, the actual bond distance between A and B is given by the relation

$$r_{A-B} = r_A + r_B - 0{\cdot}09\,(\chi_A - \chi_B) \qquad ...(1)$$

where r_A is the normal covalent radius of A (equal to half the bond distance A – A), r_B is the normal covalent radius of B (equal to half the bond distance B – B) in Å and χ_A and χ_B are the electronegativities of A and B, respectively. Several modifications of this equation have been suggested to improve upon the evaluation of r_{A-B}. The one suggested by Porterfield is

$$r_{A-B} = r_A + r_B - 0{\cdot}07\,(\chi_A - \chi_B)^2 \qquad ...(2)$$

The covalent radius of an element determined from a double or a triple bond is shorter than the normal covalent radius of the same element determined from a single bond. Thus, the covalent radius of C in ethane is 0·77 Å, in ethylene 0·67 Å and in acetylene it is 0·60 Å. This is due to the fact that in a double or a triple bond, in addition to overlapping of sigma orbitals, there is overlapping of pi orbitals as well. The additional overlapping of pi orbitals results in bringing the two atoms closer thereby reducing the bond length and the covalent radius.

The electron charge cloud around a singly bonded atom is taken as spherically symmetrical. But, this is certainly not so in the case of a multiple bonded atom. The electron charge cloud is so much distorted that it cannot be called *spherical* by any stretch of imagination. In the absence of a symmetrical spherical distribution of charge, it is not proper to call the covalent radius determined for a doubly or a triply bonded atom as 'radius' at all. When there is no sphere, there is no radius, evidently.

Although the covalent radii are not always constant, yet the average covalent radii calculated from non-polar single covalent bonds are quite helpful in determining approximate bond distances in actual or hypothetical compounds.

Most of the metals do not form covalent compounds except for those forming covalent hydrides and organometallic compounds. It is, therefore, not possible to determine the covalent radii of metals. However, *atomic volumes* of metal atoms can be easily determined by dividing their atomic masses by their respective densities. The radii calculated from *atomic volumes* are called **metallic radii**. The covalent radii determined from covalent metal hydrides and organometallic compounds and metallic radii determined from atomic volumes of metal atoms, are found to have almost similar values. It is, therefore, immaterial which term we use for radii of metal atoms.

In many cases, the size of an atom in free state and its size determined from a single, non-polar covalent bond are almost the same. Therefore, the terms covalent radii and atomic radii have been used synonymously in many books.

The covalent radii of elements belonging to various groups of the periodic table are given in Table 2.

TABLE 2

Covalent Radii (Å) of Various Elements

Group 1	Group 2	Group 13	Group 14	Group 15	Group 16	Group 17	*Group 18
H 0·37							He 0·93
Li 1·34	Be 0·90	B 0·82	C 0·77	N 0·75	O 0·74	F 0·72	Ne 1·31
Na 1·54	Mg 1·36	Al 1·18	Si 1·11	P 1·06	S 1·09	Cl 0·99	Ar 1·74
K 2·03	Ca 1·74	Ga 1·26	Ge 1·22	As 1·19	Se 1·16	Br 1·14	Kr 1·89
Rb 2·16	Sr 1·92	In 1·44	Sn 1·41	Sb 1·38	Te 1·35	I 1·33	Xe 2·09
Cs 2·35	Ba 1·98	Tl 1·48	Pb 1·47	Bi 1·46	Po –	At –	Rn 2·14

*The radii for noble gases are only the van der Waals radii. (see page 66)

It may be emphasised here that the **noble gases** which consist of monoatomic molecules, ordinarily, do not form any covalent bonds. In crystals of noble gases, therefore, no chemical forces are operating between the atoms. The van der Waals forces are the only attractive forces in these cases. Hence, *the atomic radii of noble gas atoms are only the van der Waals radii* which represent the distance of closest approach of the two adjacent atoms of the noble gas concerned in the solid state.

Periodic Trends in Covalent Radii. Generally speaking, *the covalent radii decrease in moving from left to right in any given* **period** and *increase in moving from top to bottom in any given* **group**. Explanation for these variations is given below.

Variation of covalent radii in a period. The variation of covalent radii in a period can be explained easily on the basis of electronic configurations and the effective nuclear charges. Table 3 gives the covalent radii of the elements of the second period. The effective nuclear charges (Z_{eff}) given in the table are calculated with the help of the Slater's rules, as discussed in Chapter 1.

TABLE 3

Covalent Radii of Elements of the Second Period of the Periodic Table

Element	Li	Be	B	C	N	O	F
Atomic number	3	4	5	6	7	8	9
Z_{eff} for K electrons	2·70	3·68	4·71	5·81	6·80	7·79	8·69
Z_{eff} for L electrons	1·30	1·95	2·60	3·25	3·90	4·55	5·20
Electronic configuration	$1s^2 2s^1$	$1s^2 2s^2$	$1s^2 2s^2p^1$	$1s^2 2s^2p^2$	$1s^2 2s^2p^3$	$1s^2 2s^2p^4$	$1s^2 2s^2p^5$
Covalent radius (Å)	1·34	0·90	0·82	0·77	0·75	0·73	0·72

Since the last electron in all these elements is added to L shell, one would expect their sizes (and hence their covalent radii) to be the same. But a glance at Table 3 reveals that the covalent radii are not the same. They go on decreasing with increase in the atomic number within the period. This can be explained as follows :

The greater the effective nuclear charge, the greater would be the force with which the electron is pulled towards the nucleus. It is clear from Table 3 that effective nuclear charge felt by both K and L shell electrons goes on increasing from Li to F. As a consequence, the K as well as L shell electrons tend to lie closer and closer to the nucleus. Thus, there is more and more contraction of both K and L shells and hence there is more and more reduction in the covalent radii in moving from left to right across the period (*i.e.*, from Li to F). The same trend is shown by the elements of the third and subsequent periods as well (Table 2). Since effective nuclear charge felt by K electrons is more than that felt by L electrons, K shell will get contracted to a greater extent than the L shell.

TABLE 4

Atomic Radii of Alkali Metals

Alkali metal	Atomic number	Atomic radius (Å)
Li	3	1·34
Na	11	1·54
K	19	1·96
Rb	37	2·11
Cs	55	2·55

Variation of covalent radii in a group. In order to understand the change in the size of the atoms in the **same group**, the atomic radii for the alkali metals, reproduced in Table 4, may be considered.

It is seen that there is increase in covalent radius on moving from top to bottom. This may be explained as follows : In moving down a group, the number of the principal shell increases and, therefore, the size of the atom increases. This effect, no doubt, is partly annuled by the drawing in of the electron shells on account of the increasing nuclear charge. But the effect of adding a new shell is so large that it overcomes the contractive effect of the increased nuclear charge. Hence, *the radius of the atom increases in moving from top to bottom in* a **group.**

2. Van der Waals Radius

The van der Waals radius is defined *as one half of the distance between the nuclei of two adjacent identical atoms belonging to two neighbouring molecules of an element in the solid state* (Fig. 2). It is essentially the distance between two non-bonded atoms of two adjacent molecules and is related to

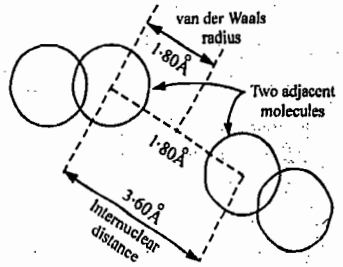

Fig. 2. The van der Waals radius of chlorine.

the effective packing size of the atom when the element is in solid state. The name van der Waals radius is used because the forces existing between the molecules are the van der Waals forces of attraction. The van der Waals radii are obtained from X-ray studies of various elements in the solid state. For example, the internuclear distance between two chlorine atoms of nearest neighbouring molecules is 3·60 Å (Fig. 2). The van der Waals radius of chlorine, therefore, is 1·80 Å.

The van der Waals and covalent radii of some common elements are given in Table 5.

TABLE 5

The van der Waals and Covalent Radii of Some Elements (in Å)

Element	H	N	O	F	Cl	Br	I
Van der Waals radius	1·20	1·50	1·40	1·35	1·80	1·95	2·15
Covalent radius	0·37	0·75	0·73	0·72	0·99	1·14	1·33

As can be seen, covalent radius is *smaller* than van der Waals radius. The reason is that in the formation of a covalent bond, the atoms have to come closer to each other. This also explains why covalent bonds are much stronger than van der Waals forces.

3. Ionic Radius

The ionic radius corresponds to the radius of an ion in an ionic crystal. It may be defined as *the distance from the nucleus of an ion up to which it has influence on its electron charge cloud.* The electron charge cloud, no doubt, may extend theoretically up to a very large distance. However, it is important to characterise each ion by some value. For this purpose, the internuclear distance in any ionic compound is determined from X-ray measurements. *This distance is taken as the sum of the radii of the two ions involved.* Knowing the radius of one, that of the other can be calculated. For example, the distance between the nuclei of Na^+ and F^- ions is determined from X-ray technique. This distance is taken as the sum of the radii of Na^+ and F^- ions. The radius of each of Na^+ and F^- ion is then determined by following the procedure described in Chapter 6 (The Structure of Solids). The radius of Na^+ ion thus obtained may be used to calculate the radii of other anions, such as Cl^-, Br^- and I^- ions, by measuring internuclear distances in NaCl, NaBr and NaI crystals. Similarly, the radius of Cl^- ion may be used to calculate the radii of other cations such as K^+ and Li^+ ions by measuring internuclear distances in KCl and LiCl crystals.

Radii of Cations and Anions. A positive ion, *i.e.*, a **cation**, results from the loss of one or more electrons from the outer shell called the valence shell of an atom. This causes in many cases the removal of the whole of the outer shell of electrons. For example, in lithium there is only one electron in the outer (L) shell. This electron is removed in the change

$$\underset{\substack{1s^2 2s^1 \\ (1{\cdot}34\ \text{Å})}}{Li} \longrightarrow \underset{\substack{1s^2 \\ (0{\cdot}65\ \text{Å})}}{Li^+} + e^-$$

The L shell, therefore, disappears. In magnesium, there are two electrons in the outer (M) shell. Both these electrons are removed in the change

$$\underset{\substack{1s^2 2s^2p^6 3s^2 \\ (1{\cdot}30\text{Å})}}{Mg} \longrightarrow \underset{\substack{1s^2 2s^2p^6 \\ (0{\cdot}65\ \text{Å})}}{Mg^{2+}} + 2e^-$$

The M shell, therefore, disappears in this case also.

Thus, in the formation of a positive ion, the outer shell of electrons is generally removed completely. *The cation*, therefore, *is much smaller than the corresponding atom.* At the same time, with the elimination of one or more *outer* electrons from an atom, the number of electrons decreases while the nuclear charge remains the same. The nuclear charge now acts on a lesser number of electrons. In other words, the effective nuclear charge per electron increases and the electrons are, therefore, pulled in more towards the nucleus than before. This effect also *tends to decrease the radius of the cation.*

The decrease in radius when an atom changes into a cation is shown below in the case of sodium, lead, aluminium, iron and manganese.

Atomic radius of Na = 1·54 Å	Atomic radius Pb = 1·47 Å
Ionic radius of Na^+ = 0·95	Ionic radius of Pb^{2+} = 1·20
Atomic radius of Al = 1·18	Ionic radius of Pb^{4+} = 0·84
Ionic radius of Al^{3+} = 0·50	
Atomic radius of Mn = 1·26	Atomic radius of Fe = 1·26
Ionic radius of Mn^{2+} = 0·80	Ionic radius of Fe^{2+} = 0·76
Ionic radius of Mn^{4+} = 0·46	Ionic radius of Fe^{3+} = 0·64

It is evident that **radius of a cation** is invariably smaller than that of the corresponding atom. The size decreases further with the loss of subsequent electrons when cations of higher valencies are formed.

During the change of an atom into a negative ion, *i.e.*, an **anion**, one or more electrons are added to the valency shell of the atom. As a result, the same nuclear charge acts on a larger number of electrons. In other words, effective nuclear charge per electron is reduced and, therefore, the electrons are held less tightly by the nucleus and the electron charge cloud expands. Thus, the **radius of a negative ion** is invariably larger than that of the corresponding atom. This is shown below in the case of chlorine, bromine, iodine, oxygen, sulphur and nitrogen.

Atomic radius of Cl = 0·99 Å	Atomic radius of O = 0·73 Å
Ionic radius of Cl^- = 1·81	Ionic radius of O^{2-} = 1·45
Atomic radius of Br = 1·14	Atomic radius of S = 1·02
Ionic radius of Br^- = 1·95	Ionic radius of S^{2-} = 1·84
Atomic radius of I = 1·33	Atomic radius of N = 0·75
Ionic radius of I^- = 2·16	Ionic radius of N^{3-} = 1·71

Variation of ionic radii in iso-electronic ions. Iso-electronic ions are those which have the same number of electrons but which differ in the charge on their nuclei (Table 6).

The effect of nuclear charge on ionic size is best illustrated by considering the radii of these iso-electronic species. All of them contain the same number of electrons. They differ only in the charge on the nucleus. It is evident that as the nuclear charge increases, the electrons are held more and more tightly by the nucleus with the result that the ionic radius decreases.

TABLE 6

Radii of Iso-electronic Ions

Ion	N^{3-}	O^{2-}	F^-	Na^+	Mg^{2+}
Number of electrons	10	10	10	10	10
Charge on the nucleus	+7	+8	+9	+11	+12
Radius (Å)	1·71	1·45	1·33	0·95	0·60

Periodic Trends in Ionic Radii. Generally speaking, the *ionic radii increase in moving from top to bottom in any given group* and *decrease in moving along a period.* The ionic radii of some common ions are given in Table 7.

TABLE 7

Ionic Radii (Å) of Some Common Ions

Group 1	Group 2	Group 13	Group 16	Group 17
Li^+ 0·60	Be^{2+} 0·31	B^{3+} 0·20	O^{2-} 1·45	F^- 1·33
Na^+ 0·98	Mg^{2+} 0·65	Al^{3+} 0·50	S^{2-} 1·84	Cl^- 1·81
K^+ 1·33	Ca^{2+} 0·99	Ga^{3+} 0·61	Se^{2-} 2·02	Br^- 1·96
Rb^+ 1·48	Sr^{2+} 1·10	In^{3+} 0·81	Te^{2-} 2·22	I^- 2·19
Cs^+ 1·67	Ba^{2+} 1·29	Tl^{3+} 0·91		

Variation in a group. It is evident from the data given in Table 7 that ionic radii increase with increase in atomic number within a group. This is easily understandable. Since the atomic size increases as we move down the group, therefore, the ionic radius also increases as we go down the group.

It can also be seen that within a group, there is a rapid increase in ionic radius as we move from one element to another amongst the first few elements but the increase is not so rapid when we do so amongst the last members. For example, the increase in ionic radius is quite rapid as we move from Li^+ to Na^+ and from Na^+ to K^+ but the increase is not that rapid as we move from K^+ to Rb^+ and from Rb^+ to Cs^+. A possible explanation for this behaviour is that between K^+ and Rb^+ ions come the elements of the First transition series. As in these elements the last occupied shell is the same, their increasing nuclear charge with increase in atomic number tends to cause contraction of electron charge clouds of the atoms and the ions. Thus, the radii of ions which follow any of the transition series would be smaller than if only eight elements had separated them from the lighter members of the family.

Variation in a period. Within a period, the radii of cations of normal elements of Groups 1, 2 and 13 decrease with increase in atomic number and so do the radii of anions of elements of Groups 16 and 17. This is again easily understandable. Since the atomic size decreases as we move along a period, the ionic radius also decreases correspondingly.

IONISATION ENERGY (*IE*)

The **ionisation energy**, *IE*, of an element is defined as *the amount of energy required to remove an electron from the outermost shell of an isolated gaseous atom of that element resulting in the formation of a positive ion.* This gives a direct measure of the ease with which an atom can change into a cation, as represented below :

$$M(g) + IE \longrightarrow M^+(g) + e^-$$

The energy required to bring about the above change is called **ionisation energy.** Evidently, *the smaller the ionisation energy, the easier it is for the neutral atom to change into a positive ion.*

Ionisation energies are generally measured by spectroscopic techniques. Another method is to have the vapours of the element in a discharge tube and connect it to a source of current. The voltage applied is gradually increased. At a certain voltage there will be a sudden rise in the current passing through the

tube. The energy corresponding to this voltage is known as the **first ionisation energy** $(IE)_1$. The sudden rise in the current is due to the liberation of an electron from each neutral atom producing an ion, M^+.

If the applied voltage is increased further, there may again be a stage when the current shows a sudden rise. This is due to *the elimination of another electron from each positively charged ion* (M^+) produced earlier. The energy corresponding to this stage is known as the **second ionisation energy,** $(IE)_2$. At this stage, doubly charged ions, M^{2+}, are produced. If the potential is increased even beyond this point, there may again be sudden and sharp rises in the current at certain points. These points correspond to the *loss of three or more electrons* and give the **third** $(IE)_3$ **or higher ionisation energies** of the element. These changes may be represented as follows :

$$M \xrightarrow{(IE)_1} M^+ + e^-$$

$$M^+ \xrightarrow{(IE)_2} M^{2+} + e^-$$

$$M^{2+} \xrightarrow{(IE)_3} M^{3+} + e^-$$

Ionisation energy is measured in electron-volts (eV) as well as in joules or kilojoules. It may be remembered that 1 eV = $1{\cdot}602\times10^{-19}$ joule or $1{\cdot}602\times10^{-22}$ kilojoule.

The values presented in electron-volts give ionisation energy *per atom* while those expressed in kilojoules represent ionisation energy *per mole* (*i.e.*, per Avogadro's number of atoms) of the element. Thus, ionisation energy of hydrogen is 13·595 eV **per atom** of hydrogen and $13{\cdot}595\times1{\cdot}602\times10^{-22}\times6{\cdot}022\times10^{23} = 1312{\cdot}0$ kJ **per mole** of hydrogen.

Let us consider the first and the second ionisation energies for lithium and sodium given below.

$$Li \longrightarrow Li + e^- \;;\; (IE)_1 = 520{\cdot}1 \text{ kJ mol}^{-1}$$
$$Li^+ \longrightarrow Li^{2+} + e^- \;;\; (IE)_2 = 7297{\cdot}2 \text{ kJ mol}^{-1}$$
$$Na \longrightarrow Na^+ + e^- \;;\; (IE)_1 = 495{\cdot}2 \text{ kJ mol}^{-1}$$
$$Na^+ \longrightarrow Na^{2+} + e^- \;;\; (IE)_2 = 4563{\cdot}5 \text{ kJ mol}^{-1}$$

As can be seen, the second ionisation energies are very much higher than the first ionisation energies.

The successive ionisation energies of some common elements are listed in Table 8.

TABLE 8

Successive Ionisation Energies (in kJ per mole) of Some Common Elements

Element	Electronic configuration	$(IE)_1$	$(IE)_2$	$(IE)_3$
Li	$1s^2\,2s^1$	520·1	7297	11810
Be	$1s^2\,2s^2$	899·3	1758	14810
B	$1s^2\,2s^2p^1$	800·1	2428	3660
C	$1s^2\,2s^2p^2$	1086·2	2353	4618
N	$1s^2\,2s^2p^3$	1402·1	2855	4577
O	$1s^2\,2s^2p^4$	1313·7	3388	5297
F	$1s^2\,2s^2p^5$	1680·8	3375	6045
Ne	$1s^2\,2s^2p^6$	2080·4	3963	6130

If one electron has been taken out of an atom, it becomes increasingly difficult to remove the second and subsequent electrons from the resulting positively charged ion on account of electrostatic attraction. This is due to the fact that after the removal of an electron, the number of electrons decreases while the nuclear charge remains the same. Consequently, the remaining electrons are held more tightly by the nucleus and it becomes difficult to remove the second electron. Therefore, the second ionisation energy is greater than the first ionisation energy and, similarly, the third ionisation energy is greater than the second ionisation energy and so on. Thus, $(IE)_3 > (IE)_2 > (IE)_1$.

The first ionization energies obtained spectroscopically for the various elements belonging to different groups are presented in Table 9.

TABLE 9

First Ionisation Energies of Various Elements (kJ mol^{-1})

Group 1	Group 2	Group 13	Group 14	Group 15	Group 16	Group 17	Group 18

Factors Determining Ionisation Energy. The ionisation energy of an element depends upon the following factors.

1. Atomic size. *The larger the atomic size, the smaller is the ionisation energy.* The reason for this is that as the size of the atom increases, the outer electrons lie farther away from the nucleus. Hence, according to Coulomb's law, the attractive pull of the nucleus on the outer electrons decreases and it becomes easier to knock out an electron from the outermost shell of the atom.

2. Nuclear charge. The force of attraction between the nucleus and the outermost electron increases with increase in nuclear charge. Thus, the greater the nuclear charge, the greater is the energy needed to pull out an electron from the atom. Hence, *ionisation energy increases with increase in nuclear charge.*

3. Number of electrons in the inner shells. *The larger the number of electrons in the inner shells, the smaller is the ionisation energy.* The electrons in the inner shells act as a screen or shield between the nucleus and the electrons in the outermost shell. This is known as **screening effect** or **shielding effect.** The larger the number of electrons in the inner shells, the greater is the screening effect. Consequently, the electrons in the valency shell experience less attraction from the nucleus. Hence, the ionisation energy would be low.

4. Penetration effect or the effect of removal of *s, p, d and f* electrons from the same energy shell. The *s* electrons in their motion around the nucleus have greater probability of coming closer to the nucleus than the *p, d* or *f* electrons of the *same principal energy shell.* In other words, *s* electrons *penetrate more* towards the nucleus than *p* electrons and the penetrating power of the electrons in the

given principal energy shell varies as $s > p > d > f$. Thus, the s electrons experience more attraction from the nucleus than the p, d or f electrons of the same principal energy shell. It follows, therefore, that *the energy required for pulling out an s electron is maximum and it decreases in pulling out a p electron, a d electron or an f electron of the same principal energy shell in the order of their mention.* We may thus say that ionisation energy corresponding to the elimination of an electron from a given energy level varies in the order $s > p > d > f$ electron.

5. Electronic configurations. Certain electronic configurations are more stable than others. For example, *if an atom has fully filled or exactly half-filled orbital* in the valency shell, *its ionisation energy is higher than expected normally from its position in the periodic table.* For example, beryllium and nitrogen in the second period and magnesium and phosphorus in the third period, have slightly higher ionisation energies than would be expected. This is due to the *extra stability of the fully completed s orbitals* in beryllium and magnesium and that of the *exactly half-filled p orbitals* in nitrogen and phosphorus.

Further, it is seen that He, Ne, Ar, Kr, Xe and Rn have highest ionisation energies in their respective periods. This shows that an atom with s^2p^6 configuration (the so-called octet configuration) in its outer shell is highly stable. In this connection it may also be noted that Li^+ and Na^+ ions, which also have s^2p^6 configurations, require very high energies, *viz.*, 7297·2 and 4563·5 kJ per mole, to permit pulling out of an extra electron from them to give Li^{2+} and Na^{2+} ions, respectively.

Variation of Ionisation Energy in the Periodic Table. The following periodic trends in ionisation energy are observed :

a. Variation in a group. *In general, the ionisation energy decreases in going from top to bottom in a* **group.** This is evident from Table 9. On moving down a group

(*i*) the nuclear charge increases

(*ii*) there is gradual increase in atomic size due to increase in the number of the principal energy shell.

(*iii*) there is increase in the number of inner electrons which shield the valence electrons from the nucleus.

The overall effect of increase in atomic size and the shielding effect is much more than the overall effect of increase in nuclear charge. Consequently, the outermost electron is less and less tightly held to the nucleus as we move down the group. Hence, ionisation energy decreases as we go down from top to bottom in any group. There are some exceptions, however. For example, the first ionization energy of indium is less than that of thallium in Group 13 and first ionization energy of Sn is less than that of Pb in Group 14. We shall discuss these exceptions in adequate details while considering the properties of the main group elements in Chapter 12.

b. Variation along a period. *In general, the ionisation energy increases as we move along a period from left to right* (Table 9).

The above variation can be explained as follows. On moving across a period, the atomic size decreases and nuclear charge increases and, therefore, the force of attraction exerted by the nucleus on electron in the outermost shell increases. Consequently, it becomes increasingly difficult to remove an electron from the outer shell of the atom and hence ionisation energy increases. The ionisation energy becomes maximum for the noble gas which has stable electronic configuration, ns^2p^6.

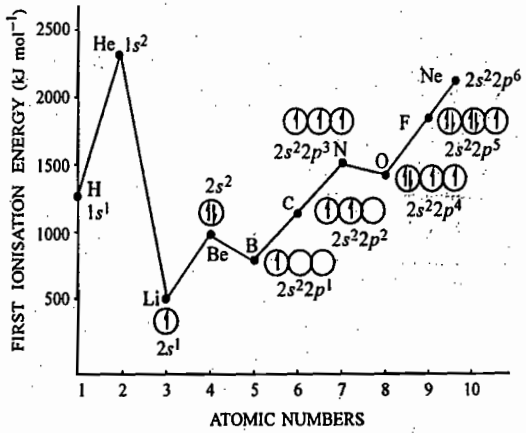

Fig. 4. Variation of ionisation energy with atomic number.

However, the variation in ionization energy along a period is not smooth (Table 9). Some irregularities are distinctly observed. This is due to the fact that atomic size is not the only factor which determines the ionization energy. The variation of ionisation energy with increase in atomic number for the elements of second period is depicted in Fig. 4. The electronic configurations of the elements are also shown in the figure.

It is clear from the figure that ionization energies of boron and oxygen are unexpectedly lower than the ionisation energies of their preceding elements beryllium and nitrogen, respectively. These anomalies are explained as follows : Electronic configuration of boron ($1s^2\,2s^2p^1$) is less stable than that of beryllium ($1s^2\,2s^2$) which has completely filled s orbitals. Moreover, in boron the outermost electron is present in $2p$ orbital which is at a slightly higher energy level than the outermost electron in beryllium. The $2p$ electron of boron is thus less tightly held by the nucleus and hence the ionisation energy of boron is less than that of beryllium. Electronic configuration of nitrogen ($1s^2 2s^2 p_x^1 p_y^1 p_z^1$), in which all the p orbitals are *exactly half-filled*, is more stable than the electronic configuration of oxygen ($1s^2 2s^2 p_x^2 p_y^1 p_z^1$). Therefore, ionisation energy of oxygen is less than that of nitrogen.

ELECTRON AFFINITY (*EA*)

Just as ionisation energy measures the tendency of an atom to change into a cation ($M \longrightarrow M^+ + e^-$), the electron affinity (*EA*) gives a measure of the tendency of an atom to change into an anion ($X + e^- \longrightarrow X^-$). **Electron affinity** is defined as *the amount of energy released when an electron is added to a gaseous isolated atom or ion.*

$$\underset{\text{Atom}}{X(g)} + e^- \longrightarrow \underset{\text{Anion}}{X^-(g)} + \text{Energy } (EA)$$

The greater the energy released in the process of taking up the extra electron, the greater is the electron affinity. The electron affinity of an atom measures *the tightness with which it binds an additional electron to itself.* The electron affinities are expressed in eV per atom or kJ mol^{-1}.

The electron affinities of the various elements belonging to different groups of the periodic table are given in Table 10.

TABLE 10

Electron Affinities of Various Elements (kJ mol^{-1})

Group 1	Group 2	Group 13	Group 14	Group 15	Group 16	Group 17	Group 18
Li 59·8	Be ≈ 0	B 26·7	C 122·3	N ≈ 0	O 140·9	F 332·6	Ne 0
Na 53·1	Mg ≈ 0	Al 45·2	Si 133·6	P 72·3	S 200·7	Cl 348·5	Ar 0
K 48·4	Ca ≈ 0	Ga 28·7	Ge 120·0	As 77·2	Se 195·0	Br 324·7	Kr 0
Rb 46·9	Sr ≈ 0	In 29·0	Sn 107·9	Sb 103·0	Te 190·1	I 295·5	Xe 0
Cs 45·5	Ba ≈ 0	Tl 19·2	Pb 35·1	Bi 91·0	Po 180·0	At 270·0	Rn 0

Variation of Electron Affinity in the Periodic Table. In general, *electron affinity decreases in going from top to bottom in a* **group** *and increases in going from left to right across a* **period.** This can be easily explained. On moving down a **group**, the atomic size increases and, therefore, the effective nuclear attraction for the electron decreases. Consequently, the atom will have less tendency to attract additional electron towards itself, *i.e.*, its electron affinity would decrease. On moving across a **period**, on the other hand, the atomic size decreases and hence the force of attraction exerted by the nucleus on the electrons increases. Consequently, the atom has a greater tendency to attract the additional electron, *i.e.*, its electron affinity increases. Thus, as expected, electron affinities of metals are low while those of non-metals are high.

It is seen that halogens have high electron affinities. This is due to their strong tendency to gain an additional electron to acquire the stable s^2p^6 configuration.

The electron affinity decreases from Cl → Br → I, *i.e.*, on moving down the group, as discussed above. However, electron affinity of fluorine is *unexpectedly low*. It cannot be explained by any simple mechanism. It is probably due to small size of the atom. The addition of an extra electron produces high electron charge density in a relatively compact 2*p* subshell resulting in *strong electron-electron repulsion*. The repulsive forces between electrons imply low electron affinity.

Apart from the size of the atom discussed above, the electronic configurations of the elements also influence their electron affinities considerably. This is illustrated below.

Electron affinities of noble gases are zero. This is because their atoms have stable s^2p^6 configurations in their valency shells and there are no chances for the addition of an extra electron.

Electron affinities of beryllium, magnesium, calcium and nitrogen are also practically zero. This is attributed to the extra stability of the fully completed *s* orbitals in Be ($2s^2$), Mg ($3s^2$) and Ca ($4s^2$) and of the exactly half-filled 2*p* orbitals in N($2s^2p_x^1p_y^1p_z^1$). Thus, if an atom has fully filled or exactly half-filled orbitals, its electron affinity would be practically zero.

The trends in electron affinities within a period are also irregular indicating once again that atomic size is not the only criterion for determining electron affinity. Thus, electron affinity of Be is less than that of Li although the atomic size of Be is less than that of Li. Similarly, electron affinity of N is less than that of O although the atomic size of O is less than that of N.

Successive Electron Affinities. Like the second and higher ionisation energies, the second and higher electron affinities are also possible. However, after the addition of one electron, the atom becomes negatively charged and the second electron is to be added to a negatively charged ion. The addition of second electron is opposed by the coulombic force of repulsion and *energy has to be supplied* for the addition of the second electron.

If an atom has a spontaneous tendency, *i.e.*, a *positive tendency*, to gain an electron, then, conventionally, its electron affinity is said to be *positive* and if an atom is reluctant to gain an electron, *i.e.*, it has a *negative tendency* to gain an electron and is forced to accept it, its electron affinity is said to be *negative*. Thus, in the case of oxygen, the first electron affinity $(EA)_1$ is positive since 140·9 kJ of energy is released when a mole of O atoms get converted to O^- ions. In other words, O atom has positive tendency to accept electron. However, the second electron affinity $(EA)_2$ is negative since 770 kJ of energy has to be supplied to convert 1 mole of O^- ions to O^{2-} ions.

Similarly, in the case of sulphur, while the first electron affinity $(EA)_1$ is positive since 200·7 kJ of energy is released when 1 mole of S atoms get converted to S^- ions, the second electron affinity $(EA)_2$ is negative since 333·2 kJ of energy has to be supplied to convert one mole of S^- ions to S^{2-} ions.

Thermodynamically, however, the energy released is given a negative sign and energy absorbed is given a *positive sign*. Accordingly, when a species has a *positive* electron affinity, ΔH, accompanying the addition of an electron to the specie, is *negative* and if it has a *negative* electron affinity, ΔH *is positive*. Thus, for the reaction $Cl + e^- \longrightarrow Cl^-$, while EA (= 348·5 kJ) is positive, ΔH for the process is negative. In various calculations involving ΔH (as, for example, in Born-Haber cycle), the value for electron affinity of chlorine would be taken as $-348{\cdot}5$ kJ mol^{-1} and not $+348{\cdot}5$ kJ mol^{-1}.

ELECTRONEGATIVITY

The term **electronegativity** has been defined differently by different investigators and each of them has suggested a method of his own to calculate electronegativities of different elements. The approaches of some of the investigators are discussed below.

Pauling's Approach. Pauling defined **electronegativity** *as the power of an atom in a molecule to attract electrons to itself*. He calculated electronegativities of different elements from thermodynamic data. He considered that in a reaction of the type

$$1/2\,(A-A) + 1/2\,(B-B) \longrightarrow A-B \qquad ...(2)$$

the bond dissociation energy of $A-B$ is higher than the mean of the bond dissociation energies of A – A and (B – B) bonds and that their difference (Δ) is related to the difference in the electronegativities of A and B according to the following empirical equation :

$$\Delta = E_A - E_B - 1/2(E_{A-A} + E_{B-B}) = 23(\chi_A - \chi_B)^2 \qquad ...(3)$$

where E_{A-B}, E_{A-A} and E_{B-B} represent the bond dissociation energies of A – B, A – A, and B – B bonds, respectively and χ_A and χ_B denote the electronegativities of A and B, respectively. Thus,

$$\Delta = 23(\chi_A - \chi_B)^2 \qquad ...(4)$$

or

$$0{\cdot}208\sqrt{\Delta} = \chi_A - \chi_B \qquad ...(5)$$

Pauling later took the geometric mean instead of the arithmetic mean of E_{A-A} and E_{B-B} and suggested the following empirical correlation :

$$E_{A-B} - (E_{A-A} \times E_{B-B})^{1/2} = \Delta' = 30(\chi_A - \chi_B)^2 \qquad ...(6)$$

or

$$0{\cdot}182\sqrt{\Delta'} = \chi_A - \chi_B \qquad ...(7)$$

In Pauling's equations, the dissociation energies are taken *in kcal* (and not in kJ) per mole.

Assuming arbitrarily the electronegativity of hydrogen to be 2·1, Pauling determined electronegativities of other elements with the help of Eq. 7. These values are given in Table 11.

TABLE 11

Electronegativities of the Main Group Elements

(Pauling's Values)

Group 1	Group 2	Group 13	Group 14	Group 15	Group 16	Group 17
H 2·1						
Li 1·0	Be 1·5	B 2·0	C 2·5	N 3·0	O 3·5	F 4·0
Na 0·9	Mg 1·3	Al 1·6	Si 1·9	P 2·2	S 2·6	Cl 3·1
K 0·8	Ca 1·0	Ga 1·8	Ge 2·0	As 2·2	Se 2·5	Br 2·9
Rb 0·8	Sr 1·0	In 1·8	Sn 1·8	Sb 2·0	Te 2·1	I 2·6
Cs 0·7	Ba 0·9	Tl 1·6	Pb 1·8	Bi 2·0	Po 2·0	At 2·2

Example 1. Calculate the electronegativity of fluorine from the following data : E_{H-H} = 104·2 kcal mol^{-1}, E_{F-F} = 36·6 kcal mol^{-1}, E_{H-F} = 134·6 kcal mol^{-1}.

Solution : According to Eq. 6,

$$\Delta = E_{H-F} - (E_{H-H} \times E_{F-F})^{1/2} = 134{\cdot}6 - (104{\cdot}2 \times 36{\cdot}6)^{1/2} = 72{\cdot}85 \text{ kcal}$$

According to Eq. 7,

$$\chi_F - \chi_H = (0{\cdot}182)\,(72{\cdot}85)^{1/2} = 1{\cdot}55$$

$$\chi_F = 1{\cdot}55 + \chi_H = 1{\cdot}55 + 2{\cdot}1 = \mathbf{3{\cdot}65}$$

Example 2. Calculate the electronegativity of carbon from the following data : E_{H-H} = 104·2 kcal mol^{-1}, E_{C-C} = 83·1 kcal mol^{-1}, E_{C-H} = 98·8 kcal mol^{-1}.

Solution : According to Eq. 6,

$$\Delta = E_{C-H} - (E_{H-H} \times E_{C-C})^{1/2} = 98{\cdot}8 - (104{\cdot}2 \times 83{\cdot}1)^{1/2} = 5{\cdot}75 \text{ kcal}$$

According to Eq. 7,

$$\chi_C - \chi_H = 0{\cdot}182\,(5{\cdot}75)^{1/2} = 0{\cdot}44$$

$$\chi_C = 0{\cdot}44 + \chi_H = 0{\cdot}44 + 2{\cdot}1 = \mathbf{2{\cdot}54}$$

Allred and Rochow's Approach. Allred and Rochow defined **electronegativity** *as the electrostatic force of attraction exerted by the nucleus of an atom on the valency electrons.* Making use of the effective nuclear charge at the periphery of the atom, Z_{eff}, as calculated by Slater's rules, they proposed the following empirical relation for calculating the electronegativity :

$$\chi = 0{\cdot}359 \times Z_{eff}/r^2 + 0{\cdot}744 \qquad ...(8)$$

where χ is the electronegativity and r is the covalent radius of the atom in angstrom units. The electronegativities as calculated with the help of Eq. 8 are found to be remarkably close to those reported by Pauling.

Example 3. Calculate the electronegativity of carbon atom following Allred-Rochow's approach. The covalent radius of carbon atom is 0·77 Å.

Solution : According to Slater's rules (Chapter 1),

Z_{eff} at the periphery of C atom $= Z_{actual} - S = 6 - (0{\cdot}35 \times 4 + 0{\cdot}85 \times 2) = 2{\cdot}90$

According to Eq. 8, $\chi_C = 0{\cdot}359 \times 2{\cdot}90\,(0{\cdot}77)^2 + 0{\cdot}744 = \mathbf{2{\cdot}50}$

Example 4. Calculate the electronegativity of silicon following Allred-Rochow approach. Covalent radius of Si = 1·175 Å.

Solution : Electronic configuration of Si is $1s^2 2s^2 p^6 3s^2 p^2$

According to Slater's rules (Chapter 1),

$$Z_{eff} = Z_{actual} - S = 14 - (0{\cdot}35 \times 4 + 0{\cdot}85 \times 8 + 1{\cdot}0 \times 2) = 3{\cdot}80$$

According to Eq. 8, $\chi_{Si} = 0{\cdot}359 \times 3{\cdot}80/(1{\cdot}175)^2 + 0{\cdot}744 = \mathbf{2{\cdot}50}$

Mulliken's Approach. Mulliken suggested that *the average of the ionization energy (IE) and electron affinity (EA) of an atom should be a measure of the* **electronegativity** (χ_M) *of the atom*, that is,

$$\chi_M = 1/2(IE + EA) \qquad ...(9)$$

However, the ionisation energy and the electron affinity of an atom in Mulliken's definition are not the experimentally observed values for the isolated gaseous atom in its ground state. These are instead the calculated values for the atom in its valence state, *i.e.*, when the atom forms a part of a molecule.

For instance, in BeF_2, the ionisation energy of Be atom used in Mulliken's formula is not the one which is experimentally observed for an isolated Be atom having $1s^2 2s^2$ configuration but is the *hypothetical*

energy required to remove an electron from an *sp* hybrid orbital of Be atom. In other words, it is the average of energies *IE(s)* and *IE(p)* required to remove 2*s* and 2*p* electrons from the promoted valence state of Be atom in BeF_2 molecule :

$$\underset{\text{(ground state of Be)}}{1s^2 2s^2} \longrightarrow \underset{\text{(promoted valence state)}}{1s^2 2s^1 2p^1} \xrightarrow{IE\,(s)} 1s^2 2s^0 2p^1$$

$$1s^2 2s^1 2p^1 \xrightarrow{IE\,(p)} 1s^2 2s^1 2p^0$$

The *IE* and *EA* used in Mulliken's formula can be calculated by a complicated mathematical procedure which does not concern us here.

Several empirical equations have been proposed by chemists to bring Mulliken's values at par with the values of χ on Pauling's scale. But no such equation gives satisfactory results for all the elements. One such equation which attempts to give χ_M nearly at par with the value of χ on Pauling's scale is :

$$\chi_M = 0{\cdot}336\left[\frac{IE + EA}{2} - 0{\cdot}615\right] \qquad ...(10)$$

In this equation, *IE* and *EA* are in electron volts.

One advantage of using Mulliken's approach is that the electronegativities of an element, which is present in different oxidation or hybridisation states in different molecules can be calculated. For instance, χ_M of C in sp^3, sp^2, *sp* hybridised states, calculated by Mulliken's approach, are 2·48, 2·66, 2·99, respectively, whereas χ_P (Pauling's values) of C in all its molecules was reported to be 2·55.

Factors influencing Electronegativity. Although the electronegativity of an element is conventionally assigned a definite value, yet it may differ from one molecule to another. The ability of an atom in a molecule to attract electrons towards itself depends upon its environment in the molecule. The electronegativity of an atom would thus depend upon the nature of the other atom with which it is attached in the molecule. The factors which largely determine the electronegativity of an atom are as follows.

Charge on the atom. An atom which acquires a positive charge, either integral or partial, would tend to attract electrons more strongly than a neutral atom. Thus, a cation will be more electronegative than the parent atom which, in turn, would be more electronegative than its anion. Also, the higher the positive oxidation state of an atom in a species, the greater would be its electron-attracting power and hence the greater would be its electronegativity. For example, the oxidation state of central chlorine atom is +1 in HClO and +5 in $HClO_3$. Hence, the chlorine atom will be more electronegative in $HClO_3$ than in HClO. Accordingly, the release of hydrogen as H^+ ion in $HClO_3$ would be much easier than a similar change in HClO. In other words, $HClO_3$ *behaves as a stronger acid than* HClO.

Hybridisation. We know that *s* electrons are more penetrating than the *p* electrons. Therefore, if an atom has hybrid orbitals with a greater *s* character, the electronic charge in such orbitals would remain closer to the nucleus of that atom. This means that *the electronegativity of the atom would increase with increase in s character of its hybrid orbitals.*. For example, in methane, the carbon atom involves sp^3 hybridisation of its orbitals so that the hybrid orbitals have 25% *s* character. In ethylene, the carbon atom involves sp^2 hybridisation of its orbitals and consequently the *s* character of hybrid orbitals increases to 33%. In acetylene, the carbon atom involves *sp* hybridisation of its orbitals and, therefore, the *s* character of hybrid orbitals increases to 50%. Accordingly, the electronegativity of carbon atom increases as we move from CH_4 to C_2H_4 and to C_2H_2. Due to greater electronegativity of carbon atom in ethylene and acetylene, the electron pair of C – H bond is pulled more towards the carbon atom thereby facilitating the release of H atom as H^+ion. Thus, while methane is neutral, ethylene is slightly acidic while acetylene is considerably acidic.

Similarly, the *basicity of amines* also varies with the type of the hybridisation of the orbitals of the nitrogen atom. The higher the *s* character of the hybrid orbitals, the greater would be the electronegativity and the lower would be the electron-donating power of the nitrogen atom and hence the lower would be the basicity of the amine. For example, the molecules RCN, C_5H_5N (pyridine) and $C_6H_5NH_2$, involve, respectively, *sp*, sp^2 and sp^3 hybridisation of the orbitals of the nitrogen atom. Accordingly, the *s* character of the hybrid orbitals of nitrogen atom is 50% in RCN, 33% in pyridine and 25% in aniline. Accordingly, aniline is a stronger base than pyridine which, in turn, is a stronger base than RCN.

Effect of substituents. The electronegativity of an atom depends considerably upon the nature of the substituents attached to that atom. For example, the carbon atom in CF_3I acquires a greater positive charge than in CH_3I. Hence, the carbon atom in CF_3I is more electronegative (*i.e.*, more electron pulling) than in CH_3I. The difference in the electronegativities of an atom caused by the substituents results in different chemical behaviour of that atom. For instance, CF_3I and CH_3I yield different products on hydrolysis :

$$CF_3I + OH^- \longrightarrow CF_3H + IO^-$$

$$CH_3I + OH^- \longrightarrow CH_3OH + I^-$$

Role of ionization energies and electron affinities. According to Mulliken, electronegativity is related to the average of the ionization energy and electron affinity of the atom (Eq. 9). Evidently, the higher the ionization energy and electron affinity, the greater would be the electronegativity of the atom.

Effective nuclear charge. Variation of electronegativity in the periodic table. Allred and Rochow reasoned that the electron attracting power of an atom in a molecule is proportional to the effective nuclear charge, Z_{eff}. Thus, any factor which increases Z_{eff}, should also increase the electronegativity of the atom. For example, Z_{eff} decreases as we go down a group in the periodic table. This is because with increase in atomic number within a group, the atomic size increases. Hence, *electronegativity decreases as we move down a* **group**. Thus, the electronegativity of the halogens *decreases* in the order :

F (4·0) > Cl (3·1) > Br (2·9) > I (2·6).

Z_{eff} increases with decrease in size of the atom and the size of the atom decreases as move along a period from left to right in the periodic table. Accordingly, *electronegativity goes on increasing with increase in atomic number as we move along a* **period**. Thus, electronegativities of the elements of the second period *increase* in the order :

Li (1·0) < Be (1·5) < B (2·0) < C (2·5) < N (3·0) < O (3·5) < F (4·0)

Z_{eff} also depends upon the number of inner electrons which screen the last electron. The larger the number of inner electrons, the greater would be the screening and the lesser would be the effective nuclear charge. Thus, electronegativity would *decrease* with increase in the number of inner electrons in atoms of the elements in the same group. This is an additional reason why the electronegativity of alkali metals *decreases* in the order :

Li (1·0) > Na (0·9) > K (0·8) > Rb (0·8) > Cs (0·7).

Applications of Electronegativities. Electronegativities have very wide range of applications. Some of the important applications are given below.

1. Calculation of partial ionic character of a covalent bond. The development of ionic character in a covalent bond between two atoms, say, *A* and *B*, is due to the difference in the electronegativities of *A* and *B*. The greater the difference in the electronegativities, the greater would be the development of *ionic character and consequently the higher would be the stability of the resulting bond.*

Pauling suggested the following correlation between the electronegativity difference $\chi_A - \chi_B$ and the per cent ionic character of the covalent bond :

$$\text{Per cent ionic character} = [1 - e^{-0.25(\chi_A - \chi_B)}] \times 100 \qquad ...(11)$$

Example 5. The electronegativity difference of the elements in HF is 1·9. Calculate the per cent ionic character of the H–F bond.

Solution : According to Pauling's equation (Eq. 11),

$$\text{Percent ionic character of H–F bond} = [1 - e^{-0.25(1.9)}] \times 100 = 37.77$$

Pauling suggested an alternative empirical equation also for calculating the per cent ionic character, according to which

$$\text{Per cent ionic character} = 18\,(\chi_A - \chi_B)^{1.4} \qquad ...(12)$$

According to this equation, the per cent ionic character of HF comes out to be 44·12. This value is quite close to the one (*viz.*, 44·8) obtained by Pauling from dipole moment of HF (Chapter 4).

2. Calculation of enthalpies of formation of compounds. It is possible to calculate enthalpies of formation of compounds from electronegativities making use of the following empirical equation put forth by Pauling :

$$\Delta H_f = 23 \in (\chi_A - \chi_B)^2 - 55.4\, n_N - 26.0\, n_O \qquad ...(13)$$

where ΔH_f is the enthalpy of formation, n_N and n_O are the numbers of nitrogen and oxygen atoms in the molecule. The value of $\in$ would be 1, 2, 3, etc., depending upon the number of bonds in the molecule. For instance, $\in = 1$ for HCl, $\in = 2$ for $BeCl_2$ and so on. The values of ΔH_f obtained as above are, however, approximate.

Suppose we want to calculate the enthalpy of formation of $BeCl_2$. There are two Be–Cl bonds in this molecule. The values of χ_{Cl} and χ_{Be} are, respectively, 3·1 and 1·5 (Table 11).

$$\therefore \qquad \Delta H_f = 23 \times 2\,[(3.1 - 1.5)^2] - 0 - 0 = \mathbf{117.76\ kcal\ mol^{-1}}$$

(n_N and n_O are zero since there are no nitrogen and oxygen atoms in the molecule)

(The experimental value for ΔH_f is found to 122 kcal mol^{-1})

3. Calculation of bond length. If the two atoms A and B bonded together through a covalent bond differ in their electronegativities, then the covalent bond would acquire some ionic character, as illustrated above. In other words, the bond acquires polarity. The greater the polarity, the shorter would be the length of the bond formed between A and B. Shoemaker and Stevenson proposed the following empirical equation for calculating the bond length in such cases :

$$d_{A-B} = r_A + r_B - 0.09\,(\chi_A - \chi_B) \qquad ...(14)$$

where d_{A-B} is the actual bond distance between A and B ; r_A and r_B are the covalent radii of A and B and $\chi_A - \chi_B$ is the electronegativity difference. The normal length of the covalent bond between A and B would have been equal to $r_A + r_B$. Evidently, the shortening of the bond between A and B due to electronegativity difference is equal to $0.09(\chi_A - \chi_B)$. Due to reduction in length, the bond would be more stable.

Let us calculate the bond distance N–O with the help of Eq. 14. Covalent radii of nitrogen and oxygen atoms are, respectively, 0·75 and 0·74 Å and the electronegativities of N and O are 3·0 and 3·5, respectively. Thus,

$$d_{N-O} = 0.75 + 0.74 - 0.09\,(3.5 - 3.0) = \mathbf{1.445\ Å}$$

The actual N–O bond length is 1·46 Å

Similarly, the length of the C–O bond is given by

$$d_{C-O} = 0.77 + 0.74 - 0.09\,(3.5 - 2.5) = \mathbf{1.42\ Å}$$

The experimental value is exactly the same.

4. Explanation for bond angles. The lesser the electronegativity of the central atom in a polyatomic molecule, the lesser would be the magnitude of the bond angle. This may be explained as follows : If the electronegativity of the central atom is less, it would not be able to hold the bonding electron pairs towards itself. Therefore, the bonding electron pairs would shift more towards the other atoms attached to the central atom. This would result in a decrease in the bond pair–bond pair repulsion and hence a decrease in the bond angle.

For illustration, the bond angles and electronegativities of trifluorides of the Group 15 elements are given below. As expected, the decrease in electronegativity of the central atom results in a decrease of the bond angle.

Compound	Electronegativity of Central Atom	Bond Angle
NF_3	3·0	102°
PF_3	2·2	97°
AsF_3	2·2	96°
SbF_3	2·0	88°

5. Rationalisation of reaction mechanism. It has been observed that when CH_3I reacts with the nucleophile $[Mn(CO)_5]^-$, the following reaction takes place

$$CH_3I + Na^+[Mn(CO)_5]^- \longrightarrow NaI + CH_3Mn(CO)_5$$

The formation of the above reaction products may be explained as follows : Iodine in CH_3I is more electronegative than carbon. This creates a partial positive charge on the carbon atom. The negatively charged nucleophile, thus, attacks the positive site resulting in the formation of $CH_3Mn(CO)_5$.

On the other hand, if we carry out a similar reaction with CF_3I, a totally different product is obtained. Thus,

$$2CF_3I + Na^+[Mn(CO)_5]^- \longrightarrow NaI + Mn(CO)_5I + C_2F_6$$

Because of the presence of highly electronegative F atoms, the electron charge cloud of carbon atom is pulled towards the former. This creates electron charge deficiency at the carbon atom which is made up by the pulling of the electron charge cloud of iodine atom towards the carbon atom (the electron charge cloud of iodine is easily polarisable). This creates a partial positive charge on iodine atom. Therefore, the nucleophile $[Mn(CO)_5]^-$ now attacks the iodine site leading to the formation of $Mn(CO)_5I$.

In a similar way, we can explain the acidic or basic nature of some hydroxy compounds. Consider, for example, HOCl. The chlorine atom in this molecule is in +1 oxidation state. It is, therefore, more electron-attracting than oxygen. The chlorine atom, thus, pulls the electron pair of the O–Cl bond towards itself leaving electronic charge deficiency on the oxygen atom. In order to make up this deficiency, the oxygen atom pulls the electron pair of O–H bond towards itself. This facilitates the release of H atom as H^+ ion by the rupture of the O–H bond. Hence, the hydroxide HO–Cl behaves as an acid.

In $Be(OH)_2$, the electronegativity of Be is less than that of oxygen. Therefore, the electron pair of Be–O bond is pulled more towards oxygen. This facilitates the release of OH^- group with the rupture of the Be–O bond. Hence, $Be(OH)_2$ behaves as a base.

6. Explanation of diagonal relationship. The electronegativity *increases* as we go from Li (1·0) to Be (1·5) (variation of electronegativity in a period) but it *decreases* as we move from Be (1·5) to Mg (1·3) (variation of electronegativity in a group). As a result of these two opposite changes (one along the period and the other down the group), as we move *diagonally*, these two effects partly cancel each other and there is no marked change in electronegativity. This is the reason why Li (1·0) and Mg (1·3) have close values of electronegativities.

Because of similar values of electronegativities and hence of electron-attracting powers, Li and Mg have similar chemical properties.

7. Types of bonds. The type of bond formed between two atoms would, evidently, depend upon the difference in their electronegativities. If this difference is zero or very small, the bond formed would be *covalent* and if the difference exceeds 2·5, the bond formed would be *electrovalent*. If, however, the electronegativity difference is less than 2·5 but otherwise quite appreciable, the bond formed would be *polar covalent*.

QUESTIONS

1. State the modern periodic law. What is the cause of periodicity in the properties of elements ?
   (*a*) "There are only 2 elements in the first period, 8 elements in each of the second and third periods, 18 elements in each of the fourth and fifth periods and 32 elements in the sixth period of the periodic table." Why is it so?
   (*b*) Which of the following elements exhibit similar properties and why ?
   A : $1s^2 2s^2p^6 3s^1$ B : $1s^2 2s^2p^6 3s^2p^6d^{10} 4s^1$ C : $1s^2 2s^1$ [Ans. A and C]
2. (*a*) Explain how the elements are arranged in the long form periodic table. What is meant by a group and a period?
   (*b*) Write the electronic configurations of the elements with atomic numbers 53, 54 and 55. Classify these as a noble gas, an electropositive element and an electronegative element.
   (*c*) Account for the fact that the third period of the periodic table contains 8 and not 18 elements.
3. (*a*) Explain how the elements can be classified into *s*, *p*, *d* and *f* blocks.
   (*b*) To which block do the elements with the following electronic configurations belong :
   (*a*) $1s^2 2s^2p^6 3s^2p^6 4s^1$ (*b*) $1s^2 2s^2p^6 3s^2p^6d^{10} 4s^1$ (*c*) $1s^2 2s^2p^6 3s^2p^6d^{10} 4s^2p^1$
   (*d*) $1s^2 2s^2p^6 3s^2p^6d^{10} 4s^2p^{10}f^1 5d^1 6s^2$ (*e*) $1s^2 2s^2$ (*f*) $1s^2 2s^2p^6 3s^2p^6d^{10}4s^2$
   [Ans. (*a*) *s* (*b*) *d* (*c*) *p* (*d*) *f* (*e*) *s* (*f*) *d*]
4. The properties of elements arranged in the order of increasing atomic number recur at atomic number intervals of 2, 8, 8, 18, 18, 32 and 32. How would you account for this ?
5. (*a*) What are main group, transition and inner transition elements ? How are the transition elements distinguished from the main group elements on the basis of electronic configurations ?
   (*b*) Would you call Zn (Z = 30) and Hg (Z = 48) as *s* block or *d* block elements ? Give reasons for your answer.
6. (*a*) What is meant by atomic radius ? How do the atomic radii of elements vary when we move (*i*) down a group (*ii*) across a period ? How would you account for this variation ?
   (*b*) What do you understand by iso-electronic ions ? How does the size vary in the following series : N^{3-}, Na^+, Mg^{2+}, Al^{3+}, O^{2-}, F^- [Ans. $N^{3-} > O^{2-} > F^- > Na^+ > Mg^{2+} > Al^{3+}$]
7. Explain the following :
   (*a*) Van der Waals radius of chlorine is greater than the covalent radius of chlorine.
   (*b*) The atomic radii decrease in moving from left to right in any given period and increase in moving from top to bottom in any given group.
   (*c*) The radius of a cation is invariably smaller and that of an anion invariably larger than that of the corresponding atom.
8. (*a*) Explain the term ionisation energy of an element. On what factors does it depend ?
   (*b*) The ionisation energy of Na^+ is more than that of Ne although both have the same electronic configuration. Explain.
9. (*a*) Explain the term ionisation energy ? How is it measured ? How do the ionisation energies of elements vary as we move (*i*) along a period (*ii*) down a group and why ?
   (*b*) What is meant by the terms : First ionisation energy, second ionisation energy and third ionisation energy ? Why are second ionisation energies so much higher than the first ionisation energies ?

10. (*a*) Explain the term electron affinity. Why are electron affinities of the halogens so high ?

(*b*) Predict which element in each of the following pairs has higher ionisation energy and why :

(*i*) S, P (*ii*) Be, B (*iii*) N, C (*iv*) Ne, F (*v*) I, Br (*vi*) F, Cl (*vii*) Na, K

[Ans. (*i*) P (*ii*) Be (*iii*) N (*iv*) Ne (*v*) Br (*vi*) F (*vii*) Na]

11. (*a*) Define ionisation energy and electron affinity. How do these vary in the periodic table as the atomic number increases ?

(*b*) Account for the following trend in the electron affinities of the halogens ?

F	Cl	Br	I
332·6 kJ mol^{-1}	348·5 kJ mole^{-1}	324·7 kJ mol^{-1}	295·5 kJ mol^{-1}

(*c*) The electron affinities of noble gases are zero. Why ?

12. (*a*) Explain the term electronegativity. How is it related to electron affinity and ionisation energy ?

(*b*) Why is the radius of an atom not defined precisely ?

13. Give reasons for the following :

(*a*) The second ionisation energy of sodium is very high as compared to its first ionisation energy.

(*b*) Electron affinity of fluorine is less than that of chlorine.

(*c*) Ionic radius of K^+ is smaller than that of Cl^-.

(*d*) Electron affinity of N is almost zero while that of F is very high.

(*e*) Size of Cl^- ion is greater than that of Cl atom while that of Na^+ ion is smaller than that of Na atom.

(*f*) Electronegativity increases along a period.

(*g*) Ionisation energies of C, N and O follow the order : C < N > O.

14. Define the following and explain their trends in a period and in a group :

(*a*) Electron affinity (*b*) Electronegativity (*c*) Atomic radius (*d*) Ionisation energy

15. (*a*) "Atomic radius is a measure of the effective size of an atom and it has a different value in different environments." Discuss the statement.

(*b*) Which of the two has higher ionic radius and why ? Al^+ or Al^{3+}.

(*c*) The ionisation energy of Al to form Al^+ is less than that of Mg to form Mg^+ ion. Explain.

16. (*a*) The first and second electron affinities of oxygen are : 141 kJ mol^{-1} and –770 kJ mol^{-1}, respectively. Account for this.

(*b*) The electron affinity of chlorine is 3·7 eV. How much energy in kcal is released when 2 g of chlorine is completely converted to Cl^- ion in the gaseous state ? [Ans. 4·86 kcal]

(*c*) The electronic configurations of some neutral atoms are given below :

A : $1s^2 2s^2 p^6 3s^2$; B : $1s^2 2s^2 p^6 3s^1$; C : $1s^2 2s^2 p^5$; D : $1s^2 2s^2 p^4$

Which of these will have the lowest ionisation energy ? [Ans. B]

17. "The term electronegativity has been defined differently by different investigators." Comment on this statement. Discuss the factors which influence the electronegativity of an atom.

18. How was the term electronegativity defined by Pauling, Allred & Rochow and Mulliken ?

19. Discuss the important applications of electronegativities.

MOLECULAR SYMMETRY AND GROUP THEORY

3

Frequent reference has been made to the applications of symmetry and group theory while discussing molecular orbital theory, electronic energy levels of complexed metal ions, selection rules for electronic absorption spectroscopy, etc., in various chapters. An attempt will now be made to discuss the concepts of symmetry and the group theory in adequate details in a systematic manner using a simple and clear language.

SYMMETRY OPERATIONS AND SYMMETRY ELEMENTS

Symmetry Operations. A **symmetry operation** is the movement of a body with respect to a line, a plane or a point in such a manner that after the movement, every point of the body is coincident with an equivalent (or the same) point lying on the body before movement. That is, the position and the orientation of the body before and after the operation are indistinguishable. *A symmetry operation which brings the body back to its original position is called an* **identity operation.**

Symmetry Elements. A line, a plane or a point with respect to which one or more symmetry operations can be carried out is called a **symmetry element.**

We come across the following types of symmetry elements and symmetry operations.

1. Plane of Symmetry and Reflection Operation. For carrying out a symmetry operation with respect to a plane, the latter may be considered as a two-way mirror. If the reflections of all the atoms through this plane produce an equivalent geometry of the molecule, the plane is known as the **plane of symmetry.** A plane of symmetry must pass through the geometry of the molecule. It is to be noted that atoms of the molecule lying right on the plane of symmetry do not change their positions after the reflection operation. The standard symbol for both the symmetry plane and the reflection through symmetry plane is sigma (σ). In molecules such as NHFCl, NHF_2, CH_2Cl_2. NH_3, BF_3, $[PtCl_4]^{2-}$, CCl_4 and $[CoF_6]^{3-}$, the number of planes of symmetry is 0, 1, 2, 3, 4, 5, 6 and 9, respectively.

If the reflection process is carried out twice or for an *even* number of times through a plane of symmetry, we get back the original or an identical configuration. Thus, σ^2 (or σ^{2n}) is obviously an identity operation. Similarly, the reflection process carried out thrice or for an *odd* number of times through a plane of symmetry gives an equivalent configuration which is the same as obtained from a single reflection operation. Thus, σ^3 (or σ^{2n+1}) operation is the same as σ operation.

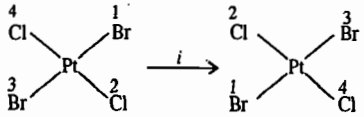
The planes of symmetry can be further subdivided into the following two categories :

a. **Horizontal plane of symmetry** (σ_h) which is perpendicular to the principal axis of symmetry.

b. **Vertical plane of symmetry** (σ_v) which passes through the principal axis of symmetry. There is yet another type of vertical plane of symmetry, *viz.*, the **dihedral plane of symmetry** (σ_d) about which we shall talk a little later in this chapter.

2. Inversion Centre and Inversion Operation. If a molecule can be brought into an equivalent configuration by inverting the coordinates of every atom through the origin (*i.e.*, by changing the coordinates (*x*, *y*, *z*) of every atom to (–*x*, –*y*, –*z*), then the origin which lies within the geometry of the molecule is called the **inversion centre.** Both the inversion centre and the inversion operation are designated by the symbol *i*. Examples of molecules containing an inversion centre are $[PtCl_4]^{2-}$,

trans $[PtCl_2Br_2]^{2-}$ and benzene. The inversion operation carried out on trans $[PtCl_2Br_2]^{2-}$ is illustrated below :

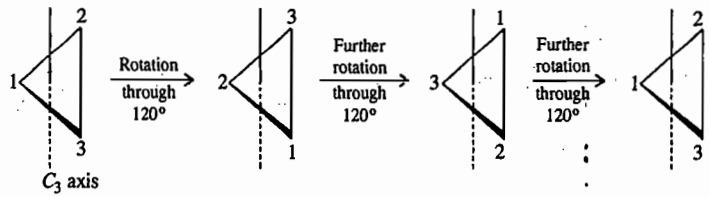


The subscripts 1, 2, 3, 4 are written to indicate which atoms shift and where, as a result of the inversion operation. The operation i^2 is obviously the identity operation.

3. Proper Axis and Proper Rotation. If, on rotation of a molecule with respect to a line, we get an equivalent or an identical configuration, the operation is called **proper rotation** and the line with respect to which such an operation is carried out is called **proper axis of rotation.**

The number of times we get an equivalent or an identical configuration in a complete rotation of 360° about a proper axis is called the **order of the proper axis.** The same symbol C_n is used for designating both the proper axis of rotation and the proper rotation operation where n is the order of the proper axis.

Let us take the example of an equilateral triangle. A line perpendicular to the plane of the triangle and passing through its centre is a proper axis of rotation of the order three since a complete rotation of this triangle through an angle of 360° around this line generates an equivalent (or an identical) configuration three times, as shown below :



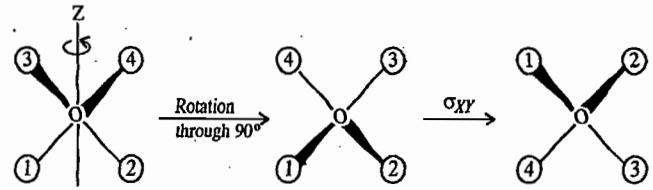
The **order of the proper axis of rotation** can be calculated mathematically by the relation $n = 360°/\theta$ where θ is the minimum angle (in degrees) required for the determination of a single rotation operation. Thus, in the above example, θ is 120° and the order of the proper axis is $360°/120° = 3$. The three symmetry operations carried out in succession as shown above are written as C_3^1, C_3^2 and C_3^3. The last operation which gives the original geometry back is, obviously, an identity operation which is written as E. It is evident that the C_n^n operation always gives back the original geometry and is thus an identity operation invariably. It can be further seen that C_3 rotation operation carried out four times, *i.e.*, C_3^4, is equal to C_3^1 and C_3^5 is equal to C_3^2. In general, $C_n^{n+m} = C_n^m$. There can be present several axes of proper rotation of the same or different order in any geometry. Thus, in the above example, there are three C_2 axes of proper rotation apart from the C_3 axis.

Another point to be emphasised here is that the subscript and superscript numbers of C_n^m can be simplified by dividing these numbers by a common permissible integral factor. Thus, C_4^2 is equal to C_2^1, C_6^2 is equal to C_3^1, C_6^3 is equal to C_2^1 and so on.

4. Improper Rotation Operation and Improper Axis of Rotation. An **improper rotation operation** is one that comprises of *a proper rotation operation around an axis followed by reflection through a plane perpendicular to it* (or vice versa). It is denoted by S_n where n is the order of the rotation axis. It is important to note that, in many cases, neither rotation about an axis nor reflection through a plane perpendicular to this axis may separately be a symmetry operation, but a combination of the two may become a symmetry operation.

Consider the line bisecting angles 3O4 and 1O2 of a regular tetrahedral molecule. If we rotate the tetrahedron through an angle of 90° about this line, we get a different configuration. Similarly, if we reflect all the atoms of the tetrahedral molecule through a plane perpendicular to this line and passing

through the point O, we get a different configuration. However, if we apply the two operations one after the other, they *together* constitute a symmetry operation, as illustrated below :



As can be seen, neither a rotation through 90° around the Z axis nor a reflection through the plane XY is a symmetry operation. But, a combination of the two generates a symmetry operation. There are two other such axes of rotation in the tetrahedron. The student is advised to identify these himself. In the above figure, the numbers are written only to clarify the rotation of the molecule. Otherwise there is no difference in the four bonds originating from the point O. The improper axis of rotation as also the improper rotation operation are indicated by the symbol S_n.

Let us now see how many symmetry operations can be performed around an S_n axis of rotation. The possible rotation operations about an S_4 axis are :

$S_4^1 = \sigma C_4$ which is a genuine improper rotation operation or rotation-reflection operation.

$S_4^2 = \sigma^2 C_4^2 = E C_4^2 = C_4^2 = C_2$; S_4^2 is thus a proper rotation operation.

$S_4^3 = \sigma^3 C_4^3 = \sigma^2 \sigma C_4^3 = E \sigma C_4^3 = \sigma C_4^3$ which is a genuine improper rotation operation.

$S_4^4 = \sigma^4 C_4^4 = E \times E = E$ which is obviously an identity operation.

Thus, an S_4 axis generates four symmetry operations in all, two of which are genuine improper rotation operations, the third is a proper rotation operation and the fourth one is an identity operation. In general, an S_n axis (n is even) generates n symmetry operations some of which are genuine improper rotation operations and some are not.

Let us now see how many symmetry operations can be generated about an S_5 axis. The possible symmetry operations are :

$S_5^1 = \sigma C_5^1$ which is a genuine rotation–reflection operation or improper rotation operation.

$S_5^2 = \sigma^2 C_5^2 = E C_5^2 = C_5^2$ which is a proper rotation operation.

$S_5^3 = \sigma^3 C_5^3 = \sigma^2 \sigma C_5^3 = E \sigma C_5^3 = \sigma C_5^3$ which is a genuine improper rotation operation.

$S_5^4 = \sigma^4 C_5^4 = E C_5^4 = C_5^4$ which is a proper rotation operation.

$S_5^5 = \sigma^5 C_5^5 = \sigma^4 \sigma C_5^5 = E \sigma C_5^5 = E \sigma E = \sigma$ which is a reflection operation.

$S_5^6 = \sigma^6 C_5^6 = E C_5^1 = C_5^1$ which is a proper rotation operation.

$S_5^7 = \sigma^7 C_5^7 = \sigma^6 \sigma C_5^2 = E \sigma C_5^2 = \sigma C_5^2$ which is a genuine improper rotation operation.

$S_5^8 = \sigma^8 C_5^8 = E C_5^3 = C_5^3$ which is a proper rotation operation.

$S_5^9 = \sigma^9 C_5^9 = \sigma^8 \sigma C_5^9 = E \sigma C_5^4 = \sigma C_5^4$ which is a genuine improper rotation operation.

$S_5^{10} = \sigma^{10} C_5^{10} = E C_5^5 = E$ which is an identity operation.

Thus, an S_5 axis generates 10 symmetry operations four of which are genuine improper rotation operations, four are proper rotation operations, one is reflection operation and the tenth is the identity operation. In general, an S_n axis (n is odd) generates $2n$ symmetry operations some of which are

genuine improper rotation operations and some are not.

Equivalent Symmetry Elements and Equivalent Atoms

If a symmetry element A is carried to a symmetry element B by a symmetry operation X, then B can be carried back to A by the reverse of the operation, *i.e.*, X^{-1}. The symmetry elements A and B are then called **equivalent symmetry elements.** Consider, for instance, a square plane. There are four C_2 axes lying in the square plane, as shown in Fig.1.

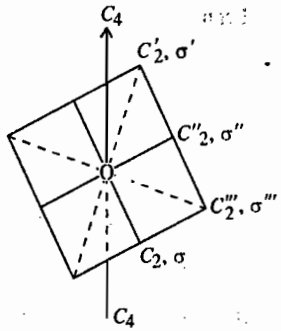


Fig. 1. A square plane

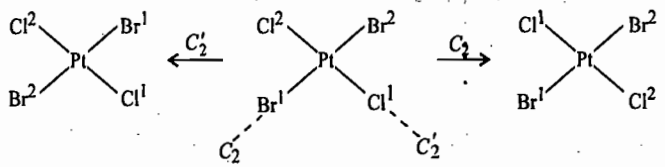
If we carry out C_4 operation around the symmetry axis which is perpendicular to the square plane and passes through O, the C_2 axis is carried to the position of C_2'' and C_2' is carried to the position of C_2'''. But, it is not possible to carry C_2 to C_2' position and C_2'' to C_2''' position by applying any symmetry operation about any symmetry element of the square planar geometry. Thus, C_2 and C_2'' are equivalent as are C_2' and C_2'''. However, C_2 and C_2' are not equivalent. Likewise, C_2'' and C_2''' are not equivalent. Similarly, it can be shown that out of σ, σ', σ'' and σ''' which are perpendicular to the square plane and pass through C_2, C_2', C_2'' and C_2''', respectively, σ and σ'' are equivalent as are σ' and σ'''.

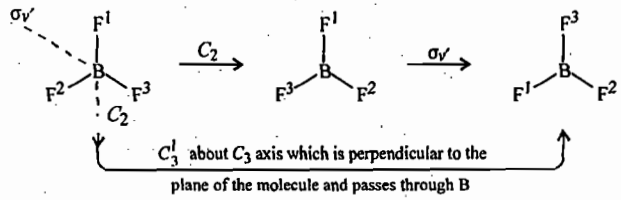
Equivalent atoms in a molecule are those which can all be interchanged by one another by appropriate symmetry operations. Obviously, equivalent atoms must belong to the same chemical species. In trans $[PtCl_2Br_2]^{2-}$ ion molecule, the two Br atoms are equivalent as are the two Cl atoms since an appropriate C_2 operation can interchange the two Cl atoms or the two Br atoms, as shown below :



Product of Symmetry Operations. Suppose we carry out symmetry operation X first and then the symmetry operation Y on a given geometry. The combination of these two operations is always a symmetry operation of that geometry. The combination, called the **'product'**, is written as $YX = Z$. By convention, the order of the symmetry operations carried out on a given geometry is written from right to left. Thus, in the above product, the symmetry operation Z is obtained by carrying out operation X followed by operation Y on the geometry. Similarly, in the product $MLXY = Z$, the symmetry operation Z is obtained by carrying out operations Y, X, L and M in that order on the geometry.

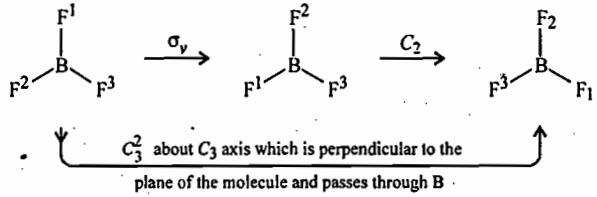
The product YX does not always give the same result as the product XY. In a case where $YX \neq XY$, we say that the operations X and Y *do not commute.* If, however, $YX = XY$, we say that *X and Y commute with each other.*

Let us consider the product $\sigma_v' C_2$, as applied on molecule BF_3. The plane σ_v' is perpendicular to the plane of the molecule and passes through the $B—F^3$ bond (the F atoms are numbered only for better understanding of the symmetry operations). The directions of C_2 and σ_v' are as shown in the figure.



It is evident from the above figure that $\sigma_v' C_2 = C_3^1$.

Let us now find out $C_2\sigma_v'$. This is done by carrying out the two operations as illustrated below :

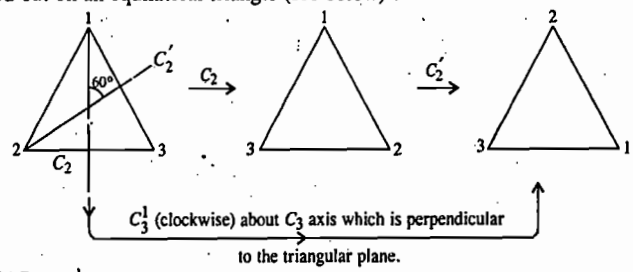


Evidently, $C_2\sigma_v' = C_3^2$. Thus, while the product $\sigma_v' C_2 = C_3^1$, the product $C_2\sigma_v' = C_3^2$, that is, $\sigma_v' C_2 \neq C_2\sigma_v'$. In other words, the operations C_2 and σ_v' do not commute.

It is important to note that the product of an identity operation with any other symmetry operation always yields that symmetry operation. Thus, $C_n^m E = C_n^m$; $\sigma C_2 E = \sigma C_2$; $\sigma_v^3 C_2 = E\sigma C_2 = \sigma C_2$ ($\because \sigma^2 = E$).

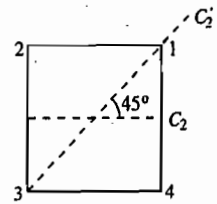
General Relations Amongst Symmetry Elements and Symmetry Operations. The following general relations hold good amongst symmetry elements and symmetry operations.

1. The product of two proper rotations is itself a proper rotation, as is evident from the symmetry operations carried out on an equilateral triangle (see below) :

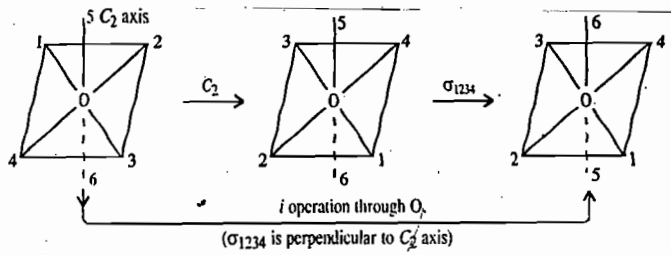


Thus, $C_2' C_2 = C_3^1$

2. The product of two C_2 rotations about axes which intersect at an angle θ, is a rotation by 2θ about an axis which is perpendicular to the plane containing the two C_2 axes. As shown in the example given above, the product of two C_2 rotations about C_2 and C_2' axes which intersect at an angle of 60° is equal to rotation through an angle $2 \times 60°$, *i.e.*, 120° about an axis which is perpendicular to the plane containing the two axes. Similarly, it can be shown that in a square plane, the product $C_2' C_2$ about the two axes which are inclined at an angle of 45° is equal to rotation about the C_4 axis through an angle of 2×45, *i.e.*, 90°. The C_4 axis is perpendicular to the plane containing the two C_2 axes.

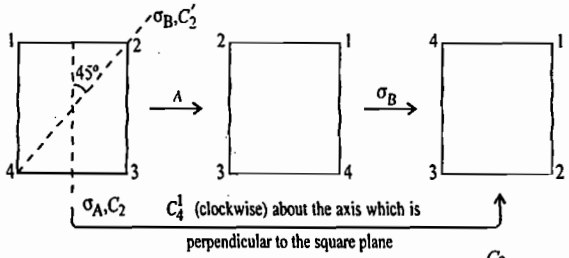


3. A proper axis of even order and a perpendicular reflection plane generate an inversion centre. Consider the example of a regular octahedral molecule which is operated upon as shown below :

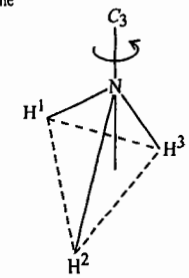


It is clearly evident from the figure that $\sigma_{1234}\, C_2 = i$.

4. The product of two reflections in planes σ_A and σ_B intersecting at an angle θ_{AB} is a rotation through $2\theta_{AB}$ about the axis defined by the line of intersection of the two planes. Consider a square planar geometry in which planes σ_A and σ_B are passing through C_2 and C_2', respectively and are perpendicular to the square plane. The angle between these two planes is 45°. The line of intersection of the two planes σ_A and σ_B is obviously perpendicular to the square plane and is collinear with C_4 symmetry axis. As can be seen from the figure shown, the reflection through σ_A and σ_B is equal to C_4^1 rotation operation about the line of intersection of the two planes.



5. When there is a rotation axis C_n and a plane of symmetry containing it, there must be n-1 more planes like the previous plane. Consider, for example, a pyramidal molecule such as NH_3. It has a three-fold axis of symmetry as shown in the figure. There is a plane of symmetry passing through this C_3 axis and the N—H_1 bond bisecting the angle H^2NH^3. We can easily visualise that there are two more planes of symmetry of this type passing through the C_3 axis.



SYMMETRY ELEMENTS AND SYMMETRY OPERATIONS IN MOLECULES OF SPECIAL SYMMETRY

1. Linear Molecules. Let us consider a CO_2 molecule. The OCO bond axis is the C_∞ axis of symmetry about which infinite number of rotations can be carried out. Similarly, any line perpendicular to OCO bond axis and passing through the middle of the molecule is a two-fold axis of symmetry. One can draw infinite number of such lines. Similarly, one can draw infinite number of planes of symmetry passing through OCO. There is also a plane of symmetry which is perpendicular to OCO bond axis and passes through the centre of the molecule. Apart from this, there is a centre of inversion in the middle of the molecule. Such symmetrical linear molecules are said to belong to $D_{\infty h}$ symmetry point group. Other examples of such molecules are O_2, H_2, N_2, etc.

Let us now consider an unsymmetrical molecule such as NO. There is a C_∞ axis collinear with the bond axis and there are infinite number of σ_vs passing through the C_∞ axis. However, there is no symmetry axis perpendicular to the NO bond and passing through the middle of the NO bond. Such a molecule is said to belong to $C_{\infty v}$ group.

2. Tetrahedral Molecules. A regular tetrahedron can be derived from a cube, as shown in Fig. 2.

Let us consider a regular tetrahedral molecule CH_4 and determine its symmetry elements and symmetry operations :

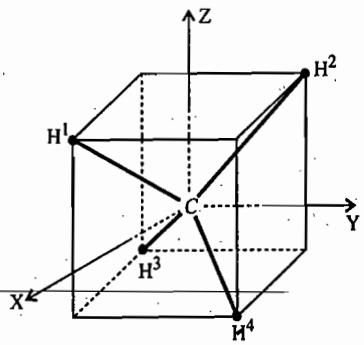


Fig. 2. Derivation of a regular tetrahedron from a cube

(*i*) The molecule has three S_4 axes. If we rotate the tetrahedral molecule shown in the figure through 90° about Z axis and then reflect the resulting geometry through a plane perpendicular to Z axis, *i.e.*, through XY plane, we get an equivalent geometry. Similar operations can be carried out about Y and X axes. Thus, X, Y and Z axes are S_4 axes of improper rotation. Each S_4 axis can generate four symmetry operations, *viz.*, S_4^1, *i.e.*, σC_4^1 ; S_4^2, *i.e.*, $\sigma^2 C_4^2$ which, in fact, is EC_2 or C_2 operation; S_4^3, *i.e.*, $\sigma^3 C_4^3$ or σC_4^3 and S_4^4, *i.e.*, $\sigma^4 C_4^4$ or E operation. Thus, each S_4 axis generates

two genuine rotation-reflection operations or improper rotation operations. Therefore, six S_4 operations are possible on this geometry.

(*ii*) There are three C_2 axes collinear with X, Y and Z axes (each C_2 axis bisects a pair of tetrahedral angles). Each C_2 axis generates one symmetry operation (rotation of the molecule twice about any of the three C_2 axes yields identical geometry). Thus, three C_2 operations are possible in a tetrahedral molecule.

(*iii*) There are four C_3 axes of symmetry, *viz.*, C-H^1, C-H^2, C-H^3 and C-H^4, in this case. Each C_3 axis generates two symmetry operations, *viz.*, C_3^1 and C_3^2 (C_3^3 is an identity operation). Thus, eight genuine C_3 operations are possible in this case.

(*iv*) There are six planes of symmetry each of them passing through two of the six C-H bonds. Each plane of symmetry generates one symmetry operation (each reflection operation carried out twice constitutes an identity operation). Thus, there are six reflection operations.

In all there are twenty four symmetry operations comprising of six S_4 operations, three C_2 operations, eight C_3 operations, six σ operations and one identity operation, which can be carried out on a regular tetrahedral molecule.

3. Octahedral Molecules. Let us now consider an octahedral species ML_6 shown in Fig. 3 and determine its symmetry elements and symmetry operations :

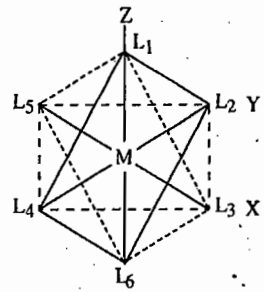

Fig.3. An octahedral species ML_6

(*i*) There are three S_4 axes (along X, Y and Z axes) in this case. Each S_4 axis can generate S_4^1, S_4^2, S_4^3 and S_4^4 operations. But, S_4^2 and S_4^4 are, in fact, C_2 and E operations, respectively. Thus, each S_4 axis generates two improper rotation operations (S_4^1 and S_4^3) and hence three S_4 axes would generate six improper rotation operations.

(*ii*) There are three C_4 axes collinear with S_4 axes (*i.e.*, along X, Y and Z axes). Each C_4 axis generates two genuine C_4 rotation operations, *viz.*, C_4^1 and C_4^3 since C_4^2 is a C_2 operation and C_4^4 is an identity operation. Thus, six C_4 operations are possible on this geometry.

(*iii*) There are three C_2 axes collinear with C_4 axis about which three C_2 operations can be carried out. It may be noted again that $C_2^2 = E$.

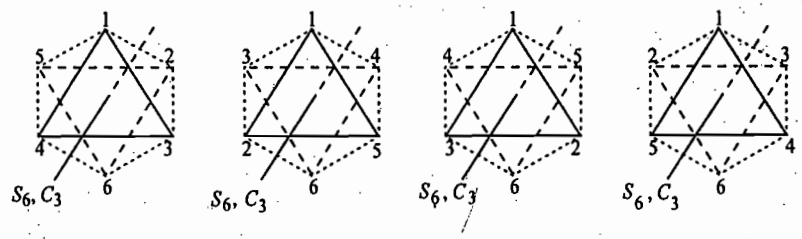
(*iv*) There are six C_2 axes which bisect the angles L_1ML_5, L_1ML_3, L_2ML_3, L_2ML_5, L_1ML_2 and L_1ML_4. These generate six C_2 operations.

(*v*) There are three planes of symmetry marked separately by dotted lines, solid lines and dashed lines in the above figure which pass through the four vertices of the octahedron. These generate three reflection operations.

(*vi*) There are six planes of symmetry, each passing through a C_4 axis and bisecting the angles mentioned in (*iv*) above. These generate six reflection operations.

(*vii*) There is a centre of inversion at M which generates one i operation.

(*viii*) There are four C_3 axes each passing through the centre of opposite triangular face of the octahedron. These can be represented as shown in the following figures :



Each C_3 axis generates two C_3 operations, *viz.*, C_3^1 and C_3^2 (C_3^3 is an identity operation). Thus, the four C_3 axes generate eight C_3 operations.

(*ix*) Collinear with the above mentioned C_3 axis, are the four S_6 axes which means that we rotate the figure through 60° about these axes and then apply the reflection operation through a plane which is in between the two opposite triangular faces. The four pairs of opposite triangular faces and the four S_6 axes are shown in the figure given above. Each such S_6 axis can generate the following six symmetry operations :

S_6^1 which is $\sigma^1 C_6^1$ and is a genuine improper rotation or rotation-reflection operation.

S_6^2 which is $\sigma^2 C_6^2$ or EC_3 or C_3

S_6^3 which is $\sigma^3 C_6^3$ or $E\sigma\, C_2$ or σC_2 or i

S_6^4 which is $\sigma^4 C_6^4$ or $E\, C_3^2$ or C_3^2

S_6^5 which is $\sigma^5 C_6^5$ or $E\sigma C_6^5$ or σC_6^5 which is a genuine improper rotation or rotation-reflection operation.

S_6^6 which is E.

As can be seen, only two of the above mentioned operations are genuine improper rotation operations. Since there are four S_6 axes in the system, these generate eight S_6 symmetry operations.

Thus, in a regular octahedron, forty eight symmetry operations including six S_4, six C_4, nine C_2, nine σ, one i, eight C_3, eight S_6 and one E operations are possible.

SYMMETRY CLASSIFICATION OF MOLECULES

It can be shown that all the axes and the planes of symmetry of any geometry must intersect at least at one common point. Therefore, the collection of symmetry elements of any geometry is known as the **symmetry point group** of that geometry. The symmetry point groups to which the various molecules belong are determined by following the procedure outlined below :

1. Determine whether the molecule belongs to any of the following special symmetry point groups : $C_{\infty v}$, $D_{\infty h}$, T_d, O_h.

2. If the molecule does not belong to any of the above mentioned special groups, search for a proper or an improper rotation axis. If no such axis is present, then look for a plane of symmetry or the centre of symmetry. If only a plane of symmetry is present and there is no other element of symmetry, the molecule belongs to C_s point group. Two symmetry operations, σ and E, can be carried out on such molecules. If only a centre of inversion is present and there is no other element of symmetry, the molecule belongs to C_i symmetry point group. Again two symmetry operations, i and E, can be performed on such molecules. If no symmetry element is present at all, the molecule belongs to C_1 symmetry point group. Only one symmetry operation E can be carried out on such a molecule.

3. If a molecule has an improper axis of rotation of even order and no other element of symmetry (except for a proper axis of rotation collinear with the improper axis of rotation) is present, the molecule belongs to S_4 or S_6 or S_8, etc., symmetry point group. In such a molecule, n symmetry operations about the S_n axis are possible, as already explained.

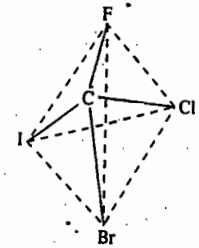
4. If the molecule does not belong to any of the above mentioned groups, look for a highest-order proper axis of rotation C_n, called the principal axis. If there are several proper axes of rotation, choose that axis as principal axis which is of highest order. If there are several proper axes of rotation of highest order, choose that axis as principal axis which is unique in some way. If all proper axes of rotation are alike, the principal axis of rotation is selected at random.

Now look for n C_2 axes perpendicular to the principal axis. If these axes exist, we proceed to step 5. If not, the molecule belongs to C_n or C_{nv} or C_{nh} symmetry point group as the case may be. If there are no symmetry elements other than C_n axis, the molecule belongs to C_n symmetry point group. A total of n

symmetry operations can be carried out around this C_n axis. If there are n σ_vs alongwith a C_n axis, the molecule belongs to C_{nv} symmetry point group. In such molecules, 2n symmetry operations are possible. But, if there is only a horizontal plane of symmetry which is perpendicular to the principal axis of symmetry C_n, the molecule belongs to C_{nh} symmetry point group. Again, 2n symmetry operations are possible in such cases.

5. If, in addition to C_n, n C_2 axes which are all perpendicular to the C_n axis are also present, the molecule belongs to D_n, D_{nh} or D_{nd} symmetry point group. If no symmetry elements except for C_n and n C_2 axes which are perpendicular to C_n axis, are present, the molecule belongs to D_n symmetry point group. But, if apart from C_n axis and n C_2 axes perpendicular to C_n, a horizontal plane of symmetry is also present, the molecule belongs to D_{nh} symmetry point group. Such molecules would essentially contain n vertical planes of symmetry as well. In molecules with D_{nh} symmetry, 4n symmetry operations are possible. If there is no σ_h but there are n C_2 axes perpendicular to C_n axis and n vertical planes which pass between the C_2 axes, the molecule belongs to D_{nd} point group. In such molecules, 4n symmetry operations are possible. It is to be noted that whereas in molecules with D_{nh} symmetry, there is an S_n improper rotation axis, there exists an S_{2n} improper rotation axis in molecules with D_{nd} symmetry.

The above mentioned notation of symmetry point groups based on the use of C, σ, i symbols for symmetry elements is known as **Schoenfless notation.**

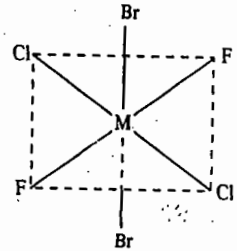


Let us now determine **symmetry point groups of some typical molecules.**

1. Symmetry Point Group of CFClBrI Molecule. It has no element of symmetry and hence it belongs to C_1 **symmetry point group.** The only symmetry operation that can be carried out on the geometry of the molecule is E.

2. Symmetry Point Groups of  **and**  **Molecules.** Each of these molecules contains only a plane of symmetry which is also the plane of the molecule. Thus, both the molecules belong to C_s **symmetry point group.** The symmetry operations that can be performed on these molecules are σ and $\sigma^2 (= E)$.

3. Symmetry Point Group of trans $[MF_2Cl_2Br_2]^{n-}$ Ion. This ion has a C_2 axis (along the Br–M–Br bond) which can be taken as the principal axis and two C_2 axes perpendicular to the principal axis. Apart from this, there is a σ_h axis which is perpendicular to the principal axis. The molecule thus belongs to D_{2h} **symmetry point group.**



Apart from the above mentioned symmetry elements, two σ_vs and a centre of symmetry are also present in the molecule. The eight symmetry operations that can be carried out on this molecule are : three C_2s, two σ_vs, i, σ and E.

4. Symmetry Point Group of NH_3 Molecule, 
. The molecule contains a C_3 axis which is the principal axis of symmetry. Apart from this, there are three σ_vs each of which passes through the C_3 axis and one N—H bond that bisects the angle between the other two N—H bonds. The molecule thus belongs to C_{3v} **symmetry point group.** The six symmetry operations that can be performed on this molecule are C_3^1, C_3^2, C_3^3 $(= E)$ and three σ_vs.

5. Symmetry Point Group of Trans N_2F_2 Molecule, $F{/}N{=}N{/}F$, This molecule contains a C_2 axis passing through the middle of N=N bond and perpendicular to the plane of the molecule which is also a plane of symmetry (σ_h). Apart from this, there is a centre of inversion in the middle of N=N bond. The molecule, thus, belongs to C_{2h} **symmetry point group.** The four symmetry operations possible in this geometry are C_2, σ_h, i and E.

A Complete Set of Symmetry Operations as a Mathematical Group

A complete set of symmetry operations of a geometry behaves like a mathematical group. We shall, first of all, define a mathematical group and then describe the rules which the elements of the group follow. Having done that, we shall show that a complete set of symmetry operations follow these rules and thus constitute a mathematical group.

A **mathematical group** is a collection of elements which are interrelated according to the following rules :

1. The product (or multiplication) of any two elements in the group and the square of each element must be an element in the group. The product or multiplication of elements here means combination of elements of the group. The square of an element means multiplying an element with itself. The product of two elements A and B of the group can be BA or AB. The product AB may not always be equal to BA. Quite often the product AB may give the element C of the group whereas BA may give another element D of the same group. If, for the two elements $AB = BA$, we say that the elements A and B commute with each other. If $AB \neq BA$, we say that the elements A and B do not commute. As a convention, we start multiplying the elements of a combination from right towards left. Thus, in ABC, we multiply C with B to get, say D and then multiply D with A.

2. There is one element in each mathematical group which must commute with all other elements of the group and leave them unchanged. Such an element is known as the **identity element.** Suppose E is an identity element while A is some other element of a group. Then, $EA = AE = A$.

3. The elements of a mathematical group obey the associative law of multiplication, *i.e.*, $AB(CDE) = A(BC)(DE) = (AB)(CD)E$ where A, B, C, D and E are the elements of the same mathematical group.

4. Each element of a mathematical group must have a reciprocal which is also an element of the group. When an element is multiplied by its reciprocal, we get the identity element E of the group, *i.e.*, $AA^{-1} = A^{-1}A = E$. The reciprocal of two or more elements is equal to the product of the reciprocals in the reverse order. Thus, $(ABC)^{-1} = C^{-1}B^{-1}A^{-1}$. The number of elements in a finite group is known as the **order of the group.**

Let us consider the product $X^{-1}AX$ in which X, A and X^{-1} are the elements of a mathematical group. Suppose $X^{-1}AX = B$. Then, B is known as **similarity transform** of A by X and A and B are known as the **conjugate elements.** These conjugate elements have the following properties :

a. Each element is conjugate with itself, *i.e.*, it is possible to find at least one element in the group which would transform A into A. Such an element is the identity element E. Thus, $E^{-1}AE = A$.

b. If element A is conjugate with element B as well as with C, then B and C are conjugate with each other and A, B and C are all conjugate with one another.

c. If element A is conjugate with symmetry element B, then B is conjugate with A, *i.e.*, if $X^{-1}AX = B$, then it is always possible to find another element Y of the group so that $Y^{-1}BY = A$. A complete set of elements which are conjugate with one another is termed as the **class** of the mathematical group. The order of each class, *i.e.*, the number of elements in each class, must be an integral factor of the order of the group.

A simple example of a mathematical group of elements is offered by **all integrals from** $+\infty$ **to** $-\infty$ **including zero.** If we define the product as addition, we see that this mathematical group of the order equal to ∞, obeys all the rules mentioned above. In this example of a mathematical group, zero is the identity element.

We shall now show that a complete set of symmetry operations of a geometry constitute a mathematical group. Let us take the example of planar triangular BF_3 molecule belonging to D_{3h} symmetry group, as shown in Fig. 4.

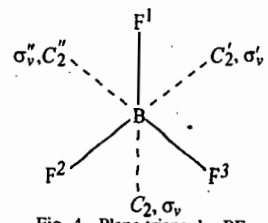


Fig. 4. Plane triangular BF_3 molecule

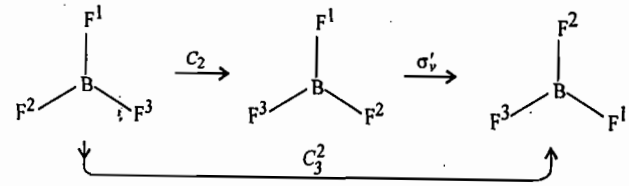
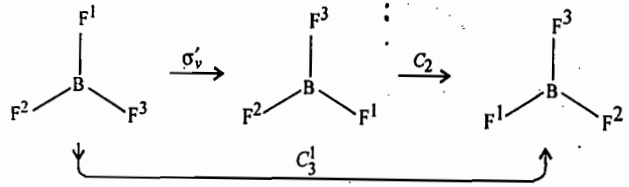
The complete set of symmetry operations that can be carried out on this molecule are : E, C_3^1, C_3^2, σ_v, σ_v', σ_v'', σ_h, C_2, C_2', C_2'', S_3^1 and S_3^5. Let us determine the product $\sigma_v' C_2$. As already mentioned, we always start multiplying from right to left, Accordingly, the operations carried out on the molecule would be as shown below :



As is obvious from the above figure, the geometry resulting from the operation of $\sigma_v' C_2$ can be obtained by applying a single C_3^2 operation which is also a symmetry operation of D_{3h} group. Similarly, we can take the product of any other two or three symmetry operations. We shall see that the resulting geometry would also be obtained by applying another appropriate single symmetry operation of D_{3h} symmetry group. Thus, the complete set of symmetry operations mentioned above obeys the first rule followed by the elements of a mathematical group.

It is to be noted that in the present case, the product $C_2\sigma_v'$ does not commute with the product $\sigma_v' C_2$ since $C_2\,\sigma_v' = C_3^1$, as shown below :



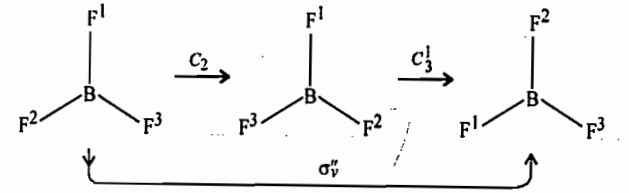
The second rule which the elements of a mathematical group must obey is that there should be at least one element amongst the complete set of elements of the group which when combined with any other element of the group would leave it unchanged. In a complete set of symmetry operations of D_{3h} group, the identity operation E is an operation of this type. Thus, $EC_2 = C_2E = C_2$ and so on.

Let us now consider the product $C_3^1(C_2\sigma_v')$ of three symmetry operations of D_{3h} symmetry point group. The product $(C_2\sigma_v')$ has already been shown to be equal to C_3^1. Hence,

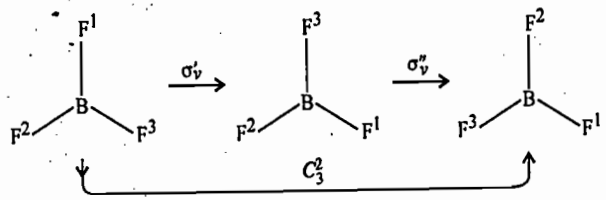
$$C_3^1(C_2\sigma_v') = C_3^1 C_3^1 = C_3^2$$

Let us now evaluate the product $\left(C_3^1 C_2\right)\sigma_v'$.

The product $C_3^1 C_2$ is equal to σ_v'', as shown below :



Hence, $(C_3^1 C_2)\sigma_v' = \sigma_v''\sigma_v'$ which is equal to C_3^2, as shown below :



Thus, $C_3^1(C_2\sigma_v') = (C_3^1 C_2)\sigma_v' = C_3^2$. This shows that the symmetry operations in the present case obey the associative law of multiplication which is the third rule that the elements of a mathematical group must obey.

Consider the product $C_3^2 C_3^1$. This is equal to E. Therefore, the reciprocal of C_3^1 is C_3^2 and of C_3^2 is C_3^1. Similarly, C_2, C_2', C_2'', σ_v', σ_v'', σ_v, σ_h are all their own reciprocals. Thus, like the symmetry elements of a mathematical group, each symmetry operation of D_{3h} point group has a reciprocal which also is a symmetry operation of the point group. Similarly, we can take any other point group and show that *a complete set of symmetry operations of a point group constitutes a mathematical group.*

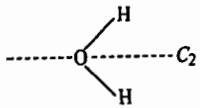
A table which includes the products of the elements of a mathematical group is called **group multiplication table (GMT).**

Each row and each column of such a table is headed by a symmetry element of the group. The product of two symmetry elements AB of the group is the symmetry element at the crossing point of *Bth row and Ath column*. Since the symmetry operations of a point group behave like the symmetry elements of a mathematical group, we can construct a group multiplication table for the products of the symmetry operations. One such group multiplication table of C_{2v} point group, taking H_2O molecule as an example of this point group, is given in Table 1 :

TABLE 1

GMT of C_{2v} Point Group

C_{2v}	E	C_2	σ_v	σ_v'
E	E	C_2	σ_v	σ_v'
C_2	C_2	E	σ_v'	σ_v
σ_v	σ_v	σ_v'	E	C_2
σ_v'	σ_v'	σ_v	C_2	E



(σ_v is the plane of the H_2O molecule, σ_v' is perpendicular to the plane of the molecule passing through C_2.)

Suppose we wish to determine $C_2\sigma_v$. It is evident from GMT that the crossing point of σ_vth row and C_2th column is σ_v'. Thus, $C_2\sigma_v = \sigma_v'$. Similarly, the crossing point of C_2th row and σ_vth column is σ_v'. Thus, $\sigma_v C_2$ is also equal to σ_v'.

Classes of Symmetry Operations

Consider the anion $[CoF_5Br]^{3-}$ belonging to point group C_{4v}, whose geometry and symmetry elements are as shown in Fig. 5.

All the vertical planes and dihedral planes of symmetry pass through the C_4 axis. The symmetry operations possible in this case are C_4^1, C_4^3, E, $\sigma_{v(1)}$, $\sigma_{v(2)}$, $\sigma_{d(1)}$, $\sigma_{d(2)}$ and C_2.

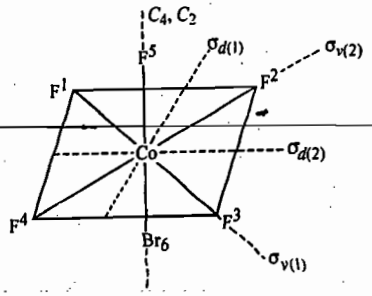


Fig. 5. Geometry and symmetry elements of the anion $[CoF_5Br]^{3-}$

The results of **similarity transformations** of these symmetry elements by C_4^1 and $\sigma_{v(1)}$ are as given below :

$$C_4^{-1} E C_4^1 = E \qquad \sigma_{v(1)}^{-1} E \sigma_{v(1)} = E$$
$$C_4^{-1} C_4^1 C_4^1 = C_4^1 \qquad \sigma_{v(1)}^{-1} C_4^1 \sigma_{v(1)} = C_4^3$$
$$C_4^{-1} C_4^3 C_4^1 = C_4^3 \qquad \sigma_{v(1)}^{-1} C_4^3 \sigma_{v(1)} = C_4^1$$
$$C_4^{-1} C_2 C_4^1 = C_2 \qquad \sigma_{v(1)}^{-1} \sigma_{v(1)} \sigma_{v(1)} = \sigma_{v(1)}$$
$$C_4^{-1} \sigma_{v(1)} C_4^1 = \sigma_{v(2)} \qquad \sigma_{v(1)}^{-1} \sigma_{v(2)} \sigma_{v(1)} = \sigma_{v(2)}$$
$$C_4^{-1} \sigma_{v(2)} C_4^1 = \sigma_{v(1)} \qquad \sigma_{v(1)}^{-1} \sigma_{d(1)} \sigma_{v(1)} = \sigma_{d(2)}$$
$$C_4^{-1} \sigma_{d(1)} C_4^1 = \sigma_{d(2)} \qquad \sigma_{v(1)}^{-1} \sigma_{d(2)} \sigma_{v(1)} = \sigma_{d(1)}$$
$$C_4^{-1} \sigma_{d(2)} C_4^1 = \sigma_{d(1)} \qquad \sigma_{v(1)}^{-1} C_2 \sigma_{v(1)} = C_2$$

As already mentioned, the symmetry operations which are transformed into one another by similarity transformations constitute a **class** of symmetry operations. Thus, there are the following classes of symmetry operations of C_{4v} point group :

$$E\,;\ C_4^1,\ C_4^3;\ \sigma_{v(1)}, \sigma_{v(2)}\,;\ \sigma_{d(1)}, \sigma_{d(2)} \text{ and } C_2$$

The number of symmetry elements in each class is known as its **order**; the order of a class is an integral factor of the order of the group.

Representation of Symmetry Operations by Matrices

Consider a point (x_1, y_1, z_1) in a Cartesian coordinate system. If we reflect this point through XY plane, we get the point (x_2, y_2, z_2), as illustrated in Fig. 6.

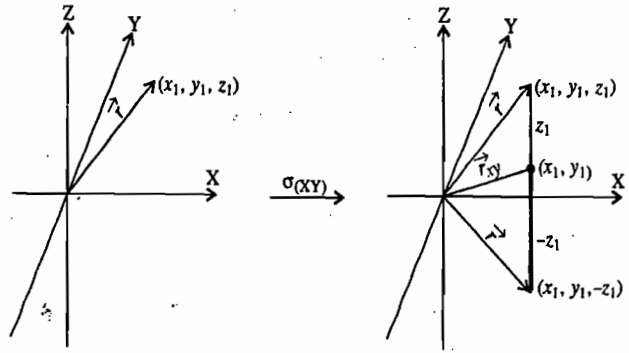

Fig. 6. Reflection of point (x_1, y_1, z_1) in a Cartesian coordinate system through XY plane.

Obviously,

$$x_2 = x_1 = 1x_1 + 0y_1 + 0z_1$$
$$y_2 = y_1 = 0x_1 + 1y_1 + 0z_1$$
$$z_2 = -z_1 = 0x_1 + 0y_1 - 1z_1$$

We can write the above result in the following matrix form :

$$\sigma_{XY}\begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix} = \begin{bmatrix} x_2 \\ y_2 \\ z_2 \end{bmatrix} = \begin{bmatrix} x_1 \\ y_1 \\ -z_1 \end{bmatrix} = \begin{bmatrix} 1x_1 + 0y_1 + 0z_1 \\ 0x_1 + 1y_1 + 0z_1 \\ -x_1 + 0y_1 - 1z_1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix}\begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix}$$

Thus, the operation σ_{XY} on the point (x_1, y_1, z_1) can be represented by the matrix $\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix}$.

In a similar manner, we can show that the operations σ_{XZ} and σ_{YZ} on the point (x_1, y_1, z_1) can be represented by the matrices $\begin{bmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$ and $\begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$, respectively.

We shall show that a rotation operation can also be represented by a matrix. Let us consider the rotation of the point (x_1,y_1,z_1) around the Z axis which gives the point (x_4,y_4,z_4). Since the rotation of the point (x_1,y_1,z_1) through any angle around the Z axis, cannot change the z coordinate, z_4 is the same as z_1. In other words, only x and y coordinates of the point will change.

In order to understand the rotation operation better, we shall consider the rotation of the projection of the vector r in the XY plane. Let us call the projection of r in the plane XY as r_{XY}, as shown in Fig. 7. Let the vector r_{XY} in its original position make an angle α with X axis so that

$$x_1 = \vec{r}_{XY} \cos \alpha$$

$$y_1 = \vec{r}_{XY} \sin \alpha$$

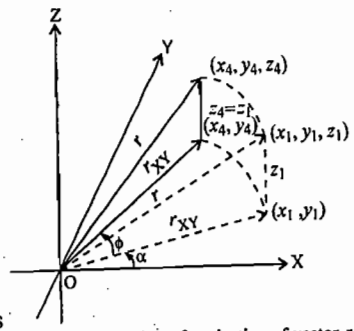

Fig. 7. Rotation of projection of vector r in XY plane

Rotation of vector $\vec{r}_{XY}$ around Z axis by an angle ϕ changes the coordinates of the point from (x_1, y_1) to (x_4, y_4) so that

$$x_4 = \vec{r}_{XY}\cos(\phi+\alpha) = \vec{r}_{XY}\cos\phi\cos\alpha - \vec{r}_{XY}\sin\phi\sin\alpha = x_1\cos\phi - y_1\sin\phi$$

$$y_4 = \vec{r}_{XY}\sin(\phi+\alpha) = \vec{r}_{XY}\sin\phi\cos\alpha + \vec{r}_{XY}\cos\phi\sin\alpha = x_1\sin\phi + y_1\cos\phi$$

$$z_4 = z_1$$

or
$$\begin{bmatrix} x_4 \\ y_4 \\ z_4 \end{bmatrix} = \begin{bmatrix} x_1\cos\phi & -y_1\sin\phi & +0z_1 \\ x_1\sin\phi & +y_1\cos\phi & +0z_1 \\ 0x_1 & +0y_1 & +1z_1 \end{bmatrix}$$

We can write the above result in the following matrix form:

$$C_{Z(\phi)}\begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix} = \begin{bmatrix} x_4 \\ y_4 \\ z_4 \end{bmatrix} = \begin{bmatrix} \cos\phi & -\sin\phi & 0 \\ \sin\phi & \cos\phi & 0 \\ 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix}$$

Thus, $C_{Z(\phi)}$ can be represented by the matrix $\begin{bmatrix} \cos\phi & -\sin\phi & 0 \\ \sin\phi & \cos\phi & 0 \\ 0 & 0 & 1 \end{bmatrix}$.

The operation i changes the coordinates of the point from (x_1, y_1, z_1) to $(-x_1, -y_1, -z_1)$ so that

$$i\,(x_1, y_1, z_1) = (-x_1, -y_1, -z_1)$$

Writing the result in the matrix form, we have

$$i\begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix} = \begin{bmatrix} -x_1 \\ -y_1 \\ -z_1 \end{bmatrix} = \begin{bmatrix} -x_1 & +0y_1 & +0z_1 \\ 0x_1 & -y_1 & +0z_1 \\ 0x_1 & +0y_1 & -z_1 \end{bmatrix} = \begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{bmatrix}\begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix}$$

Thus, i can be represented by the matrix $\begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{bmatrix}$.

Lastly we consider improper rotation operation on the point (x_1, y_1, z_1) around the Z axis. This may be represented as follows :

$$S_Z\begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix} = \sigma_{XY}\, C_{Z(\phi)}\begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix} = \sigma_{XY}\begin{bmatrix} x_4 \\ y_4 \\ z_4 \end{bmatrix} = \sigma_{XY}\begin{bmatrix} x_1\cos\phi & -y_1\sin\phi & +0z_1 \\ x_1\sin\phi & +y_1\cos\phi & +0z_1 \\ 0x_1 & +0y_1 & +1z_1 \end{bmatrix}$$

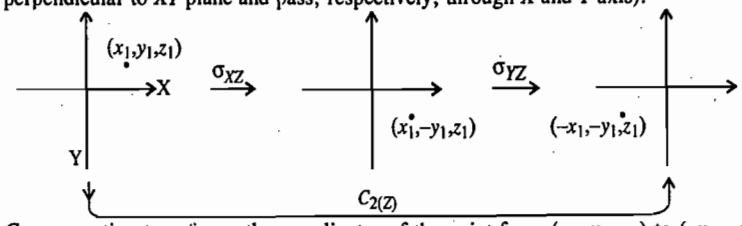
Now
$$\sigma_{XY}\begin{bmatrix} x_4 \\ y_4 \\ z_4 \end{bmatrix} = \begin{bmatrix} x_4 \\ y_4 \\ -z_4 \end{bmatrix} = \begin{bmatrix} x_1\cos\phi & -y_1\sin\phi & +0z_1 \\ x_1\sin\phi & +y_1\cos\phi & +0z_1 \\ 0x_1 & +0y_1 & -1z_1 \end{bmatrix} = \begin{bmatrix} \cos\phi & -\sin\phi & 0 \\ \sin\phi & \cos\phi & 0 \\ 0 & 0 & -1 \end{bmatrix}\begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix}$$

(σ_{XY} operation leaves x and y coordinates of the point unchanged but changes the sign of z coordinate).

Thus, S_Z can be represented by the matrix $\begin{bmatrix} \cos\phi & -\sin\phi & 0 \\ \sin\phi & \cos\phi & 0 \\ 0 & 0 & -1 \end{bmatrix}$.

Similarly, the identity operation on the point (x, y, z) can be written by the matrix, $\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$.

The matrix representations of symmetry operations function exactly as do the symmetry operations themselves. For instance, it can be easily shown that $\sigma_{YZ}\,\sigma_{XZ} = C_{2(Z)}$ (see below). (The σ_{XZ} and σ_{YZ} planes are perpendicular to XY plane and pass, respectively, through X and Y axis).



Since $C_{2(Z)}$ operation transforms the coordinates of the point from (x_1, y_1, z_1) to $(-x_1, -y_1, z_1)$, the matrix representing $C_{2(Z)}$ can be shown to be $\begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$.

Let us now multiply matrices representing $\sigma_{YZ}\,\sigma_{XZ}$. The product is the matrix representing C_{2Z}, as shown below :

$$\underset{\sigma_{YZ}}{\begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}}\underset{\sigma_{XZ}}{\begin{bmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix}} = \underset{C_{2(Z)}}{\begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix}}$$

We have already written matrices representing C_2, σ_{XZ}, σ_{YZ} and E which are the symmetry operations of C_{2v} point group. We did this by taking a point in three-dimensional space. We can also take a set of vectors, atomic orbitals or molecular orbitals, instead of taking a point and obtain sets of matrices which also represent symmetry operations of the point group. Instead of taking H_2O molecule

as the example of C_{2v} point group (as we did before), we can take other molecules such as CH_2Cl_2, cis N_2F_2, cis butadiene ($H_2C{=}CH{-}CH{=}CH_2$), etc., as examples of C_{2v} point group and write different sets of matrices representing the operations of the point group. Thus, a large number of sets of matrices which represent the same set of symmetry operations of the same symmetry point group can be written. A set of matrices representing a complete set of symmetry operations of a point group is known as a **'representation'** of that point group. It is designated by the symbol Γ.

Most of the times, it is very cumbersome to write a 'representation' in terms of a set of full matrices for the symmetry operations. Therefore, instead of writing full matrices, we generally write the **characters** (χ) of the matrices while writing a 'representation'. Thus, the representation corresponding to symmetry operations of C_{2v} point group carried out on point (x_1, y_1, z_1) is given below :

	E	C_2	$\sigma_{v(XZ)}$	$\sigma_{v(YZ)}$
Γ	3	-1	1	1

(Full matrices representing the symmetry operations on the point (x_1, y_1, z_1) have already been given above).

The numerical figures in the above representation give the characters of the matrices representing the symmetry operations whose symbols are written above these numerals.

Let us now, for the sake of practice, write down some more representations of C_{2v} point group taking into consideration the H_2O molecule. Let us associate three mutually perpendicular unit vectors with each atom of H_2O molecule, as shown in Fig. 8 and apply all the symmetry operations of C_{2v} point group on these vectors.

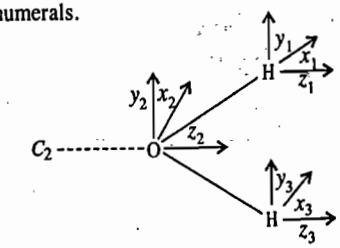


Fig. 8. Association of three mutually perpendicular unit vectors to each atom of H_2O molecule.

It can be shown that

1. All symmetry operations of C_{2v} point group to which H_2O molecule belongs can be represented by matrices of 9×9 dimensions. One such matrice is written below. The student is advised to write other matrices himself.

$$C_2 \begin{bmatrix} x_1 \\ y_1 \\ z_1 \\ x_2 \\ y_2 \\ z_2 \\ x_3 \\ y_3 \\ z_3 \end{bmatrix} = \begin{bmatrix} -1x_3 \\ -1y_3 \\ +1z_3 \\ -1x_2 \\ -1y_2 \\ +1z_2 \\ -1x_1 \\ -1y_1 \\ +1z_1 \end{bmatrix} = \begin{bmatrix} 0x_1+0y_1+0z_1+0x_2+0y_2+0z_2-1x_3+0y_3+0z_3 \\ 0x_1+0y_1+0z_1+0x_2+0y_2+0z_2+0x_3-1y_3+0z_3 \\ 0x_1+0y_1+0z_1+0x_2+0y_2+0z_2+0x_3+0y_3+1z_3 \\ 0x_1+0y_1+0z_1-1x_2+0y_2+0z_2+0x_3+0y_3+0z_3 \\ 0x_1+0y_1+0z_1+0x_2-1y_2+0z_2+0x_3+0y_3+0z_3 \\ 0x_1+0y_1+0z_1+0x_2+0y_2+1z_2+0x_3+0y_3+0z_3 \\ -1x_1+0y_1+0z_1+0x_2+0y_2+0z_2+0x_3+0y_3+0z_3 \\ 0x_1-1y_1+0z_1+0x_2+0y_2+0z_2+0x_3+0y_3+0z_3 \\ 0x_1+0y_1+1z_1+0x_2+0y_2+0z_2+0x_3+0y_3+0z_3 \end{bmatrix} = \begin{bmatrix} 0&0&0&0&0&0&-0&0&0 \\ 0&0&0&0&0&0&0&-0&0 \\ 0&0&0&0&0&0&0&0&1 \\ 0&0&0&-1&0&0&0&0&0 \\ 0&0&0&0&-1&0&0&0&0 \\ 0&0&0&0&0&+1&0&0&0 \\ -1&0&0&0&0&0&0&0&0 \\ 0&-1&0&0&0&0&0&0&0 \\ 0&0&1&0&0&0&0&0&0 \end{bmatrix} \begin{bmatrix} x_1 \\ y_1 \\ z_1 \\ x_2 \\ y_2 \\ z_2 \\ x_3 \\ y_3 \\ z_3 \end{bmatrix}$$

The character of the matrix representing C_2 operation on the nine vectors $x_1, y_1, z_1, x_2, y_2, z_2, x_3, y_3, z_3$ is obviously $(-1 - 1 + 1)$, *i.e.*, -1. The characters of matrices representing E, $\sigma_{v(xz)}$, $\sigma_{v(yz)}$ can be worked out in a similar manner.

2. The vector which shifts its position during a symmetry operation contributes zero to the character of the matrix representing that symmetry operation.

3. The vector which does not change direction and which does not shift its position in space during a symmetry operation contributes $+1$ to the character of the matrix representing that symmetry operation.

4. The vector which reverses its direction during a symmetry operation contributes -1 to the character of the matrix representing that symmetry operation.

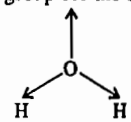
On applying C_2 operation, the vector z_2 remains unaltered whereas vectors x_2 and y_2 reverse their

directions. Therefore, $\chi_{C_2} = -1-1+1 = -1$. Reflecting all the vectors through the plane of the molecule, *viz.*, *YZ*, leaves y_1, y_2, y_3, z_1, z_2 and z_3 unaltered whereas x_1, x_2 and x_3 reverse in direction giving $\chi_{\sigma_{v(YZ)}} = 6-3=3$. Similarly, reflecting all the vectors through *XZ* plane, leaves x_2 and z_2 unaltered whereas y_2 reverses in direction giving $\chi_{\sigma_{v(XZ)}} = 2-1 = 1$. An identity operation will leave all the vectors unchanged in position as well as in direction so that $\chi_E=9$. The representation thus obtained is shown below :

	E	C_2	$\sigma_{v(YZ)}$	$\sigma_{v(XZ)}$
Γ	9	-1	3	1

Proceeding as above, we can write the following representation of C_{2v} point group for the symmetric stretching mode of vibration of H_2O molecule.

	E	C_2	$\sigma_{v(YZ)}$	$\sigma_{v(XZ)}$
Γ	3	1	3	1



(*YZ* is the plane of the molecule as already shown)

However, all the representations written above in terms of characters of matrices corresponding to the various symmetry operations of C_{2v} point group are made up of some finite number of fundamental representations. The representations which are additions of two or more fundamental representations of a symmetry point group are known as **reducible representations** of that point group. The fundamental representations which cannot be reduced (or cannot be broken up) further into simpler representations are called **irreducible representations.**

We shall now discuss the rules with the help of which we can determine the number of fundamental or irreducible representations of any symmetry point group. These rules are :

1. The number of irreducible representations in a group is equal to the number of classes of symmetry operations of the group.

2. The sum of the squares of dimensions of irreducible representations of a point group is equal to the order of the group. Since the square matrix representing the identity operation has all diagonal elements equal to 1, the character under column E of an irreducible representation is obviously equal to the dimension of each matrix of that representation.

3. The sum of the squares of characters of an irreducible representation is equal to the order of the group.

4. In a given representation (reducible or irreducible), the characters of matrices belonging to the symmetry operations in the same class are identical.

5. The two vectors whose components are characters of two different irreducible representations are orthogonal, *i.e.*,

$$\sum_R \chi_{i(R)}\chi_{j(R)} = 0 \qquad ...(1)$$

where R is symmetry operation of the group ; χ_i and χ_j are characters of the same symmetry operation R in ith and jth representations. Alternatively, the sum of the products of characters under each symmetry operation of any two irreducible representations of a group is equal to zero.

Let us find out irreducible representations of some simple symmetry point groups with the help of the above mentioned rules. We shall first of all consider a C_{2v} group. The symmetry operations that are possible in this case are E, C_2, σ_v and σ_v'. It can be seen that each of these operations is a distinct class in itself. Thus, there are four irreducible representations of the symmetry operations in this group. Since $l_1^2 + l_2^2 + l_3^2 + l_4^2 = 4$, hence, $l_1^2 = l_2^2 = l_3^2 = l_4^2 = 1$ (l represents the dimension of matrix of irreducible representation).

Also in each irreducible representation,

$$\chi^2_E + \chi^2_{C_2} + \chi^2_{\sigma_v} + \chi^2_{\sigma_v'} = 4$$

Therefore, χ for each operation in any irreducible representation is ± 1. One of the representations is obviously as given below :

	E	C_2	σ_v	σ_v'
Γ_1	1	1	1	1

The other representations should be such that

$$\chi_{1E}\chi_{iE} + \chi_{1C_2}\chi_{iC_2} + \chi_{1\sigma_v}\chi_{i\sigma_v} + \chi_{1\sigma_v'}\chi_{i\sigma_v'} = 0$$

Since χ under E is always positive, therefore, two of the remaining three χ_is (*viz.*, χ_{iC_2}, $\chi_{i\sigma_v}$ and $\chi_{i\sigma_v'}$) should be -1. Accordingly, the other three representations are :

	E	C_2	σ_v	σ_v'
Γ_2	1	-1	-1	1
Γ_3	1	-1	1	-1
Γ_4	1	1	-1	-1

Let us now consider C_{3v} point group. Its symmetry operations are : E, two C_3s and three σ_vs. There are three classes of these symmetry operations. Hence there are three irreducible representations in this group. Since $l_1^2 + l_2^2 + l_3^2 = 6$, therefore, l_1^2, l_2^2 and l_3^2 are, respectively, 1, 1 and 2 ($1^2 + 1^2 + 2^2 = 6$). The two representations of dimensions 1 should have $\chi_E^2 + 2\chi_{C_3}^2 + 3\chi_{\sigma_v}^2 = 6$. Since $\chi^2_E = 1$, hence, χ_E, χ_{C_3} and χ_{σ_v} can each be either $+1$ or -1 and the two representations should be

	E	$2C_3$	$3\sigma_v$
Γ_1	1	1	1
Γ_2	1	1	-1

It can be seen that the two representations are orthogonal to each other since $1\times1 + 2\times1\times1 + 3\times1\times(-1) = 0$. The third representation Γ_3 is of dimension 2. Therefore, χ_E for this representation is 2. Since Γ_3 and Γ_1 are orthogonal to each other as are Γ_2 and Γ_3, therefore,

$$1\times2 + 2\times1\times a + 3\times1\times b = 0$$
$$1\times2 + 2\times1\times a + 3\times(-1)\times b = 0$$

where a and b are, respectively, χ_{C_3} and χ_{σ_v} of the third representation.

$\therefore$ $$2a + 3b = -2$$

and $$2a - 3b = -2$$

From the above two equations, we get $a = -1$ and $b = 0$. Therefore, the third representation is :

	E	$2C_3$	$3\sigma_v$
Γ_3	2	-1	0

so that the complete set of irreducible representations of C_{3v} point group is as follows :

	E	$2C_3$	$3\sigma_v$
Γ_1	1	1	1
Γ_2	1	1	-1
Γ_3	2	-1	0

As mentioned above, the number of irreducible representations of a point group is fixed but one can write a large number of reducible representations which are, in fact, additions of some irreducible representations.

Suppose ε, A, B, C,..... are matrices which represent symmetry operations of a **reducible** representation. In order to find irreducible representations which add up to give the reducible representation,

we diagonalise each and every matrix of the representation through similarity transformation, by a suitable matrix X, also of the representation, as shown below :

$$X^{-1}\varepsilon X = \varepsilon_1 = \begin{bmatrix} \boxed{\varepsilon'} & & \\ & \boxed{\varepsilon''} & \\ & & \boxed{\varepsilon'''} \end{bmatrix}, \qquad X^{-1}AX = A_1 = \begin{bmatrix} \boxed{A'} & & \\ & \boxed{A''} & \\ & & \boxed{A'''} \end{bmatrix},$$

$$X^{-1}BX = B_1 = \begin{bmatrix} \boxed{B'} & & \\ & \boxed{B''} & \\ & & \boxed{B'''} \end{bmatrix}, \qquad X^{-1}CX = C_1 = \begin{bmatrix} \boxed{C'} & & \\ & \boxed{C''} & \\ & & \boxed{C'''} \end{bmatrix}$$

Then the set of submatrices ε', A', B', C',..... forms an irreducible representation contained in the reducible representation ε, A, B, C,..... . Similarly, (ε'', A'', B'', C'',....), (ε''', A''', B''', C''',....), etc., are irreducible representations contained in the reducible representation ε, A, B, C,..... .

But, in actual practice, we need not follow the above mentioned cumbersome procedure to 'reduce' a reducible representation into irreducible representation. A convenient correlation, *viz.*,

$$a_i = \frac{1}{h}\left[\sum_R \chi_{(R)}\,\chi_{i(R)}\right] \qquad ...(2)$$

can be derived in which a_i is the number of times the ith irreducible representation occurs in the reducible representation. $\chi_{(R)}$ and $\chi_{i(R)}$ are the characters of matrices representing symmetry operation R in the reducible representation and the ith irreducible representation, respectively. The symbol h stands for the order of the group.

We shall illustrate the procedure of reducing a reducible representation into irreducible representations by taking into consideration the reducible representations of C_{2v} point group already given and reproduced below for convenience of reference :

C_{2v}	E	C_2	$\sigma_{v(YZ)}$	$\sigma_{v(XZ)}$
Γ_1	1	1	1	1
Γ_2	1	-1	-1	1
Γ_3	1	-1	1	-1
Γ_4	1	1	-1	-1
Γ_{red_1}	3	1	3	1
Γ_{red_2}	9	-1	3	1

Let us first determine Γ_{red_1}. Using the correlation given above (Eq. 2), we have

$$a_1 = 1/4\,[3\times1 + 1\times1 + 3\times1 + 1\times1] = 2$$
$$a_2 = 1/4\,[3\times1 + 1\times(-1) + 3\times(-1) + 1\times1] = 0$$
$$a_3 = 1/4\,[3\times1 + 1\times(-1) + 3\times1 + 1\times(-1)] = 1$$
$$a_4 = 1/4\,[3\times1 + 1\times1 + 3\times(-1) + 1\times(-1)] = 0$$

Thus, Γ_{red_1} contains Γ_1 two times and Γ_3 one time. Hence, $\Gamma_{red_1} = 2\Gamma_1 + \Gamma_3$.

We can check the correctness of our result by adding characters of Γ_1 twice and of Γ_3 once :

C_{2v}	E	C_2	$\sigma_{v(YZ)}$	$\sigma_{v(ZX)}$
Γ_1	1	1	1	1
Γ_1	1	1	1	1
Γ_3	1	-1	1	-1
Γ_{red_1}	3	1	3	1

Similarly, we can show that $\Gamma_{red_2} = 3\Gamma_1 + 2\Gamma_2 + 3\Gamma_3 + \Gamma_4$

Character Tables

Character tables drawn for various symmetry point groups are widely used for various puposes. These tables are known to have the following characteristics :

1. Each character table is divided into four parts.

2. The **first part** which consists of a single vertical column contains Mulliken's symbols such as A, B, E, T in place of Γ_1, Γ_2, Γ_3, etc., for designating the various irreducible representations. A one-dimensional representation is designated as A or B, a two-dimensional as E and a three-dimensional as T. A one-dimensional representation which is symmetric with respect to the principal axis of symmetry (*i.e.*, $\chi_{C_n} = +1$) is labelled as A while the representation which is antisymmetric with respect to the principal axis of symmetry (*i.e.*, $\chi_{C_n} = -1$) is labelled as B.

If a representation is symmetric with respect to C_2 axis which is perpendicular to the principal axis (*i.e.* $\chi_{C_2} = +1$), then, numeral 1 is put as subscript to the label. If, on the other hand, the representation is antisymmetric with respect to such an axis (*i.e.*, $\chi_{C_2} = -1$), then, 2 is put as subscript to the label. If there is no such C_2 axis, then subscript 1 is put to the label of the representation which is symmetric with respect to σ_v ($\chi_{\sigma_v} = +1$) and subscript 2 is put to the label of that representation which is antisymmetric with respect to σ_v ($\chi_{\sigma_v} = -1$).

Single prime (′) is put to the label of a representation if it is symmetric ($\chi_{\sigma_h} = +1$) and a double prime (″) if it is antisymmetric ($\chi_{\sigma_h} = -1$) with respect to σ_h.

Subscript g is put to the label if the representation is symmetric ($\chi_i = +1$) and u if it is antisymmetric ($\chi_i = -1$) with respect to inversion centre.

The employment of subscripts 1 and 2 for symbols E and T is based on certain rules, the discussion of which is beyond the scope of the book.

3. The **second part** of the table contains characters of the irreducible representations.

4. The **third part** contains symbols x, y, z, R_x, R_y and R_z. These symbols indicate how the vectors x, y, z and the rotations around the X, Y and Z axes, *i.e.*, R_X, R_Y and R_Z, transform.

5. The **fourth part** gives us information about the transformation characteristics of quadratic functions.

A character table for C_{3v} symmetry point group is given below :

Character Table for C_{3v} Symmetry Point Group

C_{3v}	E	$2C_3$	$3\sigma_v$		
A_1	1	1	1	z	x^2+y^2, z^2
A_2	1	1	-1	R_z	
E	2	-1	0	(x, y) (R_x, R_y)	(x^2-y^2, xy) (xz, yz)

If the principal axis C_3 is taken to be collinear with Z axis, then σ_v, by definition, passes through Z axis. The z coordinate of the point (x, y, z), therefore, remains unchanged under E, C_3 or σ_v operations.

In other words, $E[z] = [1][z]$, $C_3[z] = [1][z]$ and $\sigma_v[z] = [1][z]$. Hence, z forms the basis of irreducible representation which has $\chi_E = 1$, $\chi_{C_3} = 1$ and $\chi_{\sigma_v} = 1$. Such a representation, as is clear from the table, is A_1. Similarly, it can be shown that x and y *together* form the basis of the irreducible representation E of C_{3v} point group.

It also follows from the table that x^2-y^2 and xy together form the basis of irreducible representation E of C_{3v} point group. Similarly, xz and yz together form the basis of representation E.

WAVE FUNCTIONS AS BASIS OF IRREDUCIBLE REPRESENTATIONS

Consider the wave equation $H\psi_i = E_i\psi_i$ where ψ_i is a non-degenerate eigen wave function of a system, E_i is the energy (eigen value) and H is Hamiltonian operator which is obtained by considering the kinetic and potential energy of the system. Suppose R is the symmetry operation to be applied on the system so that $R\psi_i$ becomes the wave function of the system after applying R on it. Since on applying R, an equivalent configuration which is physically indistinguishable from the original configuration of the system is obtained, therefore, the energy E_i and the energy operator H remain unchanged. The wave equation, after applying R on the system, becomes

$$HR\psi_i = E_iR\psi_i$$

But, $R\psi_i$ must be normalised in order that it is an eigen function. Hence,

$$\int_{-\infty}^{+\infty} R\psi_i^* R\psi_i \, d\tau = 1 \quad \text{or} \quad R^2 \int_{-\infty}^{+\infty} \psi_i^* \psi_i \, d\tau = 1$$

Since ψ_i is already normalised, hence, $R^2 = 1$ or $R = \pm 1$. Thus, we can write $R\psi_i = [+1]\psi_i$ or $[-1]\psi_i$. In other words, R (or, any symmetry operation of the system) can be represented by the matrix $[+1]$ or $[-1]$. Thus, ψ_i forms the basis of (or transforms as) irreducible representation in which R can be represented as $[+1]$ or $[-1]$. Therefore, χ_R can be represented as either $+1$ or -1.

We shall now show that a set of real or complex degenerate wave functions also forms the basis of (or transform as) irreducible representation of a symmetry point group. Let us consider a specific example of a set of degenerate p orbital wave functions which may be represented as

$$p_x = R_{(r)}\sqrt{3/4\pi}\,\sin\theta\cos\phi$$

$$p_y = R_{(r)}\sqrt{3/4\pi}\,\sin\theta\sin\phi$$

$$p_z = R_{(r)}\sqrt{3/4\pi}\,\cos\theta$$

The correlation between polar coordinates (r, θ, ϕ) and Cartesian coordinates (x, y, z) of a point is as shown in Fig. 9.

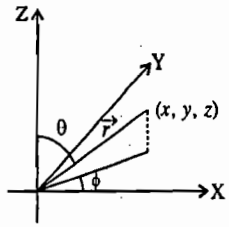


Fig. 9. Correlation between Cartesian coordinates (x, y, z) and polar coordinates (r, θ, ϕ).

Let us apply the symmetry operation of C_{3v} point group on the above set of p orbital wave functions. Accordingly,

$$E(p_x) = p_x; \quad E(p_y) = p_y; \quad E(p_z) = p_z$$

It can be easily visulalised that

$$C_{3(Z)}(p_x) = R_{(r)}\sqrt{3/4\pi}\,\sin\theta\cos(\phi + 120°)$$

$$= -1/2\, R_{(r)}\sqrt{3/4\pi}\,\sin\theta\cos\phi - \sqrt{3/2}\, R_{(r)}\sqrt{3/4\pi}\,\sin\theta\sin\phi = -1/2\, p_x - \sqrt{3/2}\, p_y$$

$$C_{3(Z)}(p_y) = R_{(r)}\sqrt{3/4\pi}\,\sin\theta\sin(\phi + 120°)$$

$$= \sqrt{3/2}\, R_{(r)}\sqrt{3/4\pi}\,\sin\theta\cos\phi - 1/2\, R_{(r)}\sqrt{3/4\pi}\,\sin\theta\sin\phi = \sqrt{3/2}\, p_x - 1/2\, p_y$$

and $C_{3(Z)}(p_z) = p_z$

It may be noted that the $C_{3(Z)}$ operation leaves θ unchanged. It, however, changes ϕ to $(\phi + 120°)$].

Since $\sigma_{v(XZ)}$ operation leaves θ unaltered and changes ϕ to $-\phi$, hence,

$$\sigma_{v(XZ)}\ p_x = R_{(r)}\sqrt{3/4\pi}\ \sin\theta\cos(-\phi) = R_{(r)}\sqrt{3/4\pi}\ \sin\theta\cos\phi = p_x$$

$$\sigma_{v(XZ)}\ p_y = R_{(r)}\sqrt{3/4\pi}\ \sin\theta\sin(-\phi) = -R_{(r)}\sqrt{3/4\pi}\ \sin\theta\ \sin\phi = -p_y$$

$$\sigma_{v(XZ)}\ p_z = R_{(r)}\sqrt{3/4\pi}\ \cos\theta = p_z$$

Thus, we observe that each one of p_x and p_y wave functions transforms into a mixed wave function of p_x and p_y on applying the symmetry operations and they have to be considered together. The wave function p_z, however, transforms into p_z by applying all the symmetry operations of the group. It follows from the above equations, therefore, that

$$E\begin{bmatrix}p_x\\p_y\end{bmatrix} = \begin{bmatrix}1 & 0\\0 & 1\end{bmatrix}\begin{bmatrix}p_x\\p_y\end{bmatrix}; \qquad \therefore\ E = \begin{bmatrix}1 & 0\\0 & 1\end{bmatrix} \text{ and } \chi_E = 2. \text{ Accordingly,}$$

(i) $$C_{3(Z)}\begin{bmatrix}p_x\\p_y\end{bmatrix} = \begin{bmatrix}-1/2 & -\sqrt{3}/2\\ \sqrt{3}/2 & -1/2\end{bmatrix}\begin{bmatrix}p_x\\p_y\end{bmatrix} \text{ and hence, } C_{3(Z)} = \begin{bmatrix}-1/2 & -\sqrt{3}/2\\ \sqrt{3}/2 & -1/2\end{bmatrix} \text{ so that } \chi_{C_{3(Z)}} = -1$$

(ii) $$\sigma_{v(XZ)}\begin{bmatrix}p_x\\p_y\end{bmatrix} = \begin{bmatrix}1 & 0\\0 & -1\end{bmatrix}\begin{bmatrix}p_x\\p_y\end{bmatrix} \text{ and hence, } \sigma_{v(XZ)} = \begin{bmatrix}1 & 0\\0 & -1\end{bmatrix} \text{ so that } \chi_{\sigma_{v(XZ)}} = 0$$

In other words, p_x and p_y together form the basis of E representation of C_{3v} point group (or p_x and p_y together transform as E representation of the group).

Also $E[p_z] = [1][p_z]$; $C_{3(Z)}[p_z] = [1][p_z]$; $\chi_{\sigma_{v(XZ)}}[p_z] = [1][p_z]$. Thus, $\chi_E = 1$, $\chi_{C_3(Z)} = 1$ and $\chi_{\sigma_{v(XZ)}} = 1$. Hence, p_z transforms as A_1 representation of C_{3v} symmetry point group. Similarly, by taking sets of real d orbital or f orbital wave functions, it can be shown that they too transform as irreducible representation of the point group to which the system belongs.

We arrive at similar type of result if instead of taking real degenerate wave functions, we take into consideration a set of complex degenerate wave functions. Consider, for instance, the following complex wave functions of p orbitals :

$$p_{+1} = R_{(r)}\,\Theta_1^{+1}\,1/\sqrt{2\pi}\ e^{i\phi}$$

$$p_{-1} = R_{(r)}\,\Theta_1^{-1}\,1/\sqrt{2\pi}\ e^{i\phi}$$

$$p_0 = R_{(r)}\,\Theta_1^{0}\,1/\sqrt{2\pi}\ e^{0}$$

Applying symmetry operations of the group (keeping in mind that Θ_1^{+1} and Θ_1^{-1} are identical), we get the following results :

$$E\begin{bmatrix}p_{+1}\\p_{-1}\end{bmatrix} = \begin{bmatrix}1 & 0\\0 & 1\end{bmatrix}\begin{bmatrix}p_{+1}\\p_{-1}\end{bmatrix} \text{ and}$$

$$\sigma_{v(XZ)}\begin{bmatrix}p_{+1}\\p_{-1}\end{bmatrix} = \begin{bmatrix}R_{(r)}(\Theta)_1^{+1}\,1/\sqrt{2\pi}\,e^{-i\phi}\\R_{(r)}(\Theta)_1^{-1}\,1/\sqrt{2\pi}\,e^{+i\phi}\end{bmatrix} = \begin{bmatrix}p_{-1}\\p_{+1}\end{bmatrix} = \begin{bmatrix}0 & 1\\1 & 0\end{bmatrix}\begin{bmatrix}p_{+1}\\p_{-1}\end{bmatrix} \qquad (\because \Theta_1^{+1} = \Theta_1^{-1})$$

($\sigma_{v(XZ)}$ transforms angle ϕ into $-\phi$ but it leaves angle θ unaltered)

Hence, $$E = \begin{bmatrix}1 & 0\\0 & 1\end{bmatrix} \text{ and } \chi_E = 2 \quad ; \quad \sigma_{v(XZ)} = \begin{bmatrix}0 & 1\\1 & 0\end{bmatrix} \text{ and } \chi_{\sigma_{v(XZ)}} = 0$$

Since rotation through 120° (or $2\pi/3$ radian), around Z axis changes ϕ to $\phi + 2\pi/3$ and leaves θ

unaltered, hence,

$$C_{3(Z)}\begin{bmatrix}p_{+1}\\p_{-1}\end{bmatrix} = \begin{bmatrix}R_{(r)}(\Theta)_1^{+1}\,1/\sqrt{2\pi}\,e^{+i\phi}e^{i2\pi/3} + 0\,R(\Theta)_1^{-1}\,1/\sqrt{2\pi}\,e^{-i\phi}\\ 0\,R(\Theta)_1^{+1}\,1/\sqrt{2\pi}\,e^{+i\phi} + R(\Theta)_1^{-1}\,1/\sqrt{2\pi}\,e^{-i\phi}e^{-i2\pi/3}\end{bmatrix}$$

$$= \begin{bmatrix}p_{+1}e^{i2\pi/3} + 0\,p_{-1}\\ 0\,p_{+1} + p_{-1}e^{-i2\pi/3}\end{bmatrix} = \begin{bmatrix}e^{i2\pi/3} & 0\\0 & e^{-i2\pi/3}\end{bmatrix}\begin{bmatrix}p_{+1}\\p_{-1}\end{bmatrix}$$

and hence $\chi_{C_3} = e^{i2\pi/3} + e^{-i2\pi/3} = -1$ $\qquad (\because e^{ix} = \cos x + i\sin x)$

Thus, p_{+1} and p_{-1} together transform as E representation of C_{3v} point group.

Also $E[p_0] = [1][p_0]$; $C_{3(Z)}[p_0] = [1][p_0]$ and $\sigma_{v(XZ)}[p_0] = [1][p_0]$, therefore, $\chi_E = 1$; $\chi_{C_3} = 1$ and $\chi_{\sigma_v} = 1$. Thus, p_0 transforms as A_1 representation of the group.

Direct Products of Matrices

The direct product of two square matrices A and B of dimensions 1 and m, respectively, is a square matrix of dimension $1\times m$. The character of the direct product matrix is the product of characters of A and B. *It is to be noted that the direct product of matrices is different from the product of matrices.* Since in a representation we mention the character of matrices representing symmetry operations of the point group, the representation due to direct product of Γ_a and Γ_b is obtained by multiplying characters, under each symmetry operation, of the representations Γ_a and Γ_b. Similarly, the representation due to direct product of Γ_a, Γ_b and Γ_c is obtained by multiplying characters, under each symmetry operation, of the representations Γ_a, Γ_b and Γ_c.

Various representations obtained from the direct products of the irreducible representations of C_{3v} point group are given below :

C_{3v}	E	$2C_3$	$3\sigma_v$
A_1	1	1	1
A_2	1	1	-1
E	2	-1	0
$A_1 \times A_2\ (= A_2)$	1×1	1×1	$1\times(-1)$
$A_2 \times A_2\ (= A_1)$	1×1	1×1	$(-1)\times(-1)$
$E \times A_1\ (= E)$	2×1	$(-1)\times 1$	0×1
$E \times E\ (= E + A_1 + A_2)$	2×2	$(-1)(-1)$	0×0
$A_1 \times A_2 \times E\ (= E)$	$1\times 1\times 2$	$1\times 1\times(-1)$	$1\times(-1)\times 0$

The direct products of representations (or, in brief, direct products) are reducible (or irreducible) representations of the group. From the data given in the above table, it can be easily worked out that $A_1\times A_1 = A_1$, $A_1\times A_2 = A_2$, $A_2\times A_2 = A_1$, $E\times A_1 = E$ and $A_1\times A_2\times E = E$. It should be remembered that if f_a and f_b are the functions which form the basis of irreducible representations Γ_a and Γ_b, respectively, of the group, then the function $f_a f_b$ forms the basis of (or transforms as) the direct product representation $\Gamma_a \times \Gamma_b$.

APPLICATIONS OF GROUP THEORY

We shall, briefly, discuss only those applications of group theory which are of interest to inorganic chemistry students. These applications are :

1. Evaluation of Integrals 2. Explanation of Allowed and Forbidden Electronic Transitions 3. Hybridisation of Atomic Orbitals 4. Nature of Bonding in Octahedral and Tetrahedral Complexes 5. Energy Terms in Octahedral Complexes 6. Splitting of Orbitals and Terms in a Chemical Environment 7. Relaxation of Selection Rules for Electronic Transitions 8. Establishing States of Symmetry by the Method of Descending Symmetry and 9. Study of Electron Absorption Spectra using Plane Polarised Light.

1. Evaluation of Integrals

In wave mechanics we frequently come across integrals of the type $\int \psi_a \psi_b \, d\tau$ and $\int \psi_a \psi_b \psi_c \, d\tau$. Most of the times we are only interested in finding out whether these integrals are zero or non-zero. Group theory gives us a quick procedure to find out that. The integral $\int_{-\infty}^{+\infty} f_a f_b \, d\tau$ will be zero unless the integrand $f_a f_b$ is invariant (or a term in it remains invariant) under all the symmetry operations of the point group to which the system belongs. In other words, $f_a f_b$ (or a term in it) should form the basis of a totally symmetric representation in order that $\int_{-\infty}^{+\infty} f_a f_b \, d\tau$ is non-zero. That is, each $R(f_a f_b)$ should be equal to $[+1](f_a f_b)$. In other words, $f_a f_b$ should form the basis of that irreducible representation which contains $\chi_R = +1$ for every symmetry operation of the group. An A_1 representation has a character of $+1$ under all symmetry operations of the group. In other words, A_1 remains invariant under all symmetry operations of the group and hence is a totally symmetric representation.

As already explained, the representation to which $f_a f_b$ forms the basis, can be obtained from the direct product of Γ_a and Γ_b. Thus, the direct product of Γ_a and Γ_b should either be totally symmetric representation A_1 or should contain A_1 irreducible representation of the point group in order that the integral $\int_{-\infty}^{+\infty} f_a f_b \, d\tau$ is non-zero. Similarly, the integral $\int_{-\infty}^{+\infty} f_a f_b f_c \, d\tau$ is non-zero if the direct product of Γ_a, Γ_b and Γ_c is either equal to A_1 or contains A_1 irreducible representation of the point group.

2. Explanation of Allowed and Forbidden Electronic Transitions

As discussed in Chapter 30, the intensity of an electronic transition is directly related to transition moment integral Q which is equal to $\int_{-\infty}^{+\infty} \psi_{1elec} [\vec{M}] \psi_{2elec} \, d\tau$ where M is dipole moment operator and is a vector quantity. It can be resolved into three components $\vec{M}_x, \vec{M}_y$ and $\vec{M}_z$ along X, Y and Z directions. Thus,

$$Q = \int_{-\infty}^{+\infty} \psi_{1elec} \, |\vec{M}| \, \psi_{2elec} \, dt = \int_{-\infty}^{+\infty} \psi_{1elec} \, |\vec{M}_x + \vec{M}_y + \vec{M}_z| \, \psi_{2elec} \, dt$$

$$= \int_{-\infty}^{+\infty} \psi_{1elec} \, |\vec{M}_x| \, \psi_{2elec} \, dt + \int_{-\infty}^{+\infty} \psi_{1elec} \, |\vec{M}_y| \, \psi_{2elec} \, dt + \int_{-\infty}^{+\infty} \psi_{1elec} \, |\vec{M}_z| \, \psi_{2elec} \, dt$$

In order that an electronic transition is allowed, Q should be non-zero. That is, one of the three integrals on the right hand side of the above equation should be non-zero. In other words, the integrand in at least one of the three integrals should be totally symmetric, *i.e.*, the direct product corresponding to the integrands in at least one of the three integrals should be A_1 (or should contain A_1).

Let us consider $e-t_2^*$ transition in a tetrahedral complex (cf. Fig. 20, Chapter 27). The character table drawn for T_d point group is given below :

Character Table for T_d Point Group

Td	E	$8C_3$	$3C_2$	$6S_4$	$6\sigma_d$		
A_1	1	1	1	1	1		$x^2+y^2+z^2$
A_2	1	1	1	-1	-1		
E	2	-1	2	0	0		$(2z^2-x^2-y^2, x^2-y^2)$
T_1	3	0	-1	1	-1	(R_x, R_y, R_z)	
T_2	3	0	-1	-1	1	(x, y, z)	(xy, xz, yz)

It can be easily shown that d_{z^2} orbital wave function is, in fact, the function of $2z^2 - x^2 - y^2$. It is thus evident from the table, that $(d_{z^2}, d_{x^2-y^2})$ set of orbitals transforms as E representation and (d_{xy}, d_{xz}, d_{yz}) set transforms as T_2 representation. $\vec{M}_x, \vec{M}_y, \vec{M}_z$ which point towards x, y and z

directions, *together* transform as T_2 representation. Thus, the direct product of the functions in the integrand of Q, *i.e.*, $\psi_e |\vec{M}_x + \vec{M}_y + \vec{M}_z| \psi_{t_2^*}$ is $E \times T_2 \times T_2$ which reduces to $2T_1 + 2T_2 + 2E + A_2 + A_1$ and evidently contains the totally symmetric representation A_1. Thus, Q is non-zero and the electronic transition $e-t_2^*$ is symmetry allowed.

In molecules with a centre of symmetry, the totally symmetric representation, which has $\chi_R = +1$ for each symmetry operation R of the point group is A_{1g}. Therefore, in order that Q is non-zero, the direct product of the functions in the integrand must be either A_{1g} or contain a term A_{1g}. Also, since $g \times u \times g = u$, all $d-d$ transitions (which are, in fact, $g-g$ transitions) are forbidden because the direct product of the functions in the integrand Q must necessarily contain all representations of u type (as explained in Chapter 29).

Let us consider the electronic transition $t_{2g} - t_{1u}^*$ in an octahedral complex which, in effect, is essentially a $d-p$ transition. The integral Q in this case is given by

$$Q = \int_{-\infty}^{+\infty} \psi_{t_{2g}} \, |\vec{M}_x + \vec{M}_y + \vec{M}_z| \, \psi_{t_{1u}} \, d\tau$$

The components $\vec{M}_x$, $\vec{M}_y$, $\vec{M}_z$ of the dipole moment vector are similar to $\vec{x}$, $\vec{y}$ and $\vec{z}$ vectors and they together transform as T_{1u} representation in octahedral symmetry point group, as is evident from the character table for O_h point group given below :

Character Table for O_h Point Group

Oh	E	$8C_3$	$6C_2$	$6C_4$	$3C_2'$*	$i(=iE)$	$6S_4(=iC_4)$	$8S_6(=iC_3)$	$3\sigma_v(=iC_2')$	$6\sigma_d(=iC_2)$		
A_{1g}	1	1	1	1	1	1	1	1	1	1		$x^2+y^2+z^2$
A_{2g}	1	1	-1	-1	1	1	-1	1	1	-1		
E_g	2	-1	0	0	2	2	0	-1	2	0		$(2z^2-x^2-y^2, x^2-y^2)$
T_{1g}	3	0	-1	1	-1	3	1	0	-1	-1	(R_x, R_y, R_z)	
T_{2g}	3	0	1	-1	-1	3	-1	0	-1	1		(xz, yz, xy)
A_{1u}	1	1	1	1	1	-1	-1	-1	-1	-1		
A_{2u}	1	1	-1	-1	1	-1	1	-1	-1	1		
E_u	2	-1	0	0	2	-2	0	1	-2	0		
T_{1u}	3	0	-1	1	-1	-3	-1	0	1	1	(x, y, z)	
T_{2u}	3	0	1	-1	-1	-3	1	0	1	-1		

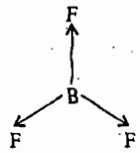
*C_2' is collinear with C_4.

The direct product of the functions in the integrand of Q in octahedral environment is $T_{2g} \times T_{1u} \times T_{1u}$ which reduces to $4T_{2g} + 3T_{1g} + 2E_g + A_{2g} + A_{1g}$. Since the direct product contains the totally symmetric representation A_{1g}, hence Q is non-zero and, therefore, the transition is symmetry-allowed.

3. Hybridistaion

Group theory is of great help in determining the atomic orbitals of the central atom of a species which can form maximum sigma overlap with orbitals of ligands in the given directions. The orbitals of the central atom then mix and give an equal number of equivalent hybrid orbitals. We shall consider examples where the central atoms utilise different types of hybrid orbitals in forming sigma bonds with the ligand orbitals.

a. Hybridisation of Atomic Orbitals of Boron in Boron trifluoride. The geometry of BF_3 molecule is plane triangular. Let us represent the directions in which the central boron atom forms sigma bonds with fluorine atoms by vectors, as shown.



If we apply on these vectors all the symmetry operations of the D_{3h} group to which BF_3 molecule belongs, we obtain the following reducible representation :

	E	$2C_3$	$3C_2$	σ_h	$2S_3$	$3\sigma_v$
Γ_{red}	3	0	1	3	0	1

It can be shown that the vector which changes position under a symmetry operation contributes nothing to the character of the matrix representing the symmetry operation. The vector which reverses in direction during a symmetry operation contributes −1 and the vector which neither changes in position nor in direction during a symmetry operation contributes +1 to the character of the matrix representing the symmetry operation.

From the character table of D_{3h} symmetry point group given below, it is clear that $\Gamma_{red} = A_1' + E'$.

Character Table for D_{3h} Point Group

D_{3h}	E	$2C_3$	$3C_2$	σ_h	$2S_3$	$3\sigma_v$		
A_1'	1	1	1	1	1	1		x^2+y^2, z^2
A_2'	1	1	−1	1	1	−1	R_z	
E'	2	−1	0	2	−1	0	(x, y)	(x^2-y^2, xy)
A_1''	1	1	1	−1	−1	−1		
A_2''	1	1	−1	−1	−1	1	z	
E''	2	−1	0	−2	1	0	(R_x, R_y)	(xz, yz)

The s orbital always transforms as a totally symmetric wave function of the point group which is A_1' in the present case. As is clear from the table given above, d_{z^2} orbital transforms as A_1', and (p_x, p_y) together or $(d_{x^2-y^2}, d_{xy})$ together transform as E'. Hence the following combinations of atomic orbitals are symmetrically most suited for forming sigma bonds in the directions of the arrows in BF_3 molecule :

$$s(a_1')+(p_x,p_y)(e');\ s(a_1')+(d_{x^2-y^2},d_{xy})(e');\ d_{z^2}(a_1')+(p_x,p_y)(e') \text{ and } d_{z^2}(a'_1)+(d_{x^2-y^2},d_{xy})(e').$$

Out of these, the combinations involving d orbitals are of higher energy. Therefore, the most suitable set of atomic orbitals of boron atom which can form sigma bonds in BF_3 molecule is $s(a_1') + (p_x, p_y)(e')$. Thus, (s, p_x, p_y) are the atomic orbitals of boron atom which hybridise to give three equivalent sp^2 hybrid orbitals which permit maximum σ overlap with orbitals of fluorine atoms.

***b.* Hybridisation of Atomic Orbitals of Phosphorus in Phosphorus penta fluoride.** The geometry of PF_5 molecule is trigonal bipyramidal. Once again we represent the directions of sigma bonds which the P atom makes with the ligands as shown in the figure. This molecule also belongs to D_{3h} symmetry point group and the reducible representation obtained in this case is as shown below :

	E	$2C_3$	$3C_2$	σ_h	$2S_3$	$3\sigma_v$
Γ_{red}	5	2	1	3	0	3

which, with the help of the character table given above for D_{3h} symmetry point group, is reduced to $2A_1'+A_2''+E'$. Thus, the set of atomic orbitals of P atom which is most suited to form sigma bonds in the directions shown in the above figure is : s, d_{z^2} (both a_1')$+p_z(a_2'')+(p_x,p_y)\,e'$. In other words, the atomic orbitals s, d_{z^2}, p_x, p_y and p_z of the central P atom hybridise to give five sp^3d hybrid orbitals which give maximum σ overlap with orbitals of fluorine atoms.

***c.* Hybridistation of Atomic Orbitals of Platinum in the Complex ion $[PtCl_4]^{2-}$.** The geometry of the complex ion is square planar. It belongs to the symmetry point group D_{4h} whose character

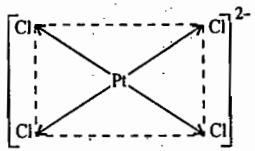


table is given below :

Character Table for D_{4h} Point Group

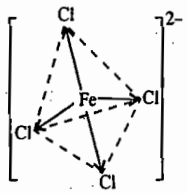
D_{4h}	E	$2C_4$	C_2	$2C_2'$	$2C_2''$	i	$2S_4$	σ_h	$2\sigma_v$	$2\sigma_d$		
A_{1g}	1	1	1	1	1	1	1	1	1	1		x^2+y^2, z^2
A_{2g}	1	1	1	−1	−1	1	1	1	−1	−1	R_z	
B_{1g}	1	−1	1	1	−1	1	−1	1	1	−1		x^2-y^2
B_{2g}	1	−1	1	−1	1	1	−1	1	−1	1		xy
E_g	2	0	−2	0	0	2	0	−2	0	0	(R_x, R_y)	(xz, yz)
A_{1u}	1	1	1	1	1	−1	−1	−1	−1	−1		
A_{2u}	1	1	1	−1	−1	−1	−1	−1	1	1	z	
B_{1u}	1	−1	1	1	−1	−1	1	−1	−1	1		
B_{2u}	1	−1	1	−1	1	−1	1	−1	1	−1		
E_u	2	0	−2	0	0	−2	0	2	0	0	(x, y)	

Following the same procedure as discussed above, we get

	E	C_4	C_2	$2C_2'$	$2C_2''$	i	$2S_4$	σ_h	$2\sigma_v$	$2\sigma_d$
Γ_{red}	4	0	0	2	0	0	0	4	2	0

Reducing the representation with the help of the above table, we get $\Gamma_{red} = A_{1g} + B_{1g} + E_u$. Thus, the orbitals of platinum atom which are symmetrically most suited for forming sigma bonds in the directions of arrows shown in the figure are either $s(a_{1g}) + d_{x^2-y^2}(b_{1g}) + p_x,p_y(e_u)$ or $d_{z^2}(a_{1g}) + d_{x^2-y^2}(b_{1g}) + (p_x,p_y)(e_u)$. Out of these two combinations, the first one is energetically more favourable. Therefore, s, $d_{x^2-y^2}$ and (p_x, p_y) orbital are most suited energetically as well as symmetrically to form sigma bonds in the required directions. Thus these four orbitals of Pt atom hybridise to give four equivalent dsp^2 or sp^2d hybrid orbitals which give maximum sigma overlap with the orbitals of the ligands.

***d.* Hybridisation of Atomic Orbitals of Fe in $[FeCl_4]^{2-}$.** The complex ion $[FeCl_4]^{2-}$ is known to have a tetrahedral geometry, as shown.



Following the same procedure as mentioned above, it can be easily shown that in a tetrahedral molecule,

	E	$8C_3$	$3C_2$	$6S_4$	$6\sigma_d$
Γ_{red}	4	1	0	0	2

From the character table of T_d symmetry point group given earlier, $\Gamma_{red} = A_1 + T_2$. Hence the combinations of atomic orbitals of Fe which are most suited to form sigma bonds in tetrahedral directions are either $s(a_1) + (p_x, p_y, p_z)(t_2)$ or $s(a_1) + (d_{xy}, d_{xz}, d_{yz})(t_2)$. Accordingly, these are the orbitals which hybridise to give four equivalent hybrid orbitals which are tetrahedrally oriented in space. Symmetry considerations predict that both the above mentioned hybridisations, *i.e.*, sp^3 and sd^3 are equally probable. Energetically, sp^3 hybridisation is more favourable, particularly for lighter atoms (such as C) because $2p$ orbitals are of considerably lower energy than $3d$ orbitals. But, in the case of transition metal atoms, the energy difference between p and d orbitals is not very large so that in tetrahedral complexes of transition metals, the sp^3 hybrid orbitals of the metal atom contain a fair amount of d orbital character as well.

***e.* Hybridisation of Atomic Orbitals of Cobalt in $[CoF_6]^{2-}$.** The complex ion $[CoF_6]^{2-}$ has an octahedral structure. By following the same procedure as described above, it can be shown that for an octahedral molecule

	E	$8C_3$	$6C_2$	$6C_4$	$3C_2(=C_4^2)$	i	$6S_4$	$8S_6$	$3\sigma_v$	$6\sigma_d$
Γ_{red}	6	0	0	2	2	0	0	0	4	2

which when reduced with the help of the character table gives $\Gamma_{red} = A_{1g} + E_g + T_{1u}$. Accordingly, the atomic orbitals of the central metal atom most suited for the formation of sigma bonds with the orbitals of the ligands in the octahedral complex are :

$$s\,(a_{1g})\ ;\ (p_x, p_y, p_z)\,(t_{1u})\ ;\ (d_{z^2}, d_{x^2-y^2})\,(e_g)$$

These six orbitals of Co atom thus hybridise to give maximum σ overlap with the orbitals of fluorine atoms. Symmetry considerations, however, do not tell whether the *d* orbitals involved in hybridisation would be inner $(n-1)d$ orbitals or outer *nd* orbitals.

4. Nature of Bonding in Octahedral and Tetrahedral Complexes

Nature of Bonding in Octahedral Complexes

Sigma Bonding. As explained earlier, the most suitable set of orbitals of the metal ion to give sigma overlap with the orbitals of the ligands in an octahedral complex is $s(a_{1g})$, $(p_x, p_y, p_z)\,(t_{1u})$ and $(d_{z^2}, d_{x^2-y^2})\,(e_g)$. Therefore, the six ligand p_σ orbital combinations forming sigma bonds with the orbitals of the metal should also be of the same symmetry, *viz.*, a_{1g}, e_g and t_{1u}.

Pi Bonding. Consider each ligand of the complex having two mutually perpendicular p_π orbitals which are together perpendicular to its p_σ orbital, as, for example, in ligands CO, F^-, Cl^-, etc. Each p_π orbital is shown by an arrow attached to each of the ligand atom positions, as shown in the figure. The head of the arrow indicates + lobe and the tale indicates – lobe of the p_π orbital. The arrows are so placed that the resultant figure retains the octahedral geometry. On applying symmetry operations of O_h symmetry point group, we get the following reducible representation :

	E	$8C_3$	$6C_2$	$6C_4$	$3C_2$	i	$6S_4$	$8S_6$	$3\sigma_v$	$6\sigma_d$
Γ_{red}	12	0	0	0	-4	0	0	0	0	0

which when reduced gives $\Gamma_{red} = T_{1u} + T_{2u} + T_{1g} + T_{2g}$. Thus, the twelve p_π orbitals of ligands will combine to give twelve ligand orbital combinations of $t_{1u} + t_{2u} + t_{1g} + t_{2g}$ symmetry which are most suited for bonding with the metal orbitals of the same symmetry. Since there are no metal orbitals with t_{2u} and t_{1g} symmetry and since t_{1u} metal orbitals are better suited for σ bonding, hence t_{2g} set of metal orbitals combine with t_{2g} ligand orbital combinations to give t_{2g}^{b} and t_{2g}^{a} π molecular orbitals.

Nature of Bonding in Tetrahedral Complexes

igma Bonding. As explained earlier, the metal orbitals which are most suited for sigma bonding in tetrahedral complexes are either $s\,(a_1)$ and $p_x, p_y, p_z(t_2)$ or $s(a_1)$ and $(d_{xy}, d_{yz}, d_{zx})t_2$. The four ligand orbitals, therefore, combine to give combinations of a_1 and t_2 symmetries. The metal and ligand orbital combinations of the same symmetry then overlap to give σ bonding and antibonding molecular orbitals, as illustrated in Chapter 4.

Pi Bonding. Let us assign individual coordinates to each atom in the tetrahedral complex AB_4, as illustrated in Fig. 10. The coordinates of B_1, B_2, B_3 and B_4 atoms are written as (x_1, y_1, z_1), (x_2, y_2, z_2), (x_3, y_3, z_3) and (x_4, y_4, z_4), respectively. Let us assume that p_z orbital of each B atom is utilised in forming A–B sigma bond. All A–B directions (*i.e.*, directions of A–B sigma bonds) are collinear with C_3 axis of symmetry. The p_x and p_y orbitals of each B atom are collinear with its *x* and *y* coordinates. The *x* coordinates of B atoms are drawn in such a manner that x_1, x_2 and the *Z* axis of the figure are in one plane where as x_3, x_4 and *Z* axis of the figure are in another plane, as shown. The p_x and p_y orbitals of each B atom

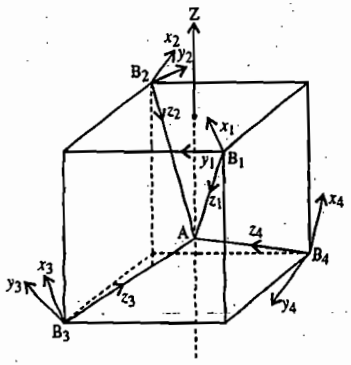


Fig.10. Individual coordinates assigned to each atom in tetrahedral complex AB_4.

are capable of forming pi bonds with the orbitals of atom A of appropriate symmetry. The pi ligand orbital combinations which are most suited to form pi bonds can be determined by following the same procedure as adopted in the case of octahedral complexes. Accordingly, Γ_{red} obtained in a tetrahedral complex is given by

	E	$8C_3$	$3C_2$	$6S_4$	$6\sigma_d$
Γ_{red}	8	-1	0	0	0

The characters of Γ_{red} for all symmetry operations except for C_3 operation can be easily determined. The two arrows x_i and y_i which signify p_{x_i} and p_{y_i} orbitals of B_i rotate at an angle of 120° around the AB_i axis (which is a C_3 axis) during a C_3 symmetry operation (B_i is any of the four ligands). It does not change its position during a C_3 operation about the AB_i axis. All the vectors of other three Bs change their positions in this operation). The new vectors x_i' and y_i', also attached to B_i, can be expressed as follows :

$$\begin{bmatrix} x_i' \\ y_i' \end{bmatrix} = C_3 \begin{bmatrix} x_i \\ y_i \end{bmatrix} = \begin{bmatrix} x_i \cos 120^\circ & -y_1 \sin 120^\circ \\ x_i \sin 120^\circ & y_i \cos 120^\circ \end{bmatrix} = \begin{bmatrix} \cos 120^\circ & -\sin 120^\circ \\ \sin 120^\circ & \cos 120^\circ \end{bmatrix} \begin{bmatrix} x_i \\ y_i \end{bmatrix}$$

Therefore, $$C_3 = \begin{bmatrix} \cos 120^\circ & -\sin 120^\circ \\ \sin 120^\circ & \cos 120^\circ \end{bmatrix} \text{ and } \chi_{C_3} = -1$$

The above result can also be obtained easily by putting $\phi = 120°$ in the already derived general relation $C_{Z(\phi)} = \begin{bmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{bmatrix}$.

It is seen from the character table drawn for the T_d symmetry point group that $\Gamma_{red} = E + T_1 + T_2$. Accordingly, the ligand orbital combinations which are most suited for pi bonding are those which have *e*, t_1 and t_2 symmetry. Since there are no metal orbitals of t_1 symmetry and t_2 set of metal orbitals are more suited for σ bonding, hence, it is only the *e* set of metal orbitals which will combine with pi ligand orbital combinations of the same symmetry to give *e* and e^* sets of pi molecular orbitals.

5. Energy Terms of Strong Field Configurations of Octahedral Complexes

In the strong field transition metal octahedral complexes, the electrostatic octahedral crystal field potential, V_{oct} is greater than inter-electronic repulsions amongst *d* electrons. Therefore, in such complexes, the weaker inter-electronic repulsion effect is considered as perturbation over stronger V_{oct} for calculating the energies of the terms. The crystal field potential, V_{oct}, splits the *d* orbitals of complexed metal ions into t_{2g} and e_g subgroups so that the strong field configurations possible for d^2 metal ions are t_{2g}^2, $t_{2g}^1\,e_g^1$ and e_g^2.

Now consider one by one the interaction between two electrons of each of the three configurations:

1. The first strong field configuration t_{2g}^2 can be considered as t_{2g}^1 configuration to which one more electron has been added. It can thus be written as $t_{2g}^1 t_{2g}^1$ and the wave function of this configuration can be written as $\Psi_{t_{2g}}\Psi_{t_{2g}}$. The direct product due to $\Psi_{t_{2g}}\Psi_{t_{2g}}$ is $T_{2g} \times T_{2g}$ which can be shown to be equal to $T_{1g} + T_{2g} + E_g + A_{1g}$ with the help of the character table of O_h point group. Thus, the energy terms which arise due to interaction between two electrons of t_{2g}^2 configuration are T_{1g}, T_{2g}, E_g and A_{1g}. It can be shown (by a complicated procedure) that complete energy terms arising out of t_{2g}^2 configuration, considering the spin multiplicities also, are $^3T_{1g}$, $^1T_{2g}$, $^1A_{1g}$ and ^1E_g. One can see that the sum of total degeneracies of all these terms is 15 (*i.e.*, $3\times3+1\times3+1\times1+1\times2$) which is also the number of electronic arrangements possible for a t_{2g}^2 configuration.

2. Now consider the second strong field configuration $t_{2g}^1\,e_g^1$ of octahedrally complexed metal ion. The wave function for this configuration can be written as $\Psi_{t_{2g}}\Psi_{e_g}$. With the help of the character table for O_h point group, the direct product $T_{2g}\times E_g$ can be shown to be equal to $T_{1g} + T_{2g}$. The complete energy terms arising out of $t_{2g}^1\,e_g^1$ configuration, considering spin multiplicities also, can be shown to be $^1T_{1g}$, $^1T_{2g}$, $^3T_{1g}$ and $^3T_{2g}$. The sum of total degeneracies of the terms of $t_{2g}^1\,e_g^1$ configuration is 12 (*i.e.*, $1\times3 + 1\times3 + 3\times3 + 3\times3$) which is also the number of electronic arrangements possible for $t_{2g}\,e_g^1$ configuration.

3. The third strong field configuration of octahedrally complexed metal ion is e_g^2, the wave function for which can be written as $\psi_{e_g}\psi_{e_g}$. The direct product $E_g \times E_g$ can be, shown to be equal to $A_{1g} + A_{2g} + E_g$. Therefore, the energy terms arising out of interaction of two electrons of e_g^2 configuration are A_{1g}, A_{2g} and E_g. The complete energy terms, considering spin multiplicities also, are $^1A_{1g}$, $^3A_{2g}$ and ^1E_g. The sum of total degeneracies of these terms is 6 (*i.e.* $1\times1 + 1\times2 + 3\times1$) which is also the number of electronic arrangements possible for e_g^2 configuration.

The total number of electronic arrangements of all the strong field configurations of octahedrally complexed metal ions are 45 (*i.e.*, 15 + 6 + 24) which is also the total number of electronic arrangements which arise out of a d^2 configuration of a free metal ion.

6. Splitting of Orbitals and Terms in a Chemical Environment

We know that according to the crystal field theory, a set of five *d* orbitals splits into t_{2g} and e_g sets in an octahedral environment and into t_2 and *e* sets in a tetrahedral environment and that a *p* set of orbitals does not split into any other sets in octahedral or tetrahedral environment. We shall make an attempt to establish the above mentioned facts by applying the group thoery to the splitting of sets of degenerate *d* orbitals into other sets in different chemical environments. We shall also apply the group theory to determine the splitting of terms of many electron systems in different chemical environments.

We start with a single electron in a set of five *d* orbitals of a metal ion under the influence of an octahedral ligand environment. We know that all the *d* orbitals are symmetric with respect to *i* so that the irreducible representations to which the *d* orbital wave functions transform in octahedral environment are only those which have a *g* subscript. It can be seen from the character table for O_h point group given earlier in this chapter that in any irreducible representation of *g* type of O_h point group, whatever is χ_{C_n} is also $\chi_{(iC_n)}$, that is, $\chi_{C_n} \equiv \chi_{iC_n}$

In order to tackle the problem in hand, it is more convenient to make use of the character table for *O* point group (given below) instead of the character table of O_h point group.

Character Table for *O* Point Group

O	E	$6C_4$	$3C_2 (= C_4^2)$	$8C_3$	$6C_2$		
A_1	1	1	1	1	1		$x^2 + y^2 + z^2$
A_2	1	−1	1	1	−1		
E	2	0	2	−1	0		$(2z^2 - x^2 - y^2, x^2 - y^2)$
T_1	3	1	−1	0	−1	(R_x, R_y, R_z) ; (x, y, z)	
T_2	3	−1	−1	0	+1		(xz, yz, xy)

We can write the character table of O_h point group by multiplying each symmetry operation of the point group *O* by the operation *i* of the O_h point group and by writing each irreducible representation of the point group *O* with a *g* as well as with a *u* subscript and by including all $\chi_{(iC_n)}$ in each irreducible representation. It should be kept in mind that, for writing irreducible representation of O_h point group from the irreducible representation of *O* group, $\chi_{(C_n)} = \chi_{(iC_n)}$ in an irreducible representation of *g* type and $\chi_{(C_n)} = -\chi_{(iC_n)}$ in an irreducible representation of *u* type (refer to character table for O_h point group given earlier.)

It can be seen from the character table for point group *O* given above that each operation in point group *O* (except for the identity operation) is a rotation operation. Consider that each rotation operation is carried around the axis from which the angle of rotation θ is measured (say, the *Z*-axis) so that no rotation operation changes the angle θ. This implies that Θ parts of the *d* orbital wave functions remain invariant

under all symmetry operations of the point group *O*. No rotation operation of point group *O* can change the magnitude of *r* so that *R*(*r*) part of the *d* orbital wave functions also remain invariant under all symmetry operations of the point group *O*. The only parts of *d* orbital wave functions which vary with the symmetry operations of point group *O* (which are all rotation operations) are those which depend upon the angle ϕ, *i.e.*, the Φ part of the wave functions. In other words, $A(R(r)\,\Theta_\theta\,\Phi_\phi) = R(r)\,\Theta_\theta\,A(\Phi_\phi)$ where *A* is any symmetry operation of the group. We shall, therefore, take into consideration only those parts of the *d* orbital wave functions which *vary* with the symmetry operations of the point group *O*. These are : $e^{i2\phi}$, $e^{i\phi}$, $e^{i0\phi}$, $e^{-i\phi}$, $e^{-i2\phi}$

(The normalising constants of Φ parts of wave functions also remain invariant under all symmetry operations and hence are not considered.)

Let us first apply the identity operation E on the variable parts of *d* orbital wave functions :

$$E\begin{bmatrix} e^{i2\phi} \\ e^{i\phi} \\ e^{i0\phi} \\ e^{-i\phi} \\ e^{-i2\phi} \end{bmatrix} = \begin{bmatrix} e^{i2\phi} \\ e^{i\phi} \\ e^{i0\phi} \\ e^{-i\phi} \\ e^{-i2\phi} \end{bmatrix} = \begin{bmatrix} 1e^{i2\phi} + 0e^{i\phi} + 0e^{i0\phi} + 0e^{-i\phi} + 0e^{-i2\phi} \\ 0e^{i2\phi} + 1e^{i\phi} + 0e^{i0\phi} + 0e^{-i\phi} + 0e^{-i2\phi} \\ 0e^{i2\phi} + 0e^{i\phi} + 1e^{i0\phi} + 0e^{-i\phi} + 0e^{-i2\phi} \\ 0e^{i2\phi} + 0e^{i\phi} + 0e^{i0\phi} + 1e^{-i\phi} + 0e^{-i2\phi} \\ 0e^{i2\phi} + 0e^{i\phi} + 0e^{i0\phi} + 0e^{-i\phi} + 1e^{-i2\phi} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} e^{i2\phi} \\ e^{i\phi} \\ e^{i0\phi} \\ e^{-i\phi} \\ e^{-i2\phi} \end{bmatrix}$$

so that $\chi_{(E)} = 5$.

The general expression for rotation operation by an angle α on the variable part of the *d* orbital wave functions can be written as :

$$C(\alpha)\begin{bmatrix} e^{i2\phi} \\ e^{i\phi} \\ e^{i0\phi} \\ e^{-i\phi} \\ e^{-i2\phi} \end{bmatrix} = \begin{bmatrix} e^{i2(\phi+\alpha)} \\ e^{i(\phi+\alpha)} \\ e^{i0(\phi+\alpha)} \\ e^{-i(\phi+\alpha)} \\ e^{-i2(\phi+\alpha)} \end{bmatrix} = \begin{bmatrix} 1e^{i2(\phi+\alpha)} + 0e^{i\phi} + 0e^{i0\phi} + 0e^{-i\phi} + 0e^{-i2\phi} \\ 0e^{i2\phi} + 1e^{i(\phi+\alpha)} + 0e^{i0\phi} + 0e^{-i\phi} + 0e^{-i2\phi} \\ 0e^{i2\phi} + 0e^{i\phi} + 1e^{i0(\phi+\alpha)} + 0e^{-i\phi} + 0e^{-i2\phi} \\ 0e^{i2\phi} + 0e^{i\phi} + 0e^{i0\phi} + 1e^{-i(\phi+\alpha)} + 0e^{-i2\phi} \\ 0e^{i2\phi} + 0e^{i\phi} + 0e^{i0\phi} + 0e^{-i\phi} + 1e^{-i2(\phi+\alpha)} \end{bmatrix}$$

$$= \begin{bmatrix} e^{i2\alpha} & 0 & 0 & 0 & 0 \\ 0 & e^{i\alpha} & 0 & 0 & 0 \\ 0 & 0 & e^{i0\alpha} & 0 & 0 \\ 0 & 0 & 0 & e^{-i\alpha} & 0 \\ 0 & 0 & 0 & 0 & e^{-i2\alpha} \end{bmatrix} \begin{bmatrix} e^{i2\phi} \\ e^{i\phi} \\ e^{i0\phi} \\ e^{-i\phi} \\ e^{-i2\phi} \end{bmatrix} \quad \text{or} \quad C(\alpha) = \begin{bmatrix} e^{i2\alpha} & 0 & 0 & 0 & 0 \\ 0 & e^{i\alpha} & 0 & 0 & 0 \\ 0 & 0 & e^{i0\alpha} & 0 & 0 \\ 0 & 0 & 0 & e^{-i\alpha} & 0 \\ 0 & 0 & 0 & 0 & e^{-i2\alpha} \end{bmatrix}$$

The character of such a matrix representing $C(\alpha)$ rotation operation on the variable parts of the *d* orbital wave functions is of the general form :

$$\chi_{C(\alpha)} = \frac{\sin\left(l + \frac{1}{2}\right)\alpha}{\sin(\alpha/2)} \qquad (\alpha \neq 0, 2\pi, 4\pi, \text{etc.})$$

For the d orbital wave functions, $l = 2$. Hence,

$$\chi_{C(\alpha)} = \frac{\sin\frac{5\alpha}{2}}{\sin\frac{\alpha}{2}} \quad \text{and} \quad \chi_{C_2} = \frac{\sin\frac{5\pi}{2}}{\sin\frac{\pi}{2}} = 1 \qquad (\because \alpha = \pi)$$

Similarly,

$$\chi_{C_3} = \frac{\sin\left(\frac{5}{2}\times\frac{2\pi}{3}\right)}{\sin\left(\frac{2\pi}{3}\times\frac{1}{2}\right)} = \frac{\sin\frac{5\pi}{3}}{\sin\frac{\pi}{3}} = -1 \ (\because \alpha = 2\pi/3)$$

$$\text{and } \chi_{C_4} = \frac{\sin\left(\frac{5}{2}\times\frac{\pi}{2}\right)}{\sin\left(\frac{\pi}{2}\times\frac{1}{2}\right)} = \frac{\sin\frac{5\pi}{4}}{\sin\frac{\pi}{4}} = \frac{-1/\sqrt{2}}{1/\sqrt{2}} = -1 \qquad (\because \alpha = \pi/2)$$

Thus, the representation obtained on applying all symmetry operations on variable parts of the d orbital wave functions is written as :

	E	$+\ 6C_4$	$+\ 3C_2 (= C_4^2)$	$8C_3$	$6C_2$
Γ_{red}	5	−1	1	−1	1

On reducing the representation, we find that

$$A_1 \text{ occurs } \frac{5\times1\times1+(-1)\times1\times6+1\times1\times3+(-1)\times1\times8+1\times1\times6}{24} = 0 \text{ time}$$

$$A_2 \text{ occurs } \frac{5\times1\times1+(-1)(-1)\times6+1\times1\times3+(-1)\times1\times8+1\times(-1)\times6}{24} = 0 \text{ time}$$

$$E \text{ occurs } \frac{5\times2\times1+(-1)\times0\times6+1\times2\times3+(-1)(-1)\times8+1\times0\times6}{24} = 1 \text{ time}$$

$$T_1 \text{ occurs } \frac{5\times3\times1+(-1)\times1\times6+1\times(-1)\times3+(-1)\times0\times8+1\times(-)\times6}{24} = 0 \text{ time}$$

$$T_2 \text{ occurs } \frac{5\times3\times1+(-1)(-1)\times6+1\times(-1)\times3+(-1)\times0\times8+1\times1\times6}{24} = 1 \text{ time}$$

Thus, $\Gamma_{red} = E + T_2$ for a single-electron d orbital wave function in point group O. Since all d orbitals have a centre of symmetry, hence $E + T_2$ irreducible representations of point group O refer to $E_g + T_{2g}$ representations of the point group O_h (also having a centre of symmetry). This result clearly establishes that a set of d orbitals containing a single electron splits into e_g and t_{2g} sets of orbitals which, on looking at the chracter tables of point groups O and O_h, can be seen clearly to be d_{z^2}, $d_{x^2-y^2}$ set of orbitals (e_g orbitals) and d_{xy}, d_{xz}, d_{yz} set of orbitals (t_{2g} orbitals).

Alternatively, we may argue that since all d orbitals have a centre of symmetry, the type of irreducible representations to which these will transform under an octahederal ligand environment will have to be g type. All g type of irreducible representations in the point group O_h have $\chi_E = \chi_{(i\,E)}$; $\chi_{C_2} = \chi_{(i\,C_2)}$; $\chi_{C_3} = \chi_{(i\,C_3)}$ and $\chi_{C4} = \chi_{(i\,C_4)}$, as already mentioned above, so that Γ_{red} for the point group O_h can be written as :

	E	$6C_4$	$3C_2 (= C_4^2)$	$8C_3$	$6C_2$	iE	$6i\,C_4$	$3i\,C_2$	$8i\,C_3$	$6i\,C_2$
$\Gamma_{red}(O_h)$	5	−1	1	−1	1	5	−1	1	−1	1

and, on reduction of the above representation of O_h character table,, we observe that

$$A_{2g} \text{ occurs } \frac{(5+6+3-8-6)\times2}{48} = 0 \text{ time}$$

$$A_{1g} \text{ occurs } \frac{(5-6+3-8+6)\times2}{48} = 0 \text{ time}$$

$$E_g \text{ occurs } \frac{(10+0+6+8+0)\times2}{48} = 1 \text{ time}$$

$$\vdots$$

$$T_{1g} \text{ occurs } \frac{(15-6-3-0-6)\times2}{48} = 0 \text{ time}$$

and

$$T_{2g} \text{ occurs } \frac{(15+6-3+0+6)\times2}{48} = 1 \text{ time}$$

(The order of point group O_h is 48 whereas that of point group O is 24).

Thus, we get the same result that a set of d orbitals having a single electron splits into e_g set and t_{2g} set under an octahedral ligand environment. It can be clearly seen from the octahedral character table that while the e_g set comprises of d_{z^2} and $d_{x^2-y^2}$ orbitals, t_{2g} set comprises of d_{xy}, d_{yz}, d_{xy} orbitals.

Let us now investigate the influence of ligand environment on p orbitals of a metal ion containing a single electron. Assuming again that the rotation oprations are carried out about an axis around which the angle θ is measured (say, the Z axis), it is seen that the parts of p orbital wave functions which are influenced by rotations are the Φ parts of the wave functions, *viz.*, $e^{i\phi}$, $e^{i0\phi}$ and $e^{-i\phi}$. The general expression for rotation about an angle α can be written as :

$$C(\alpha)\begin{bmatrix} e^{i\phi} \\ e^{i0\phi} \\ e^{-i\phi} \end{bmatrix} = \begin{bmatrix} e^{i\alpha} & 0 & 0 \\ 0 & e^{i0\alpha} & 0 \\ 0 & 0 & e^{-i\alpha} \end{bmatrix}\begin{bmatrix} e^{i\phi} \\ e^{i0\phi} \\ e^{-i\phi} \end{bmatrix}$$

The character of such a matrix can be written as :

$$\chi_{C(\alpha)} = \frac{\sin\left(l+\frac{1}{2}\right)\alpha}{\sin\frac{\alpha}{2}} = \frac{\sin\left(\frac{3}{2}\alpha\right)}{\sin\frac{\alpha}{2}} \qquad (\because l = 1)$$

Hence,

$$\chi_{C_2} = \frac{\sin\left(\frac{3}{2}\alpha\right)}{\sin\frac{\alpha}{2}} = \frac{\sin\frac{3}{2}\pi}{\sin\frac{\pi}{2}} = \frac{-1}{1} = -1$$

$$\chi_{C_3} = \frac{\sin\left(\frac{3}{2}\times\frac{2\pi}{3}\right)}{\sin\left(\frac{2\pi}{3}\times\frac{1}{2}\right)} = \frac{\sin\pi}{\sin\frac{\pi}{3}} = 0.$$

$$\chi_{C_4} = \frac{\sin\left(\frac{3}{2}\times\frac{\pi}{2}\right)}{\sin\frac{\pi}{4}} = \frac{\frac{1}{\sqrt{2}}}{\frac{1}{\sqrt{2}}} = 1$$

Further,

$$E\begin{bmatrix} e^{i\phi} \\ e^{i\,0\phi} \\ e^{-i\phi} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} e^{i\phi} \\ e^{i\,0\phi} \\ e^{-i\phi} \end{bmatrix} \quad \text{so that } \chi_E = 3.$$

Therefore, $\Gamma_{\text{reducible}}$ becomes

	E	$6C_4$	$3C_2\,(=C_4^2)$	$8C_3$	$6C_2$
Γ_{red}	3	1	−1	0	−1

which is clearly T_1 representation of the point group O. Remembering that the p orbitals have no centre of symmetry or are asymmetric with respect to the centre of symmetry, these will transform as a u type of irreducible representation or as T_{1u} type of representation of the point group O_h. In other words, the p set of orbitals containing a single electron will remain unsplit and will have the symmetry $t_{1\mu}$ in the octahedral ligand environment.

Alternatively, we may argue that since p orbitals belong to a u type of irreducible representation of the point group O_h, the complete $\Gamma_{\text{reducible}}$ of the point group O_h obtained from the $\Gamma_{\text{reducible}}$ of point group O, can be written as :

	E	$6C_4$	$3C_2\,(=C_4^2)$	$8C_3$	$6C_2$	iE	$6iC_4$	$3iC_2$	$8iC_3$	$6iC_2$
Γ_{red}	3	1	−1	0	−1	−3	−1	+1	0	+1

which is the T_{1u} irreducible representation of point group O_h. (For a u type of representation in O_h point group, $\chi_{C_n} = -\chi_{iC_n}$ as already mentioned)

Thus, p orbitals have the symmetry t_{1u} and remain unsplit (or degenerate) under an octahedral ligand environment.

Similarly, we can show, as illustrated below, that f orbitals containing a single electron split into a_{2u}, t_{1u} and t_{2u} sets of orbitals under an octahedral ligand environment. Based on the assumptions made earlier, it can be shown that $\chi(E) = 7$ and

$$C(\alpha) = \begin{bmatrix} e^{i3\alpha} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & e^{i2\alpha} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & e^{i\alpha} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & e^{i0\alpha} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & e^{-i\alpha} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & e^{-i2\alpha} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & e^{-i3\alpha} \end{bmatrix} \text{ for the point group } O_h.$$

The character of such a matrix representing rotation operation on f orbitals along a particular axis around which θ remains constant is of the form :

$$\chi_{C(\alpha)} = \frac{\sin\left(l+\frac{1}{2}\right)\alpha}{\sin\frac{\alpha}{2}} = \frac{\sin\left(3+\frac{1}{2}\right)\alpha}{\sin\frac{\alpha}{2}} = \frac{\sin\frac{7}{2}\alpha}{\sin\frac{\alpha}{2}}$$

Hence,

$$\chi_{C_2} = \frac{\sin\left(\frac{7}{2}\pi\right)}{\sin\frac{\pi}{2}} = \frac{-1}{1} = -1$$

$$\chi_{C_3} = \frac{\sin\left(\frac{7}{2}\times\frac{2\pi}{3}\right)}{\sin\left(\frac{2\pi}{6}\right)} = 1$$

$$\chi_{C_4} = \frac{\sin\left(\frac{7}{2}\times\frac{\pi}{2}\right)}{\sin\frac{\pi}{4}} = \frac{\sin\frac{7\pi}{4}}{\sin\frac{\pi}{4}} = \frac{-\frac{1}{\sqrt{2}}}{\frac{1}{\sqrt{2}}} = -1$$

so that

	E	$6C_4$	$3C_2\,(=C_4^2)$	$8C_3$	$6C_2$
Γ_{red}	7	−1	−1	1	−1

Reducing this representation of point group O into its irreducible representations, we find that

A_2 occurs $\dfrac{7\times1\times1+(-1)(-1)\times6+(-1)\times1\times3+1\times1\times8+(-1)(-1)6}{24} = 1$ time

T_1 occurs $\dfrac{7\times3\times1+(-1)\times1\times6+(-1)(-1)\times3+1\times0\times8+(-1)(-1)\times6}{24} = 1$ time

T_2 occurs $\dfrac{7\times3\times1+(-1)(-1)\times6+(-1)(-1)\times3+1\times0\times8+(-1)\times1\times6}{24} = 1$ time

Thus, $\Gamma_{red} = A_2 + T_1 + T_2$ of the point group O.

Since f orbitals are all of u type, the corresponding terms in the point group O_h are A_{2u}, T_{1u} and T_{2u}. Thus, a set of f orbitals containing a single electron split into a_{2u}, t_{1u} and t_{2u} sets of orbitals.

Alternatively, we can write complete Γ_{red} for point group O_h from Γ_{red} of point group O. Remembering that all $\Gamma_{\text{irreducible}}$ of point group O_h obtained from $\Gamma_{\text{reducible}}$ of point group O_h must be of u type (since all f orbitals are asymmetric with respect to the centre of symmetry), we can calculate the symmetries of subsets of f orbitals as follows :

The complete $\Gamma_{\text{reducible}}$ of point group O_h can be written from $\Gamma_{\text{reducible}}$ of point group O as follows :

	E	$6C_4$	$3C_2$	$8C_3$	$6C_2$	iE	$6iC_4$	$3iC_2$	$8iC_3$	$6iC_2$
$\Gamma_{red}\,(O_h)$	7	−1	−1	1	−1	−7	1	1	−1	1

in which

A_{2u} occurs

$$\frac{7\times1\times1+(-1)(-1)\times6+(-1)\times1\times3+1\times1\times8+(-1)(-1)\times6]+[(-7)(-1)\times1+1\times1\times6+1\times(-1)\times3+(-1)(-1)\times8+1\times1\times6]}{48} = 1 \text{ time}$$

T_{1u} occurs

$$\frac{7\times3\times1+(-1)\times1\times6+(-1)(-1)\times3+1\times0\times8+(-1)(-1)\times6]+[(-7)(-3)\times1+1\times(-1)\times6+1\times1\times3+(-1)\times0\times8+1\times1\times6]}{48} = 1 \text{ time}$$

and T_{2u} occurs

$$\frac{7\times3\times1+(-1)(-1)\times6+(-1)(-1)\times3+1\times0\times8+(-1)\times1\times6]+[(-7)(-3)\times1+1\times1\times6+1\times1\times3+(-1)\times0\times8+1\times(-1)\times6]}{48} = 1 \text{ time}$$

Thus, Γ_{red} of point group O_h yields A_{2u}, T_{1u} and T_{2u} irreducible representations which implies that f orbitals containing a single electron splits into a_{2u}, t_{1u} and t_{2u} subsets under octaheral ligand environment.

The results of splitting of various types of orbitals (containing a single electron) in an octahedral ligand environment are summed up in Table 2.

TABLE 2

Splitting of Various Types of Orbitals in an Octahedral Ligand Environment

Types of orbitals	χ_R				Splittings
	χ_E	χ_{C_2}	χ_{C_3}	χ_{C_4}	
s ($l=0$)	1	1	1	1	a_{1g} (why ?)
p ($l=1$)	3	−1	0	1	t_{1u}
d ($l=2$)	5	1	−1	−1	$e_g + t_{2g}$
f ($l=3$)	7	−1	+1	−1	$a_{2u} + t_{1u} + t_{2u}$
g ($l=4$)	9	1	0	1	$a_{1g} + e_g + t_{1g} + t_{2g}$
h ($l=5$)	11	−1	−1	1	$e_u + 2t_{1u} + t_{2u}$

We can also investigate with the help of the group theory, the influence of tetrahedral, tetragonal and other ligand environments on s, p, d, f, etc., orbitals containing a single electron in each case. The procedure, however, is more complicated and has not been discussed here. Only the results of investigations relating to the splitting of various orbitals in tetrahedral ligand environment are given.

Orbitals	Splittings in Tetrahedral Ligand Environment
s	a_1
p	t_2
d	$e + t_2$
f	$a_2 + t_1 + t_2$
g	$a_1 + e + t_1 + t_2$
h	$e + t_1 + 2t_2$

It is to be noted that since a tetrahedral symmetry point group (T_d) has no centre of symmetry, none of its terms listed in the above table contains g or u subscript. Further, since a T_d point group is different from an O or O_h point group, hence the general formula for $\chi_{C(\alpha)}$ obtained for point group O cannot be applied for the T_d point group. This is the reason why the procedure for calculating $\chi_{(R)}$ for all the symmetry operations of T_d point group for a set of orbitals containing a single electron in tetrahedral ligand environment is different and more complicated than that for a similar set of orbitals in an octahedral ligand environment.

We have given here a few of the important applications of the group theory because our specific aim is to expose the student to the basic concepts of the group theory at appropriate level and to impress upon him that the knowledge of this topic is of primary importance for understanding inorganic chemistry in proper depth.

Splitting of Terms under the Influence of Octahedral Ligand Environment

We shall now consider the behaviour of d^n system ($n > 1$) under the influence of octahedral ligand environment where the magnitude of interelectronic repulsions amongst d electrons are greater than the magnitude of octahedral crystal field potential (V_{oct}) generated by the ligand environment. It is assumed that the stronger interelectronic repulsions give rise to terms which are then influenced and split by the weaker octahedral crystal field potential. Therefore, we are to deal here with the splitting of term of many-electron d^n systems under the influence of octahedral ligand environment. The conclusions arrived at earlier for single-electron systems under the influence of octahedral ligand environment also apply to the splitting

of terms arising for many-electron systems under the influence of identical ligand environment. For instance, just as a single d electron in a free metal atom or ion has a five-fold degenerate wave function corresponding to five values which m may have in Φ part of the wave function, a D term arising from d^n electrons of a metal atom or ion in free state has a five-fold degenerate wave function depending upon the five values which M of the D term may have. The only variable part of the wave function for a D term, under the symmetry opertions of point group O, is $e^{iM\phi}$ (M=+2, +1, 0, −1, −2) in exact analogy with the only variable part orbital $e^{im\phi}$ (m = +2, +1, 0, −1, −2) of the single-electron d orbital wave function under identical ligand environment. Therefore, the splitting of D term wave function in an octahedral ligand environment is analogous to the splitting of single-electron d orbital wave function under the influence of identical ligand environment.

Exactly the same relationship exists between the behaviour of a set of single-electron f orbital wave functions (m = + 3, + 2, + 1, 0, −1, −2, −3) and the F term wave functions (M = + 3, +2, 1, 0, −1,−2, −3) of a d^n system under the influence of octahedral ligand environment. Similarly, the P term wave functions (M = + 1, 0, −1) of a d^n system behaves exactly in the same manner as does a set of single-electron p orbital wave functions (m = + 1, 0, −1) in an octahedral ligand environment.

It may be recalled that while small letters, s, p, d, f, etc., are used to represent the states of a single electron, the capital letters, S, P, D, F, etc., are used to represent the terms arising out of d^n systems. The splittings of the single electron states in a given ligand environment are represented by symmetry symbols such as a_{1g}, e_g, t_{2g}, etc., using small letters whereas the splittings of a term of d^n system in a ligand environment are represented by term such as A_{1g}, T_{1g}, E_g, T_{2g}, etc., using capital letters.

Further, if the point group, to which the ligand environment belongs, has a centre of symmetry, as for example, in an octahedral environment, the subscripts of the splitting terms are determined by the types of the orbitals from which the terms are derived. For instance, all terms of a d^n configuration in an octahedral environment undergo g type of splittings because all d orbitals have a centre of symmetry.

It may be mentioned in passing that under the weak V_{oct} conditions (electronic repulsion > V_{oct}) mentioned earlier, the ligand environment does not interact directly with the electron spins. Hence, the unsplit term as well as its splittings in an octahedral environment will have the same spin multiplicity.

If the point group to which the ligand environment belongs has no centre of symmetry, then no subscripts are used for the split up terms as is the case in the splittings of terms of a d^n system under the influence of a tetraheral ligand environment. Recalling that $V_{tet} = -4/9\ V_{oct}$, that is, $V_{tet} \propto (-V_{oct})$, the splittings of a term of a d^n system under the influence of tetrahedral and octahedral environments are the same. The only difference is that the splittings of the term under tetrahedral environment do not carry the subscripts g or u. However, because of the negative sign in the relationship between V_{tet} and V_{oct}, the order of the energies of split up terms in the two environments are reverse of each other.

The splittings of terms of a d^2 configuration under octahedral and tetrahedral environments are given in Table 3.

TABLE 3

Splittings of Terms of d^2 Configuration in Octahedral and Tetrahedral Environments

Free ion terms	Splittings in octahedral environment	Splittings in tetrahedral environment
^1S	$^1A_{1g}$	$^1A_1$
^1G	$^1A_{1g}$, $^1T_{2g}$, ^1E_g, $^1T_{1g}$	$^1A_1$, $^1T_2$, ^1E, $^1T_1$
^3P	$^3T_{1g}$	$^3T_1$
^1D	^1E_g, $^1T_{2g}$	^1E, $^1T_2$
^3F	$^3A_{2g}$, $^3T_{1g}$, $^3T_{2g}$	$^3A_2$, $^3T_1$, $^3T_2$

7. Relaxation of Selection Rules for Electronic Transitions

As mentioned in Chapter 30, the transition moment integral Q, is given by

$$Q = \int_{-\infty}^{\infty} \psi_{1\,elec} \left| \sum_i e_i \bar{r}_i \right| \psi_{2\,elec} d\tau \qquad ...(3)$$

where $\sum_i e_i \bar{r}_i$ is the electric dipole moment operator of the molecule. This operator is a vector quantity. However, the exact form of the transition moment integral should utilise complete wave function $\psi_{complete}$ of the molecule where $\psi_{complete} = \psi_{elec}\, \psi_{vib}\, \psi_{rot}\, \psi_{trans}$. Thus, in order that an electronic transition becomes allowed, the exact Q should be non zero, *i.e.*,

$$Q = \int \psi_{1elec}\, \psi_{1vib}\, \psi_{1rot}\, \psi_{1trans} \left| \sum_i e_i \bar{r}_i \right| \psi_{2elec}\, \psi_{2vib}\, \psi_{2rot}\, \psi_{2trans}\, d\tau \neq 0 \qquad ...(4)$$

If, as an approximation, it is assumed that ψ_{elec}, ψ_{vib}, ψ_{rot} and ψ_{trans} wave functions of the molecule are all independent of one another and if the electronic absorption spectrum of the sample is recorded in the solid or liquid phase, ψ_{rot} and ψ_{trans} are not likely to change for a molecule during the lifetime of the excited electronic state so that in the above expression for Q, the ψ_{2rot} is the same as ψ_{1rot} and the ψ_{2trans} is the same as ψ_{1trans}. Therefore, Q can be expressed as

$$Q = \int \psi_{1elec} \psi_{1vib} \left| \sum_i e_i \bar{r}_i \right| \psi_{2elec} \psi_{2vib} d\tau \int \psi_{1rot}\, \psi_{2rot}\, d\tau \int \psi_{1trans}\, \psi_{2trans}\, d\tau \qquad ...(5)$$

$$= \int \psi_{1elec}\, \psi_{1vib} \left| \sum_i e_i \bar{r}_i \right| \psi_{2elec}\, \psi_{2vib}\, d\tau \times 1 \times 1 \qquad ...(6)$$

$$= \int \psi_{1elec}\, \psi_{1vib} \left| \sum_i e_i \bar{r}_i \right| \psi_{2elec}\, \psi_{2vib}\, d\tau \qquad ...(7)$$

If we apply the same approximation that ψ_{elec} and ψ_{vib} of the molecule are independent of each other and that during an electronic transition, the vibrational state of the molecule does not change so that $\psi_{1vib} = \psi_{2vib}$, we arrive at the following expression for the transition moment integral :

$$Q = \int \psi_{1elec} \left| \sum_i e_i \bar{r}_i \right| \psi_{2elec}\, d\tau \qquad ...(8)$$

This is the same expression from which Laporte selection rule is derived for the molecules having a centre of symmetry (see Chapter 30).

However, the above expression cannot explain the observation that many Laporte-forbidden absorption bands do appear (though with low energy) in the electronic absorption spectra of such molecules. The occurrence of Laporte-forbidden transitions can be explained if we consider that ψ_{elec} and ψ_{vib} states of the molecule are interdependent on each other and are to be considered together so that

$$Q = \int \psi_{1elec}\, \psi_{1vib} \left| \sum_i e_i \bar{r}_i \right| \psi_{2elec}\, \psi_{2vib}\, d\tau \qquad ...(9)$$

The combined $\psi_{elec}\, \psi_{vib}$ state is called $\psi_{vibronic}$ and the interdependence of the two wave functions is called **vibronic coupling.**

We shall now show that a Laporte-forbidden transition can become partly allowed due to vibronic coupling. Consider an octahedral complex MA_6. There are $3n - 6$, *i.e.*, 15 fundamental modes of vibration of this complex. All these vibrational modes are perfectly symmetric in their ground state and hence belong to A_{1g} irreducible representation. The complete ψ_{vib} of a state is the product of the wave functions of all the vibrational modes, that is,

$$\psi_{vib} = \prod_{i=1}^{3n-6} \psi_{vib_i} \qquad ...(10)$$

where ψ_{vib_i} is the wave function of the *i*th vibrational mode. The representation (rep) to which the ψ_{vib} (ground state) belongs is $A_{1g} \times A_{1g} \times A_{1g} \cdots\cdots\cdots = A_{1g}$.

If, out of the 15 normal vibrational modes, one vibrational mode gets excited to its first excited state while the rest of the normal vibrational modes remain in their ground state, the representation to which ψ_{vib}(excited state) of the molecule belongs is $A_{1g} \times A_{1g} \times A_{1g} \times \cdots\cdots = \Gamma_{excited}$ ($\Gamma_{excited}$ is the irreducible representation to which the excited vibrational mode of the molecule belongs). In other words, ψ_{vib} (excited state) belongs to the same representation to which the excited vibrational mode belongs.

Let us now apply the concept of vibronic coupling to the Laporte-forbidden $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ transitions of the octahedral complex ion $[Co(NH_3)_6]^{3+}$. Only the coordinated nitrogens and Co will be considered for determining the number and the symmetry of the vibrational modes. The irreducible representations to which the first excited state of 15 normal modes of vibration of this octahedral ML_6 species belong are A_{1g}, T_{1g}, E_u, T_{1u} and T_{2u}.

The transition moment integral for the electronic transition $^1A_{1g} \rightarrow {}^1T_{1g}$, considering electronic states to be independent of vibrational states, is given by

$$Q = \int \psi_{A_{1g}} \left| \sum_i e_i \bar{r}_i^{*} \right| \psi_{T_{1g}}\, d\tau \qquad ...(11)$$

Since the direct product of $A_{1g} \times T_{1u} \times T_{1g}$ is $A_{1u} + E_u + T_{1u} + T_{2u}$ which does not contain A_{1g}, this transition moment integral is zero and the transition $^1A_{1g} \rightarrow {}^1T_{1g}$ is Laporte-forbidden. Similarly, Q for the electronic transition $^1A_{1g} \rightarrow {}^1T_{2g}$, is given by

$$Q = \int \psi_{A_{1g}} \left| \sum_i e_i \bar{r}_i \right| \psi_{T_{2g}}\, d\tau \qquad ...(12)$$

Again, the direct product of $A_{1g} \times T_{1u} \times T_{2g}$ is $A_{2u} + E_u + T_{1u} + T_{2u}$ (use octahedral character table to verify the direct product results). It does not contain A_{1g}. Hence this transition is also Laporte-forbidden.

It is observed, however, that the absorption bands due to the two above mentioned transitions do appear in the electronic absorption spectrum of $[Co(NH_3)_6]^{3+}$, though their intensities are low. This clearly indicates that there is some mechanism through which the forbidden transitions become partly allowed. Such a mechanism is vibronic coupling. Suppose, along with an electronic transition, a T_{1u} or T_{2u} vibrational mode also gets simultaneously excited. Using the expression for Q, considering vibronic coupling, we have

$$Q = \int \psi_{1elec}\, \psi_{1vib} \left| \sum_i e_i \bar{r}_i \right| \psi_{2elec}\, \psi_{2vib}\, d\tau \qquad ...(13)$$

where ψ_{1vib} belongs to A_{1g} and ψ_{2vib} belongs to T_{1u} or T_{2u} representation of the O_h group. (The subscript 1 is

The *x*, *y*, *z* components of the electric dipole vector transform as T_{1u} representation of the octahedral group.

used for the ground state wave function and 2 for the excited state wave function). Consider the electronic transition $^1A_{1g} \rightarrow {}^1T_{1g}$ along which the vibrational mode T_{1u} or T_{2u} is also excited simultaneously. The direct product $A_{1g} \times (A_{1g} \times T_{1u} \times T_{1g}) \times T_{1u}$ corresponding to the above Q is $(A_{1u} + E_u + T_{1u} + T_{2u}) \times T_{1u}$ or T_{2u} which contains a term $T_{1u} \times T_{1u}$ or $T_{2u} \times T_{2u}$. Both $T_{1u} \times T_{1u}$ and $T_{2u} \times T_{2u}$, when reduced, contain the term A_{1g}. Hence, the vibronic coupling makes $^1A_{1g} \rightarrow {}^1T_{1g}$ transition partly allowed.

Exactly similar results are obtained for $^1A_{1g} \rightarrow {}^1T_{2g}$ transition along which T_{1u} or T_{2u} vibrational mode of the molecule is also simultaneously excited. The direct product of the integrand Q in such a case will be $A_{1g} \times (A_{1g} \times T_{1u} \times T_{2u}) \times T_{1u}$ or T_{2u} which is $(A_{2u} + E_u + T_{1u} + T_{2u}) \times T_{1u}$ or T_{2u}. This contains the term $T_{1u} \times T_{1u}$ or $T_{2u} \times T_{2u}$ both of which, upon reduction, contain the term A_{1g}. This makes the transition $^1A_{1g} \rightarrow {}^1T_{2g}$ partly allowed because of vibronic coupling.

8. Establishing State of Symmetry by the Method of Descending Symmetry

We have already seen in this chapter that the strong field octahedral configuration e_g^2 can give rise to two sets of states, *viz.*, $^1A_{1g} + {}^3A_{2g} + {}^1E_g$ and $^3A_{1g} + {}^1A_{2g} + {}^1E_g$. The set that actually exists is obtained by using the method of descending symmetry. In this method, the symmetry of the complex is lowered through imagination to such an extent that each orbitally degenerate state of the original symmetry splits up into a set of non-degenerate states of lowered symmetry. The correlation Table 4 gives correlation between the states of various symmetries.

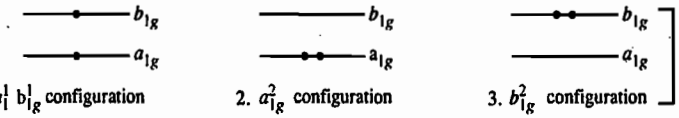
TABLE 4

Correlation between the States of Various Symmetries

O_h	O	T_d	D_{4h}	C_{4v}	C_{2v}	D_{3d}	D_3	C_{2h}
A_{1g}	A_1	A_1	A_{1g}	A_1	A_1	A_{1g}	A_1	A_g
A_{2g}	A_2	A_2	B_{1g}	B_1	A_2	A_{2g}	A_2	B_g
E_g	E	E	$A_{1g} + B_{1g}$	$A_1 + B_1$	$A_1 + A_2$	E_g	E	$A_g + B_g$
T_{1g}	T_1	T_1	$A_{2g} + E_g$	$A_2 + E$	$A_2 + B_1 + B_2$	$A_{2g} + E_g$	$A_2 + E$	$A_g + B_g + B_g$
T_{2g}	T_2	T_2	$B_{2g} + E_g$	$B_2 + E$	$A_1 + B_1 + B_2$	$A_{1g} + E_g$	$A_1 + E$	$A_g + A_g + B_g$
T_{1u}	T_1	T_2	$A_{2u} + E_u$	$A_1 + E$	$A_1 + B_1 + B_2$	$A_{2u} + E_u$	$A_2 + E$	$A_u + B_u + B_u$
T_{2u}	T_2	T_1	$B_{2u} + E_u$	$B_1 + E$	$A_2 + B_1 + B_2$	$B_{2u} + E_u$	$A_1 + E$	$A_u + A_u + B_u$

It can be seen from Table 4 that if the symmetry of the strong field octahedral complex is lowered to D_{4h} by elongating the trans pairs of the metal–ligand bonds of the octahedron, the only degenerate E_g state of e_g^2 configuration splits up into $A_{1g} + B_{1g}$ states of D_{4h} symmetry. The state A_{1g} remains A_{1g} under both the symmetry environments. The state A_{2g} of O_h symmetry becomes B_{1g} of D_{4h} symmetry.

The one-electron e_g orbitals of the octahedral complex will split up into a_{1g} and b_{1g} non-degenerate levels in the complex of lower D_{4h} symmetry. The two electrons previously present in the e_g orbitals of the octahedral complex will now occupy a_{1g} and b_{1g} non-degenerate levels of the tetragonal complex of lower D_{4h} symmetry. This can occur in the following ways :



1. $a_1^1\ b_{1g}^1$ configuration 2. a_{1g}^2 configuration 3. b_{1g}^2 configuration

Let us now consult the D_{4h} character table and see how many states arise out of each of the configurations given above. The method has already been discussed earlier in this chapter.

1. The $a_{1g}^1\ b_{1g}^1$ configuration of D_{4h} symmetry gives rise to B_{1g} state (the direct product $B_{1g} \times A_{1g} = A_{1g}$). Since there are four ways of arranging one electron in a_{1g} level and one electron in b_{1g} level, the total degeneracy (obtained by multiplying spin multiplicity with the orbital degeneracy) of the B_{1g} state arising out of $a_{1g}^1\ b_{1g}^1$ configuration must be **four** which is possible only if the spin multiplicity of B_{1g} state is 3 as well as 1 (total degeneracy of $^1\mathbf{B}_{1g}$ and $^3\mathbf{B}_{1g}$ states is $1 \times 1 + 3 \times 1 = 4$).
2. The a_{1g}^2 configuration of D_{4h} symmetry gives rise to the term A_{1g} (the direct product of $A_{1g} \times A_{1g} = A_{1g}$). Since there is only one way of placing both the electrons in the same a_{1g} level, the total degeneracy of A_{1g} state must be **one**. Thus, the state arising out of a_{1g}^2 configuration is $^1A_{1g}$ which has a spin multiplicity of 1 (total degeneracy of $^1A_{1g}$ is $1 \times 1 = 1$).
3. The a_{1g}^2 configuration of D_{4h} symmetry gives rise to A_{1g} state ($B_{1g} \times B_{1g} = A_{1g}$). Since there is only one way of arranging both the electrons in the same b_{1g} level, the total degeneracy of the A_{1g} state must be one. Thus, the state arising out of b_{1g}^2 configuration must be $^1\mathbf{A}_{1g}$.

Thus, the six electronic arrangements of two electrons occupying a_{1g} and b_{1g} levels of D_{4h} symmetry give rise to three configurations out of which a total of three states, *viz.*, $^1A_{1g}$, $^1B_{1g}$ and $^3B_{1g}$ arise. It is important to remember that *the spin multiplicity of the parent unsplit state and of its splittings due to lowering of symmetry must remain the same.*

The spin multiplicity of E_g state of octahedral environment cannot be 3 because a ^3E_g state would split into $^3A_{1g}$ and $^3B_{1g}$ states of D_{4h} symmetry. But there is no $^3A_{1g}$ state in the list of the states obtained from D_{4h} symmetry (Table 4). Thus, the spin multiplicity of E_g state for octahedral environment has to be 1. The state ^1E_g splits into $^1A_{1g}$ and $^1B_{1g}$ states of D_{4h} symmetry (Table 4).

There is one more $^1A_{1g}$ state of D_{4h} symmetry left which must correspond to $^1A_{1g}$ state of O_h symmetry. The A_{2g} state of octahedral symmetry, therefore, must correlate with $^3B_{1g}$ state of D_{4h} symmetry.

We may thus summarise the above results in the form of the following table :

O_h Symmetry	D_{4h} Symmetry
$^1A_{1g}$	$^1A_{1g}$
$^3A_{2g}$	$^3B_{1g}$
^1E_g	$^1A_{1g}$ $^1B_{1g}$

Thus, the strong field octahedral configuration e_g^2 splits into $^1A_{1g} + {}^3A_{2g} + {}^1E_g$ states.

Let us now consider the strong field octahedral configuration t_{2g}^2. This configuration gives rise to three *sets* of states, *viz.*, $(^1A_{1g} + {}^1E_g + {}^1T_{1g} + {}^1T_{2g})$, $(^1A_{1g} + {}^1E_g + {}^1T_{1g} + {}^3T_{2g})$ and $(^3A_{1g} + {}^3E_g + {}^1T_{1g} + {}^1T_{2g})$, as discussed earlier. Fifteen electronic arrangements are possible for this configuration, the total degeneracy of each set of the above mentioned states is also 15.

One of the lowered symmetries, in which each of the degenerate states arising out of strong octahedral field splits into the non-degenerate states, is the C_{2h} symmetry. In this C_{2h} symmetry, the degeneracy of one-electron t_{2g} orbitals is lifted to $a_g + a_g + b_g$ non-degenerate levels (see correlation Table 4). It can be seen from this table that A_{1g}, E_g, T_{1g} and T_{2g} states of octahedral symmetry correlate with A_g, $(A_g + B_g)$, $(A_g + B_g + B_g)$ and $(A_g + A_g + B_g)$ states, respectively, of the C_{2h} symmetry.

The t_{2g}^2 configuration of octahedral symmetry gives rise to the following states in the lowered C_{2h} symmetry :

(*i*) The a_g^2 configuration gives rise to A_g state ($A_g \times A_g = A_g$ according to C_{2h} character table). Since the two electrons are present in the same a_g level, their spins must be paired up making only one electronic arrangement possible. This implies that the a_g^2 configuration of C_{2h} symmetry gives rise to only ^1A_g state having a total degeneracy of one ($1 \times 1 = 1$).

(*ii*) The configuration a_g^2 again has both the electrons in the same a_g level. This configuration also gives rise to ^1A_g state as in (*i*).

(*iii*) The b_g^2 configuration gives rise to A_g state ($B_g \times B_g = A_g$ according to C_{2h} character table). Since both the electrons are paired in the same b_g level, the configuration b_g^2 gives rise to ^1A_g state.

(*iv*) The $a_g' a_g'$ configuration in which the two electrons are in two different a_g orbitals gives rise to A_g state ($A_g \times A_g = A_g$ according to C_{2h} character table). Since in this configuration, the spins of the two electrons present in two different a_g orbitals can give rise to four electronic arrangements, the total degeneracy of the states of this configuration must be four. In other words, the $a_g' a_g'$ configuration of C_{2h} symmetry gives rise to ^1A_g and ^3A_g states whose total degeneracy is four ($1 \times 1 + 3 \times 1 = 4$).

(*v*) The $a_g^1 b_g^1$ configuration gives rise to non-degenerate B_g state ($A_g \times B_g = B_g$ according to C_{2h} character table). Since this configuration has one electron in a_g level and one electron in b_g level, the spins of these electrons will generate four electronic arrangements. Therefore, the total degeneracy of the states of this configuration has to be four. Hence, the configuration $a'_g b'_g$ gives rise to ^1B_g and ^3B_g states having a total degeneracy of four ($1 \times 1 + 3 \times 1 = 4$).

(*vi*) The configuration $a^1_g b^1_g$ will also give rise to ^1B_g and ^3B_g states in a similar manner.

We may summarise the result, saying that the t_{2g}^2 configuration of octahedral symmetry gives rise to the following states in the lowered C_{2h} symmetry :

$$4\,^1A_g + {}^3A_g + 2\,^1B_g + 2\,^3B_g$$

From a close study of the correlation Table 4, the following correlations between the states of O_h

symmetry and C_{2h} symmetry can be obtained :

O_h Symmetry	C_{2h} Symmetry
$^1A_{1g}$	$^1A_{1g}$
^1E_g	^1A_g, ^1B_g
$^3T_{1g}$	^3A_g, ^3B_g, ^3B_g
$^3T_{2g}$	^1A_g, ^1A_g, ^1B_g

Remembering that the spin multiplicity of the parent unsplit state of higher symmetry and of its splittings in lower symmetry must remain the same, we conclude that there should be a $^3T_{1g}$ state of octahedral symmetry which splits up into ^3A_g and two ^3B_g states under C_{2h} symmetry. Similarly, there must be a $^1T_{2g}$ state of octahedral symmetry which splits up into two ^1A_g and one ^1B_g state and an ^1E_g state of octahedral symmetry which splits up into $^1A_g + {}^1B_g$ states under C_{2h} symmetry. The $^1A_{1g}$ state of octahedral symmetry correlates with ^1A_g state of C_{2h} symmetry. Thus, the t^2_{2g} configuration of octahedral symmetry splits up into $^1A_{1g} + {}^1E_g + {}^3T_{1g} + {}^1T_{2g}$ states.

9. Study of Electron Absorption Spectra using Plane Polarised Light

The electric dipole vector $\sum_i e_i \vec{r}_i$ of the molecule can be expressed as the vectorial sum $\sum_i e_i \vec{x}_i + \sum_i e_i \vec{y}_i + \sum_i e_i \vec{z}_i$ so that the transition moment integral splits into the following three integrals :

$$Q_x = \int \psi_1 \left| \sum_i e_i \vec{x}_i \right| \psi_2 \, d\tau$$

$$Q_y = \int \psi_1 \left| \sum_i e_i \vec{y}_i \right| \psi_2 \, d\tau$$

$$Q_z = \int \psi_1 \left| \sum_i e_i \vec{z}_i \right| \psi_2 \, d\tau$$

Since e_i, the charge on the ith electron is a scalar quantity, $\sum_i e_i \vec{x}_i$, $\sum_i e_i \vec{y}_i$, $\sum_i e_i \vec{z}_i$ will have the same symmetry properties as $\vec{x}$, $\vec{y}$ and $\vec{z}$, respectively.

In an octahedral complex, the $\vec{x}$, $\vec{y}$ and $\vec{z}$ components of the electric dipole of the molecule are equivalent. Hence, the direction of the oscillating electric vector of light will not alter the extent of interaction with dipole moment operator of the molecule. But, this is not the case in molecules in which one or more of the x, y, z components of the dipole operator belong to *different* representations of the group. For example,

the tetragonal complex, trans $[Co(en)_2Cl_2]^+$, has D_{4h} symmetry. Had the symmetry of the complex been octahedral, two strong crystal field transitions $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ would have been possible. In the tetragonal symmetry (D_{4h}) obtained by elongating the two trans bonds of octahedral symmetry, the A_{1g}, T_{1g} and T_{2g} of O_h symmetry correlate with A_{1g}, $(A_{2g} + E_g)$ and $(B_{2g} + E_g)$ of D_{4h} symmetry, respectively (see correlation Table 5 given below). Thus, in the above mentioned tetragonal trans $[Co(en)_2Cl_2]^+$ complex, the $^1A_{1g} \rightarrow {}^1A_{2g}$, $^1A_{1g} \rightarrow {}^1E_g$, $^1A_{1g} \rightarrow {}^1B_{2g}$ and $^1A_{1g} \rightarrow {}^1E_g$ electronic transitions are possible. This is illustrated in Fig. 11.

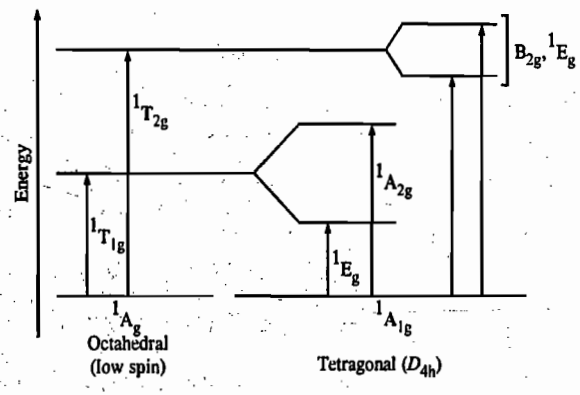


Fig. 11. Electronic energy levels for octahedral (low spin) and tetragonal Co^{3+} complex.

In a tetragonal complex, x and y components of the electric dipole belong to the representation E_u and its z component belongs to the representation A_{2u} of the D_{4h} character table. The transition moment integrals corresponding to the above mentioned electronic transitions in trans $[Co(en)_2Cl_2]^+$ complex, considering electronic wave functions alone, are given in Table 5.

TABLE 5

Correlation between Transition Moment Integral, Q_{elec} and Direct Product Corresponding to its Integrand ΓQ_{elec}

Transition Moment Integral (Q_{elec})	Direct Product Corresponding to its Integrand ΓQ_{elec}
$\int \psi_{A_{1g}} \lvert \sum_i e_i \bar{x}_i + \sum_i e_i \bar{y}_i \rvert \psi_{A_{2u}} d\tau$	$A_{1g} \times E_u \times A_{2g} = E_u$
$\int \psi_{A_{1g}} \lvert \sum_i e_i \bar{x}_i + \sum_i e_i \bar{y}_i \rvert \psi_{B_{2g}} d\tau$	$A_{1g} \times E_u \times B_{2g} = E_u$
$\int \psi_{A_{1g}} \lvert \sum_i e_i \bar{x}_i + \sum_i e_i \bar{y}_i \rvert \psi_{E_g} d\tau$	$A_{1g} \times E_u \times E_u = A_{1u} + A_{2u} + B_{1u} + B_{2u}$
$\int \psi_{A_{1g}} \lvert \sum_i e_i \bar{z}_i \rvert \psi_{A_{2g}} d\tau$	$A_{1g} \times A_{2u} \times A_{2g} = A_{2u}$
$\int \psi_{A_{1g}} \lvert \sum_i e_i \bar{z}_i \rvert \psi_{B_{2g}} d\tau$	$A_{1g} \times A_{2u} \times B_{2g} = B_{1u}$
$\int \psi_{A_{1g}} \lvert \sum_i e_i \bar{z}_i \rvert \psi_{E_g} d\tau$	$A_{1g} \times A_{2u} \times E_u = E_u$

As can be seen, none of the expressions given above, contains A_{1g}. Thus, all the transitions should be Laporte-forbidden. However, the electronic absorption spectrum of this complex does contain low intensity absorption bands. This is due to the interdependence of electronic and vibrational states of the complex species. Therefore, we should use $\psi_{vibronic}$, instead of ψ_{elec} alone, in the transition moment integrals as shown in Table 5.

The transition moment integrals would thus be written as :

$$Q_{vibronic\,(x,y)} = \int \psi_{1elec}\psi_{1vib} \lvert \sum_i e_i \bar{x}_i + \sum_i e_i \bar{y}_i \rvert \psi_{2elec}\psi_{2vib}\, d\tau$$

$$Q_{vibronic\,(z)} = \int \psi_{1elec}\psi_{1vib} \lvert \sum_i e_i \bar{z}_i \rvert \psi_{2elec}\psi_{2vib}\, d\tau$$

We have already observed that the ground vibrational state of this complex belongs to the totally symmetric representation A_{1g} whereas the excited vibrational state belongs to the representation to which the first excited vibrational mode belongs. The symmetries of the first excited vibrational modes of the tetragonal complex are $^2A_{1g}$, B_{1g}, B_{2g}, E_g, $^2A_{1u}$, B_{1u} and $3E_u$. The direct product corresponding to $Q_{vibronic}$ *viz.*, $\Gamma_{vibronic}$, is obtained by multiplying the direct product of Q_{elec} with $\Gamma\psi_{vibronic}$ (ground state) and $\Gamma_{vibronic}$ (excited state). Since $\Gamma_{vibronic}$ (ground state) is A_{1g} and it will not change the result of the direct product, the direct product relating to $Q_{vibronic}$ is obtained simply by multiplying the direct product relating to Q_{elec} with $\Gamma_{vibronic}$ (excited state) which is the same as $\Gamma_{vibronic\ mode}$ (excited state).

Direct product relating to $Q_{vibronic}$ is equal to direct product relating to $Q_{elec} \times \Gamma_{vibronic}$. If this direct product contains a representation multiplied with itself, then it must contain the perfectly symmetric representation A_{1g}. That is, $A_{1u} \times A_{1u}$, $B_{1u} \times B_{1u}$, $E_u \times E_u$, $A_{2u} \times A_{2u}$ etc., must contain A_{1g} representation.

We can easily see that $Q_{vibronic}$ $(^1A_{1g} \rightarrow {}^1A_{2g})$ becomes non zero and the electronic transition $^1A_{1g} \rightarrow {}^1A_{2g}$ becomes allowed if the vibrational mode E_u of the complex also gets simultaneously excited because $\Gamma Q_{vibronic}$ $(^1A_{1g} \rightarrow {}^1A_{2g}) = \Gamma Q_{elec\,(x,y)}$ $(^1A_{1g} \rightarrow {}^1A_{2g}) \times E_u = E_u \times E_u$ and must contain the perfectly symmetric term A_{1g}. Similarly, it can be shown that the electronic transition $^1A_{1g} \rightarrow {}^1B_{2g}$ becomes allowed since $\Gamma Q_{vibronic\,(x,y)}$ $(^1A_{1g} \rightarrow {}^1B_{2g})$ becomes non zero if the vibrational mode E_u is simultaneously excited because

$$\Gamma Q_{vibronic\,(x,y)}\,(^1A_{1g} \rightarrow {}^1B_{2g}) = \Gamma Q_{elec\,(x,y)}\,(^1A_{1g} \rightarrow {}^1B_{2g}) \times E_u = E_u \times E_u$$

Table 6 predicts from $Q_{vibronic\,(x,y)}$ and $Q_{vibronic\,(z)}$ whether the electronic transitions of the tetragonal complex ion, trans $[Co(en)_2Cl_2]^+$, are forbidden or allowed.

TABLE 6

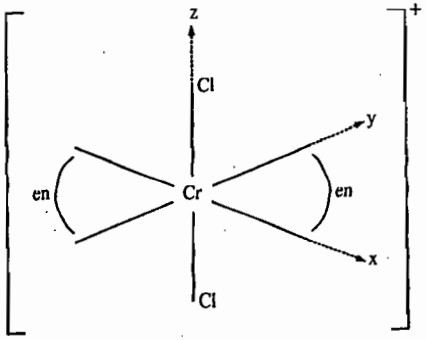
Prediction of Forbidden or Allowed Electronic Transitions in the case of Teragonal Complex Ion trans $[Co(en)_2Cl_2]^+$

Transitions	$A_{1g} \rightarrow A_{2g}$	$A_{1g} \rightarrow B_{2g}$	$A_{1g} \rightarrow E_g$
Direct product corresponding to $\int \psi_{1elec} \lvert \sum_i e_i \bar{z}_i \rvert \psi_{2elec}\, d\tau$	$A_{1g} \times A_{2u} \times A_{2g} = A_{2u}$ (forbidden for all vibrational modes)	$A_{1g} \times A_{2u} \times B_{2g} = B_{1u}$* (allowed by B_{1u} vibrational mode)	$A_{1g} \times A_{2u} \times E_g = E_u$* (allowed by E_u vibrational mode)
Direct product corresponding to $\psi_{1elec} \lvert \sum e_i \bar{x}_i + \sum e_i \bar{y}_i \rvert \psi_{2elec}\, d\tau$	$A_{1g} \times E_u \times A_{2g} = E_u$* (allowed by E_u vibrational mode)	$A_{1g} \times E_u \times B_{2g} = E_u$* (allowed by E_u vibrational mode)	$A_{1g} \times E_u \times E_g = A_{1u} + A_{2u} + B_{1u} + B_{2u}$ (allowed by B_{1u} and A_{1u} vibrational modes)

*$B_{1u} \times B_{1u}$ vibrational mode, $E_u \times E_u$ vibrational mode, $B_{1u} \times B_{1u}$ vibrational mode and $A_{1u} \times A_{1u}$ vibrational mode all contain A_{1g}.

If we grow a *single crystal of the complex* $[Co(en)Cl_2]^+$, with structure as shown, determine its principal axis (called z-axis) by X-ray technique and record the electronic absorption spectra using plane polarized light as source, it is expected that when the z-axis of the complex is mounted parallel to the plane of polarised light, the oscillating electric vector of the polarised light will interact with only the z component of the electric dipole of the complex ion and *not with its x and y components*. The absorption of light will then

depend only on Q_z. If Q_z in such a situation is non zero, the polarised light will be absorbed by the complex ion and the resulting absorption band is called *z* polarised band. If we mount the crystal in such a manner that the principal axis lies perpendicular to the plane of polarized light (*i.e., the plane of the complex ion is parallel to the plane of polarised light*), the oscillating electric vector of plane polarised light will interact only with *x* and *y* components of the electric dipole of the species. If, in such a case, $Q_{x,y}$ is non zero, the complex ion will absorb the polarised light and will thus give rise to *x*, *y* polarised absorption band.



As can be seen from Fig. 11, when octahedral symmetry of the low spin Co^{3+} complex is lowered to D_{4h} symmetry, the $^1T_{1g}$ and $^1T_{2g}$ states split into $A_{2g} + E_g$ and $B_{2g} + E_g$ states so that four transitions in all are possible for a tetragonal Co^{3+} (low spin) complex, as shown in Fig. 11. All the four transitions, being (*x*, *y*) allowed, polarised transitions should appear as (*x*, *y*) polarised absorption bands when the single crystal of the complex is mounted in such a manner that its principal axis (*z*-axis) is perpendicular to the plane of polarised light. On the other hand, if the single crystal of the complex is mounted in such a manner that its principal axis is parallel to the plane of polarised light, only three *z*-polarised absorption bands would appear due to the three *z*-allowed polarised transitions. The transition $A_{1g} \rightarrow A_{2g}$ will not be observed under such conditions as it is *z*-forbidden (see Table 6). The actual (*x*, *y*) polarised electron absorption spectrum of the trans $[Co(en)_2Cl_2]^+$ complex is shown in Fig. 12. As can be seen, three absorption bands are clearly observed. The first two absorption bands are due to $^1A_{1g} \rightarrow {}^1E_g$ and $^1A_{1g} \rightarrow {}^1A_{2g}$ transitions and the third broad and higher frequency absorption band is an unresolved composite band due to $^1A_{1g} \rightarrow {}^1T_{2g}$ and $^1A_{1g} \rightarrow {}^1E_g$ transitions. (It may be noted that the energy gap between the splittings of T_{2g} octahedral state into E_g and B_{2g} states is much smaller than the energy gap between the splittings of T_{1g} octahedral state into A_{2g} and E_g tetragonal states). In the actual *z*-polarised absorption spectrum, however, the *second absorption band is not observed*. This is due to the fact that the transition $^1A_{1g} \rightarrow {}^1A_{2g}$, which should have given rise to the second absorption band, is a *z-forbidden transition* (Table 6).

The first absorption band which appears under both conditions is, therefore, due to $^1A_{1g} \rightarrow {}^1E_g$ transition. The electronic absorption spectrum of trans $[Co(en)_2Cl_2]^+$ using plane polarised light as the source is given in Fig. 12.

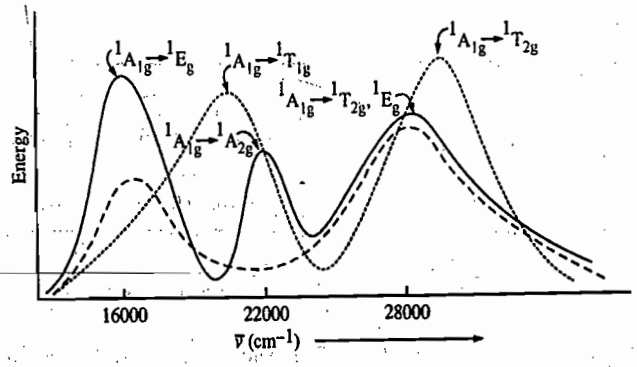


Fig. 12. Electron absorption spectrum of trans $[Co(en)_2Cl_2]^+$ in solid phase. The dotted line (.....) shows the absorption spectrum when the plane of polarised light is ∥ to the principal axis (*i.e.*, *z*-axis). The solid line shows the absorption spectrum when the plane of polarised light is ⊥ to the principal axis. Spectrum of $[Co(en)_3]^{3+}$ shown by dash-dot (-----) line, has been given for the sake of comparison.

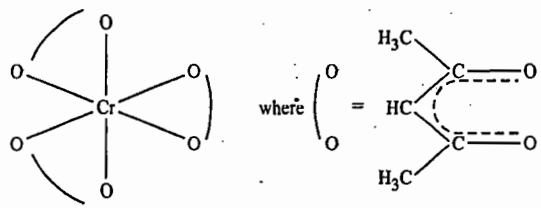
Had the complex been perfectly octahedral, it would have shown two absorption bands in its electronic absorption spectrum due to $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ transitions (Fig. 11). But, because of the lower symmetry of the trans $[Co(en)_2Cl_2]^+$ complex, the T_{1g} state splits into A_{2g} and E_g states so that the $^1A_{1g} \rightarrow {}^1T_{1g}$ transition absorption band of O_h symmetry splits into $^1A_{1g} \rightarrow {}^1A_{2g}$ and $^1A_{1g} \rightarrow {}^1E_g$ absorption bands occurring at 22000 cm^{-1} and 16000 cm^{-1}, respectively. The higher energy T_{2g} state also splits into B_{2g} and E_g states and, therefore, the $^1A_{1g} \rightarrow {}^1T_{2g}$ absorption band should have also split into absorption bands corresponding to $^1A_{1g} \rightarrow {}^1B_{2g}$ and $^1A_{1g} \rightarrow {}^1E_g$ transitions. But, due to a very small energy gap between the B_{2g} and E_g splittings of T_{2g} state, only a composite broad band is observed at 28000 cm^{-1} in this case.

It is not always necessary that only a vibronic wave function is required to explain the appearance of electronic absorption spectra in polarized light. Amongst the complexes having lower than octahedral symmetry, for example, the complex tri(acetyl acetonato) Cr(III), can be taken as octahedral if we consider the coordinated oxygen atoms only and neglect the chelate rings altogether. The structure of the complex is shown below :



Under the assumed octahedral symmetry, the three transitions possible are : $^4A_{2g} \rightarrow {}^4T_{2g}$, $^4A_{2g} \rightarrow {}^4T_{1g}$(F) and $^4A_{2g} \rightarrow {}^4T_{1g}$(P). However, all these transitions should be Laporte-forbidden and hence no absorption band should appear. But, the actual symmetry of the complex is D_3. The lowering of the symmetry of the complex from O_h to D_3 would transform the A_{2g}, T_{2g} and T_{1g} states of octahedral symmetry to A_2, $(A_2 + E)$ and $(A_1 + E)$ states, respectively, of D_3 symmetry. Also the *x*, *y* components of the electric dipole vector of the complex transform as E and its *z* component transforms as A_2 representation of D_3 group. It is to be remembered that the D_3 symmetry has no centre of symmetry and hence is not governed by Laporte selection rule.

The possible types of transitions with the predictions whether these are allowed or forbidden are given in Table 7.

TABLE 7

Various Transitions with Predictions whether Allowed or Forbidden

Transition	$A_2 \rightarrow A_2$	$A_2 \rightarrow E$	$A_2 \rightarrow A_1$
Direct product relating to $\int \psi_{1elec} \lvert \sum_i e_i \bar{x}_i + \sum_i e_i \bar{y}_i \rvert \psi_{2elec}\, d\tau$	$A_2 \times A_2 \times A_2 = A_2$ (forbidden)	$A_2 \times A_2 \times E = E$ (forbidden)	$A_2 \times A_2 \times A_1 = A_1$ (allowed)
Direct product relating to $\int \psi_{1elec} \lvert \sum_i e_i \bar{x}_i + \sum_i e_i \bar{y}_i \rvert \psi_{2elec}\, d\tau$	$A_2 \times E \times A_2 = E$ (forbidden)	$A_2 \times E \times E = A_1 + A_2 + E$ (allowed)	$A_2 \times E \times A_1 = E$ (forbidden)

As can be seen from Table 7, $A_2 \rightarrow A_2$ transition is a totally forbidden transition whereas the $A_2 \rightarrow E$ transition is *z*-forbidden but (*x*, *y*) allowed. The transition $A_2 \rightarrow E$ will show an absorption band in the electron absorption spectrum of the complex when the principal axis (called *z*-axis) of the single crystal of the complex tri(acetyl acetonato) Cr(III) is mounted perpendicular to the plane of polarised light. The electronic transition $A_2 \rightarrow A_1$ is *z*-allowed and (*x*, *y*) forbidden (Table 7). The absorption band due to $A_2 \rightarrow A_1$ transition will appear in the electron absorption spectrum of the complex only when the principal axis of its single crystal is held parallel to the plane of polarised light incident on the crystal.

CHARACTER TABLES FOR IMPORTANT SYMMETRY GROUPS

Character tables for a few symmetry groups have already been given in this chapter 3. However, for convenience of reference, character tables for all the important symmetry groups have been consolidated at one place here.

1. The C_{nv} Groups

C_{2v}[a]	E	C_2	$\sigma_v(xz)$	$\sigma'_v(yz)$		
A_1	1	1	1	1	z	x^2, y^2, z^2
A_2	1	1	−1	−1	R_z	xy
B_1	1	−1	1	−1	x, R_y	xz
B_2	1	−1	−1	1	y, R_x	yz

* For a planar molecule, the x-axis is taken perpendicular to the plane.

C_{3v}	E	$2C_3$	$3\sigma_v$		
A_1	1	1	1	z	x^2+y^2, z^2
A_2	1	1	−1	R_z	
E	2	−1	0	(x, y) (R_x, R_y)	(x^2-y^2, xy) (xz, yz)

C_{4v}[a]	E	$2C_4$	C_2	$2\sigma_v$	$2\sigma_d$		
A_1	1	1	1	1	1	z	x^2+y^2, z^2
A_2	1	1	1	−1	−1	R_z	
B_1	1	−1	1	1	−1		x^2-y^2
B_2	1	−1	1	−1	1		xy
E	2	0	−2	0	0	(x, y) (R_x, R_y)	(xz, yz)

* If the C_{4v} molecule contains a square array of atoms, the σ_v planes should pass through the larger number of atoms of the square array or should intersect the largest possible number of bonds.

C_{5v}	E	$2C_5$	$2C_5^2$	$5\sigma_v$		
A_1	1	1	1	1	z	x^2+y^2, z^2
A_2	1	1	1	−1	R_z	
E_1	2	2cos 72°	2 cos 144°	0	(x, y) (R_x, R_y)	(xz, yz)
E_2	2	2 cos 144°	2 cos 72°	0		(x^2-y^2, xy)

C_{6v}	E	$2C_6$	$2C_3$	C_2	$3\sigma_v$	$3\sigma_d$		
A_1	1	1	1	1	1	1	z	x^2+y^2, z^2
A_2	1	1	1	1	−1	−1	R_z	
B_1	1	−1	1	−1	1	−1		
B_2	1	−1	1	−1	−1	1		
E_1	2	1	−1	−2	0	0	(x, y) (R_x, R_y)	(xz, yz)
E_2	2	−1	−1	2	0	0		(x^2-y^2, xy)

2. The C_{nh} Groups

C_{2h}	E	C_2	i	σ_h		
A_g	1	1	1	1	R_z	x^2, y^2, z^2, xy
B_g	1	−1	1	−1	R_x, R_y	xz, yz

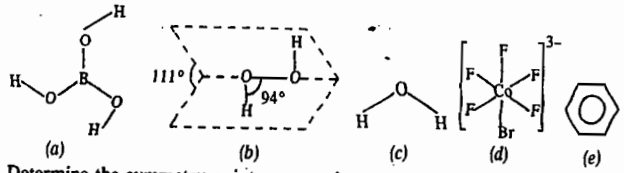
QUESTIONS

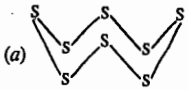
1. Write down the symmetry point groups of the following molecules. How many and which symmetry operations are possible in each case ?



(a) (b) (c) (d) (e)

[Ans. (a) C_{3h}, (b) C_2, (c) C_{2v} (d) C_{4v} (e) D_{6h}]

2. Determine the symmetry point groups, the symmetry elements and the symmetry operations that are possible in the following molecules :

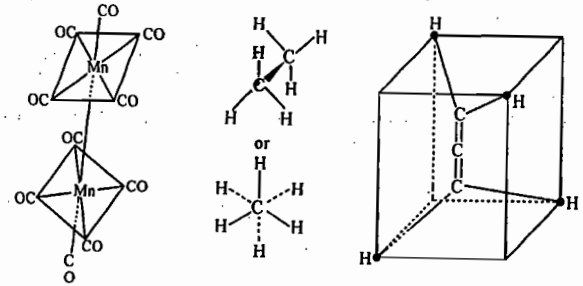


(a) (b) trans $[Co(NH_3)_4ClBr]^+$ (ignore the positions of hydrogens) [Ans. (a) D_{4d} (b) C_{4v}]

3. Determine the symmetry point groups of the molecules given below. Also determine the symmetry operations that can be carried out on the geometry of each molecule.

(a)  (b) PF_5 (c) $PtCl_4^{2-}$ (d) Ferrocene [Ans. (a) D_{2h} (b) D_{3h} (c) D_{4h} (d) D_{5d}]

4. Give the symmetry point groups of the following molecules :



(a) (b) (c)

[Ans. (a) D_{4d} (b) D_{3d} (c) D_{2d}]

5. Determine symmetry point groups of the following :

1. Benzene	2. Ruthacene	3. $Co(NH_3)_4Cl_2$ (trans)	4. *p*-Dichlorobenzene
5. Acetaldehyde	6. Trans N_2F_2	7. Diborane	8. BF_3
9. N_2O_4	10. $[Co(NH_3)_4ClBr]$ (trans)	11. $POCl_3$	12. NO_2^-.

[Ans. 1. D_{6h} 2. D_{5h} 3. D_{4h} 4. D_{2h} 5. C_s 6. C_{2h} 7. D_{2h} 8. D_{3h} 9. D_{2h} 10. C_{4v} 11. C_{3v} 12. C_{2v}]

6. (a) Describe the rules relating to the determination of symmetry point groups of molecules.
   (b) Determine the product of C_2 and σ_v (which is perpendicular to C_2) by taking a point (x_1, y_1, z_1) in space.
7. Construct a Group Multiplication Table for C_{3v} point group by taking NH_3 as an example.
8. Represent NH bonds of ammonia by arrows. Taking these arrows as basis, write down Γ_{red} and show that $\Gamma_{red} = A_1 + E$.
9. What information is conveyed by a Character Table ? Explain by taking a suitable example. List all the rules for writing Mulliken's symbols for irreducible representations.
10. ~~Show that in a tetrahedral molecule, p_x, p_y and p_z *together* transform as T_2 representation of the group.~~
11. What is 'direct product' ? How is it helpful in determining allowed and forbidden electronic transitions ?
12. How is group theory helpful in understanding σ and π bonding in (i) $[M_nO_4]^-$ and (ii) $[Co(CN)_6]^{3-}$?
13. Show that in a strong field octahedral complex, t_{2g}^2 configuration gives rise to $^3T_{1g}$, $^1T_{2g}$, $^1A_{1g}$ and ^1E_g terms whereas e_g^2 configuration gives rise to $^3A_{2g}$, ^1E_g and $^1A_{1g}$ terms.
14. Discuss briefly the various applications of the group theory.

4 CHEMICAL BONDING

Atoms, except those of noble gases, do not have free existence. They readily combine with one another to form molecules. According to the classical view, the phenomenon of combination, called **chemical bonding**, involves *the union of two or more atoms through redistribution of electrons in their outer most shells involving either transference of electrons from one atom to another or sharing of electrons amongst themselves so that all the atoms acquire the stable noble gas configurations of minimum energy.* If the union takes place by the *transference of electrons* from one atom to another, the bonding is said to be **ionic** and if it takes place by the *mutual sharing of electrons* between the atoms concerned, the bonding is said to be **covalent.** There is yet another type of bonding called **coordinate covalent bonding** in which both the electrons shared between the atoms are contributed by one atom only.

In addition to the above, some other types of chemical bonds such as *metallic bond* and *hydrogen bond* are also known.

IONIC BOND

An **ionic bond** results from *complete transference of one or more electrons from the outermost energy shell (valency shell) of one atom to the outermost energy shell of the other atom.* In this way, both the atoms acquire electronic configurations of the nearest noble gases. The atom from which the electrons are transferred, *i.e.,* the atom which *loses the electrons,* acquires a *positive charge* and becomes, what is called, a **positive ion.** The atom which *gains the electrons,* acquires a *negative charge* and becomes, what is called, a **negative ion.** *The electrostatic attraction between the oppositely charged ions results in the formation of a bond between them. This is called an* **ionic bond.** *The number of electrons transferred from or to the atom of an element in order to acquire the stable s^2p^6 configuration in the outer most shell is called the* **electrovalency** *of the element.*

The formation of ionic bond (in fact, of any type of chemical bond) is invariably accompanied by decrease in energy. As an example, we may consider the **decrease in energy in the formation of sodium chloride.** The essential processes which occur in the formation of sodium chloride (*solid*) from sodium (*solid*) and chlorine (*gas*) are as follows :

(i) $$Na\,(s) \xrightarrow[= 108{\cdot}5\ kJ\ mol^{-1}]{\text{Sublimation energy}} Na\,(g)$$

(ii) $$Cl_2\,(g) \xrightarrow[= 243{\cdot}0\ kJ\ mol^{-1}]{\text{Dissociation energy}} 2Cl\,(g)$$

(iii) $$Na\,(g) \xrightarrow[= 495{\cdot}2\ kJ\ mol^{-1}]{\text{Ionization energy}} Na^+\,(g) + e^-$$

(iv) $$Cl\,(g) + e^- \xrightarrow[= -348{\cdot}3\ kJ\ mol^{-1}]{\text{Electron affinity}} Cl^-\,(g)$$

$$(v) \qquad Na^+(g) + Cl^-(g) \xrightarrow[= -758{\cdot}7 \text{ kJ mol}^{-1}]{\text{Lattice energy}} [Na^+][Cl^-](s)$$

The net change of energy involved in all the five steps put together amounts to $108{\cdot}5 + \frac{1}{2}(243{\cdot}0) + 495{\cdot}2 - 348{\cdot}3 - 758{\cdot}7 = -381{\cdot}8$ kJ mol^{-1}. This is the **decrease in energy** in the formation of ionic bond between sodium (*s*) and chlorine (*g*) to form sodium chloride (*s*).

The net energy change obtained by adding all the energy terms, as in the above example, is denoted by ΔH and is referred to as the *enthalpy of formation of the ionic bond*. Evidently, if ΔH is negative, the formation of ionic bond is feasible.

Factors Influencing the Formation of Ionic Bond. The following factors facilitate the formation of an ionic bond between a metal and a non-metal.

1. Ionization Energy. It is defined as *the amount of energy required to remove the most loosely bound electron from an isolated gaseous atom of an element.* The lesser the ionization energy, the greater is the ease of the formation of a cation. Alkali metals and alkaline earth metals have low ionization energies and, therefore, they form metal cations very easily.

2. Electron Affinity. It is defined as *the amount of energy released when an electron is added to an isolated gaseous atom of an element.* The formation of an anion occurs with the addition of one or more electrons to an atom, generally a non-metal atom. The greater the energy released during this process, the easier will be the formation of an anion, evidently. Thus, high electron affinity of a non-metal favours the formation of an anion.

Thus, low ionization energy of an atom (generally a metal atom) and a high electron affinity of another atom (generally a non-metal atom) facilitate the formation of an ionic bond between them.

3. Lattice Energy. It is defined as *the amount of energy released when cations and anions are brought from infinity to their respective equilibrium sites in the crystal lattice to form one mole of the ionic compound.* The higher the magnitude of the lattice energy, the greater is the tendency of the formation of an ionic bond.

For lattice energy to be high, the force of electrostatic attraction between the constituent ions should be high. The force of attraction between two oppositely charged ions in air (vacuum) is given by the well known Coulomb's law as $F = q_1q_2/r^2$ where q_1 and q_2 are the respective charges on the ions and r is the distance between them. This distance is obtained by adding the radii of the positive and negative ions.

The higher the charges on the ions and the smaller the distance between them, the greater is the force of attraction between the ions. Thus, the third factor mentioned above stipulates that *the cation and anion should be small in size and should have high electric charge so that the electrostatic attraction between them is high.*

To take an example, Na^+ ion is smaller than Cs^+ ion. Hence, the force of attraction between Na^+ ion and Cl^- ion in Na^+Cl^- is more than that between Cs^+ and Cl^- ions in Cs^+Cl^-. The lattice energy of Na^+Cl^- is, therefore, more than that of Cs^+Cl^-. The lattice energies of various alkali metal halides are given in Table 1.

TABLE 1

Lattice Energies of Various Alkali Metal Halides (kJ mol^{-1})

Halide ion	Li^+	Na^+	K^+	Rb^+	Cs^+
F^-	−994·5	−894·5	−790·2	−756·7	−719·0
Cl^-	−802·6	−758·7	−681·4	−660·6	−618·7
Br^-	−760·8	−714·8	−656·3	−631·3	−593·6
I^-	−710·6	−668·8	−618·7	−597·7	−564·3

It can be easily visualised that *for a given anion, the smaller the radius of the cation, the greater is the strength of the ionic bond.* Similarly, *for a given cation, the smaller the radius of the anion, the greater is the strength of the ionic bond.*

Tendency of Elements to form Ionic Bonds in Relation to their Position in the Periodic Table

As is well known, the elements on the left of the periodic table have *low ionisation energies* while those on the right have *high electron affinities*. Hence, ionic bonds are possible between the elements on the left (metals) and those on the right of the periodic table (non-metals). The elements of Group 1 (alkali metals), for example, react readily with elements of Group 17 (the halogens) to form ionic compounds. The elements of Group 2 (alkaline earth metals) also react with elements of Group 17, but not so readily. The reason is that these metals have two electrons in the valency shells and they have to lose both of them to acquire the stable s^2p^6 configuration in ther outermost shells. The elimination of two electrons from a metal M may be represented as below :

$$M \xrightarrow{(IE)_1} M^+ + e^- \quad ; \quad M^+ \xrightarrow{(IE)_2} M^{2+} + e^-$$

$(IE)_1$ represents the first ionisation energy while $(IE)_2$ represents the second ionisation energy of the metal. When the first electron is taken out of an atom, it becomes increasinlgy difficult to remove the second electron from the resulting positively charged ion. Thus, $(IE)_2$ is very much higher than $(IE)_1$. In order to remove two electrons, evidently, the energy needed is $(IE)_1 + (IE)_2$. Hence, *elements of Group 2 do not have as strong a tendency to form ions as the elements of Group 1 have.*

Amongst the non-metals, elements of Groups 16 and 17 change into negatively charged ions (anions) readily. However, the non-metals of Group 16 (oxygen, sulphur, etc.) do so less readily compared to the non-metals of Group 17. The reason is that their outer configuration is s^2p^4 and thus there are two vacancies in their valency shell. The addition of one electron is accompanied by release of energy giving rise to an ion with a single negative charge but the addition of the second electron takes place with difficulty because of repulsion from its own negative ion. Hence, *energy has to be supplied to add the second electron.* For example, 140·9 kJ mol^{-1} of energy is *released* when oxygen is converted to O^- ion but 769·9 kJ mol^{-1} of energy has to be *supplied* to convert O^- to O^{2-} ion. Thus,

$$O + e^- \longrightarrow O^- ; \qquad \text{Energy released, } \Delta H_1 = -140{\cdot}9 \text{ kJ mol}^{-1}$$

$$O^- + e^- \longrightarrow O^{2-} ; \qquad \text{Energy required, } \Delta H_2 = +769{\cdot}9 \text{ kJ mol}^{-1}$$

Hence, *formation of oxides or sulphides is not so easy as the formation of fluorides or chlorides.*

Tendency to form Cations. *The larger the size of an atom, the greater is the ease with which the valency electrons can be eliminated from it.* Since the atomic volume (atomic mass/density) and hence the atomic radius increases on moving down the group of alkali metals from Li → Na → K → Rb → Cs, the tendency of alkali metals to change into cations increases in the same order. Thus, Na changes into Na^+ ion more easily than Li. Similarly, K changes into K^+ ion more easily than Na and so on. Cesium, the last element of the group which has the largest atomic size, ionises most readily while lithium, the first element which has the smallest atomic size, ionises least readily.

Similarly, amongst the alkaline earth metals (Group 2), Ba, which is the heaviest element with the largest atomic radius, ionises most readily while Be, with the smallest atomic radius in this group, ionises least readily.

Tendency to form Anions. *The smaller the atom, the greater will be its tendency to accept extra electron* (or electrons) *to change into an anion.* For example, amongst the halogens, fluorine, with the smallest atomic size, forms an anion most readily. It is for this reason that *fluorides* of mercury, aluminium and tin are *ionic compounds* while the *chlorides* of these metals are largely *covalent* in character.

Formation of Ions of Higher Charges. As mentioned before, the formation of ions with two positive charges or two negative charges is not so easy as the formation of ions with one positive or one negative charge. The formation of simple ions with three positive or three negative charges is extremely

difficult and, therefore, highly unlikey. Consider, for example, aluminium of Group 13. Its outer electronic configuration is $3s^2p^1$. The successive ionisation energies of aluminium are as follows :

$$Al \xrightarrow{(IE)_1} Al^+ + e^-; \qquad (IE)_1 = 577{\cdot}4 \text{ kJ mol}^{-1}$$

$$Al^+ \xrightarrow{(IE)_2} Al^{2+} + e^-; \qquad (IE)_2 = 1833{\cdot}0 \text{ kJmol}^{-1}$$

$$Al^{2+} \xrightarrow{(IE)_2} Al^{3+} + e^-; \qquad (IE)_3 = 2703{\cdot}5 \text{ kJ mol}^{-1}$$

Thus, a total of 5113·9 kJ mol^{-1} of energy is needed to remove all the three valency electrons to form the trivalent Al^{3+} ion. This is not a feasible proposition since rarely more than 1500 kJ mol^{-1} of energy is available when chemical reactions take place. It is, therefore, easy to understand why the elements of Groups 13 and 14 do not form ionic compounds ordinarily. Instead, they form covalent compounds by the process of sharing of electrons which we shall consider shortly.

Experience shows that simple ions carrying more than two positive charges are rare. However, complex ions carrying more than two positive charges are well known. We shall consider here only one example. Aluminium chloride, $AlCl_3$, is largely a covalent compound. When it is dissolved in water, it undergoes hydration as represented below :

$$AlCl_3 + 6H_2O \longrightarrow AlCl_3.6H_2O \text{ or } [Al(H_2O)_6]^{3+}3Cl^-$$

The hydrated aluminium chloride contains the trivalent complex ion, $[Al(H_2O)_6]^{3+}$. The question arises : How does Al atom now lose three electrons to change into hydrated Al^{3+} ion ? The answer is that the hydration of aluminium chloride is an exothermic process and, therefore, a lot amount of energy is released in the reaction. This energy becomes available to accomplish the release of three electrons from aluminium atom to form hydrated Al^{3+} ion.

Now let us consider why it is not possible, ordinarily, to have anions carrying more than two negative charges. The formation of anions carrying one negative charge, *e.g.*, halides (Group 17) and two negative charges, *e.g.*, sulphides (Group 16) have already been considered. The question arises : Can we have easily anions carrying three negative charges, *e.g.*, nitrides, N^{3-} and phosphides, P^{3-} (Group 15) ? The answer is : No. The reason is that the outer configuration of these atoms is s^2p^3. The addition of three electrons to nitrogen or phosphorus atom requires much more energy than is ordinarily available in chemical reactions. The same is true for other elements of Group 15.

Thus, while formation of simple positive ions is limited, generally, to the atoms of metals of Groups 1 and 2, the formation of simple negative ions is limited, generally, to the atoms of non-metals of Groups 16 and 17. The atoms of elements of middle Groups 13, 14 and 15 do not form ionic compounds ordinarily. As we shall see, they form covalent bonds more readily by sharing their electrons with other atoms.

Variable Valency of Cations. Alkali metals and alkaline earth metals *show only one valency* which is 1 in the case of the former and 2 in the case of the latter. This is because the monovalent cations of alkali metals (such as Na^+, K^+, Rb^+) and divalent cations of alkaline earth metals (such as Mg^{2+}, Ca^{2+}, Ba^{2+}) have most stable noble gas configurations (s^2p^6) in their valency shells.

Several other cations, particularly those of the transition metals, do not have the stable s^2p^6 configuration in their valency shells. In such cases, the outermost shell of the cations is not stable. It further loses one or more electrons giving rise to metal ions of higher valencies. The transition metals thus show variable valency. Iron, cobalt and nickel, for example, form divalent as well as trivalent ions with the loss of 2 or

3 electrons from their valence $3d4s$ orbitals. In fact, most of the transition metals show variable valency by the loss of one or more electrons from their $(n-1)d\ ns$ orbitals.

COVALENT BOND

Lewis Concept of Covalent Bond. G. N. Lewis was the first to suggest, in 1916, that atoms may combine with one another by *sharing of electrons* in their valency shells so that the combining atoms attain the nearest noble gas configurations in their valency shells. The shared electrons contribute towards the stability of both the atoms. This type of linkage is called **covalent linkage** or **covalent bond.** The compounds formed by this mechanism are called **covalent compounds.**

For example, hydrogen and chlorine atoms share one electron each to form HCl.

$$H\cdot + \ddot{\underset{\cdot\cdot}{Cl}}: \longrightarrow H:\ddot{\underset{\cdot\cdot}{Cl}}: \quad \text{or} \quad H-Cl$$

In this process, while hydrogen atom acquires electronic configuration of helium, chlorine atom acquires electronic configuration of the nearest noble gas argon.

In the formation of oxygen molecule, each oxygen atom has six electrons in the valence shell and, therefore, they contribute two electrons each for sharing. Thus, two electron pairs are shared and there is a **double bond** between the two oxygen atoms.

$$:\ddot{O}: + :\ddot{O}: \longrightarrow :\ddot{O}::\ddot{O}: \quad \text{or} \quad O=O$$

According to Lewis concept, *the number of electrons which an atom contributes for sharing in a covalent bond* is called its **covalency**. Thus, covalency of hydrogen, chlorine and oxygen is 1, 1 and 2, respectively.

Decrease of Energy in the Formation of Hydrogen Molecule. The formation of a chemical bond of any type is possible only if the approach of the atoms towards one another is accompanied by decrease in energy. When any two atoms approach each other, new forces of attraction and repulsion are set in. The forces of attraction are between the nucleus of one atom and the electrons of the other. The forces of repulsion are between two nuclei amongst themselves as well as between the electrons of the two atoms amongst themselves. The net result of these forces may be attraction or repulsion.

If the net result is **attraction**, *the total energy of the system decreases and a chemical bond results.*

If the net result is **repulsion**, *the total energy of the system increases and no chemical bonding is possible.*

Let us see how the approach of two hydrogen atoms towards each other results in decrease of energy of the system and thus results in the formation of a covalent bond to give hydrogen molecule (H_2).

Consider two hydrogen atoms A and B with nuclei H_A and H_B and corresponding electrons e_A and e_B respectively. When the two atoms approach each other, the following additional attractive and repulsive forces start operating :

a. Attractive forces between electron of atom A (e_A) and nucleus of atom B (H_B) and electron of atom B (e_B) and nucleus of atom A (H_A). These forces decrease the energy of the system.

b. Repulsive forces between two nuclei (H_A and H_B) and two electrons (e_A and e_B) of the two atoms. These forces increase the energy of the system.

The attractive and repulsive forces are pictorially shown in Fig. 1.

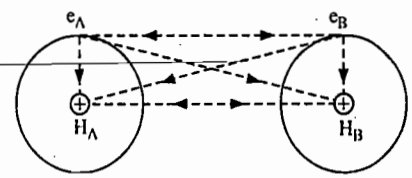


Fig. 1. Attractive and repulsive forces between H atoms in H_2 molecule.

The manner in which the potential energy of the system changes as the hydrogen atoms are brought closer to each other is represented graphically in Fig. 2.

Initially, when the hydrogen atoms lie far away, say, at infinite distance from each other, the electrostatic potential energy of one atom is independent of the presence of the other atom. By convention, this energy is taken arbitrarily as zero. This fact is represented at the far end towards the right of the graph. As the two atoms are brought closer and closer, the electrostatic potential energy goes on decreasing because attractive forces go on becoming more and more dominant. The decrease of potential energy continues till a certain minimum value is attained. If the atoms are brought still closer, the potential energy shows a *sharp rise*. This is due to the fact that the repulsive forces at such small internuclear distances become dominant. Since repulsion always causes increase in energy, the energy of the system increases, as shown in the figure. The formation of a covalent bond between two hydrogen atoms takes place at the point which corresponds to the *minimum* in the potential energy curve.

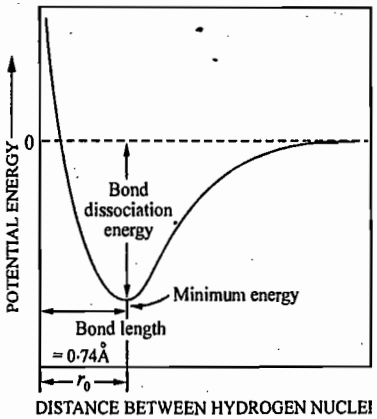

Fig. 2. Variation of potential energy with nuclear distance in the formation of hydrogen molecule.

The position of minimum energy also corresponds to the minimum distance upto which the two nuclei can be brought together before the force of repulsion between them becomes dominant. In other words, this distance corresponds to the bond length. **Bond length** *is, thus, defined as the distance between the nuclei of the two atoms constituting a chemical bond.* In the case of hydrogen molecule, the distance between the two hydrogen atoms coresponding to minimum energy is 0·74 Å. The decrease in potential energy in the formation of H_2 molecule has been found to be 458 kJ mol^{-1}. Evidently, because of decrease of energy, H_2 molecule would be much more stable than H atoms.

*ATOMIC ORBITAL OVERLAP CONCEPT OF COVALENCY

It may be recalled that an orbital can accommodate a maximum of two electrons having opposite spins. *As long as such electron pairs are present in orbitals, they are not available for chemical combination.* If, however, only a single electron is present in an orbital of the outer shell, it will have a tendency to combine with a similar electron present in the orbital of the outer shell of another atom. This results in the formation of a covalent chemical bond between the two atoms. Thus, according to the **orbital overlap concept,** *formation of a covalent bond between two atoms results from the coupling of electrons with opposite spins belonging to orbitals of outermost shells of the two atoms.* The orbitals containing such unpaired electrons are said to *overlap with each other* so that the electron pair now belongs to both the orbitals. This may be illustrated by considering a few examples.

Formation of hydrogen molecule. Hydrogen atom has only one electron in its valency shell. It needs one electron more to complete this shell. In the formation of a stable hydrogen molecule, H_2, the two hydrogen atoms having unpaired electrons approach each other and their 1*s* atomic orbitals overlap when the two approaching atoms reach a point at which the potential energy is minimum. The electrons shared between the two atoms are located in the region of space between the nuclei of the atoms concerned, as represented in Fig. 3. The 1*s* orbitals of

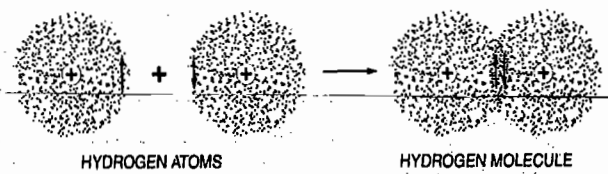

Fig. 3. Formation of hydrogen molecule by overlapping of 1*s* orbitals of both the atoms. The paired electrons have opposite spins.

*The atomic orbital overlap concept of covalency, in fact, forms the basis of the modern theories of covalent bonding (specially the valence bond theory). These theories would be discussed in details a little later in this chapter.

both the atoms, thus, get fully occupied. The bond formed between two hydrogen atoms in this manner is called an ***s – s* bond** since it involves overlapping of *s* orbitals of the two hydrogen atoms. The overlapping of the orbitals takes place along the same axis, as shown. When a bond is formed by overlapping of the orbitals along the same axis, it is known as a **sigma bond.** This type of overlapping takes place to a substantial extent and, therefore, the resulting bond is very strong. The greater the extent of the overlapping of orbitals, the stronger is the covalent bond.

Formation of fluorine molecule. Fluorine atom with electronic configuration $1s^2 2s^2 p_x^2 p_y^2 p_z^1$ has one half-filled *p* orbital. It needs one more electron to fill this orbital. In the formation of fluorine molecule, this half-filled *p* orbital of one atom overlaps with a similar *p* orbital of another atom to form a molecule of fluorine, F_2. This is shown in Fig. 4. In the figure, only *p* orbitals are shown. The completely filled *s* orbitals are omitted for the sake of clarity.

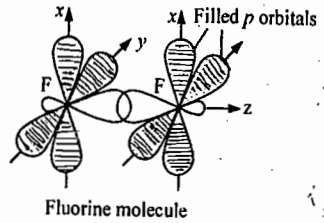

Fig. 4. Formation of fluorine molecule by overlapping of 2*p* orbitals of both the fluorine atoms.

Formation of hydrogen fluoride molecule. As has been shown earlier, the 1*s* orbital of hydrogen can accommodate one electron more. Also one of the 2*p* orbitals of fluorine is only half-filled and, therefore, there is room for one electron more. Hence, 1*s* orbital of hydrogen and the half-filled 2*p* orbital of fluorine overlap and form a covalent bond. This is shown in Fig. 5.

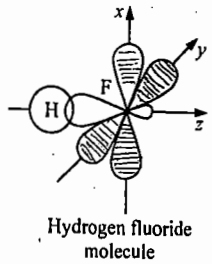

Fig. 5. Formation of hydrogen fluoride molecule by overlapping of 1*s* orbital of hydrogen atom and 2*p* orbital of fluorine atom.

Pi (π) Bonds. As discussed above, the overlapping of atomic orbitals along the same axis results in the formation of sigma bond. There is also another type of bond known as **pi (π) bond.** *This type of bond is formed by the sidewise overlapping (also called lateral overlapping) of the two half-filled orbitals.* The formation of pi bonds may be illustrated by reference to the formation of oxygen and nitrogen molecules.

Formation of oxygen molecule. The electronic configuration of oxygen (Z = 8) is $1s^2 2s^2 2p_x^2 p_y^1 p_z^1$. Oxygen atom has two half-filled 2*p* orbitals. When two oxygen atoms approach each other, one of the two half-filled *p* orbitals of each atom overlaps along the internuclear axis forming a *p – p* sigma bond. The second half-filled *p* orbital of each atom overlaps sidewise to form a pi bond. This is shown in Fig. 6.

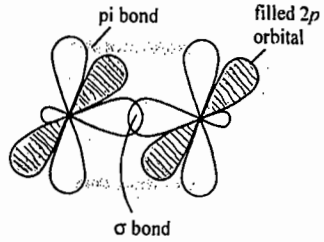

Fig. 6. Formation of oxygen molecule by overlapping of the two half-filled *p* orbitals of each oxygen atom.

Thus, in oxygen molecule, the two oxygen atoms are held together by a *double bond* comprising of one sigma bond and one pi bond.

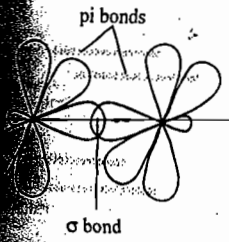

Fig. 7. Formation of nitrogen molecule by overlapping of the two half-filled *p* orbitals of each nitrogen atom.

Formation of nitrogen molecule. The electronic configuration of nitrogen is $1s^2 2s^2 p_x^1 p_y^1 p_z^1$. All the three *p* orbitals are only half-filled in accordance with Hund's rule. Hence, the three half-filled *p* orbitals of one nitrogen atom overlap with the three corresponding half-filled *p* orbitals of another nitrogen atom to form N_2 molecule. This is represented in Fig. 7.

Thus, in nitrogen molecule the two nitrogen atoms are held together by a *triple bond* made up of one sigma bond and two pi bonds.

Relative Strengths of sigma and pi bonds. The strength of a covalent bond depends upon the extent of overlapping of half-filled atomic orbitals. The extent of overlapping between two atoms is always greater when there is end to end overlapping of orbitals than when there is lateral overlapping of orbitals. Hence, a sigma bond is always stronger than a pi bond.

Variable Covalency. Maximum Covalency

Ordinarily, the covalency of an element is equal to the number of unpaired *s* or *p* electrons present in the outermost shell of its atom in the ground state. Thus, hydrogen (electronic configuration : $1s^1$) has its solitary *s* electron unpaired and hence its covalency is one. Fluorine (electronic configuration : $1s^2 2s^2 p_x^2 p_y^2 p_z^1$ has only *one* unpaired *p* electron and its covalency is also 1. Oxygen (electronic configuration : $1s^2 2s^2 p_x^2 p_y^1 p_z^1$ has *two* unpaired *p* electrons and its covalency is 2. Nitrogen (electronic configuration : $1s^2 2s^2 p_x^1 p_y^1 p_z^1$) has *three* unpaired *p* electrons and its covalency is 3. None of these atoms contains *d* orbitals in its electronic configuration.

The outer electronic configuration of sulphur atom in the ground state, *i.e.*, the lowest energy state is $3s^2 p_x^2 p_y^1 p_z^1$. Like oxygen, it has *two* unpaired electrons and exhibits a covalency of 2 (in compounds such as H_2S, SF_2, etc.). Sulphur atom belongs to the third period ($n = 3$). Hence, it has *d* orbitals also which, however, are vacant. When sulphur combines with more electronegative elements such as fluorine, oxygen, chlorine or bromine, sufficient amount of energy is released to cause unpairing of *s* and *p* electrons which get promoted to the vacant *d* orbitals. This unpairing of electrons increases the covalency of sulphur. Thus, if only the *p* electrons are unpaired, the total number of unpaired electrons will be four and if both *p* and *s* electrons get unpaired, the total number of unpaired electrons will be six. The covalency of sulphur in the former case will be 4 and in the latter case 6. This is illustrated in Fig. 8.

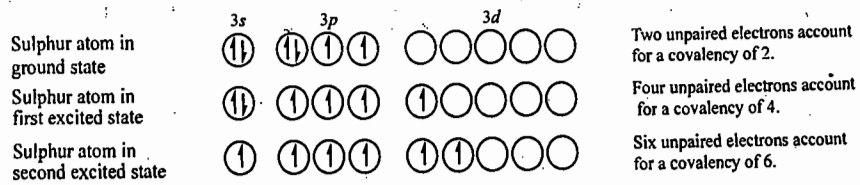

Fig. 8. Variable covalency exhibited by sulphur.

Thus, sulphur exhibits tetracovalency in the formation of compounds like SF_4 and SOF_2 and hexacovalency in the formation of compounds such as SF_6.

The halogens (excepting fluorine) also contain vacant *d* orbitals in their valency shells. These vacant *d* orbitals allow for easy excitation of *p* as well as of *p* and *s* electrons and account for higher covalencies of 3, 5 and 7 in the case of the halogens (other than fluorine). This is illustrated in Fig. 9.

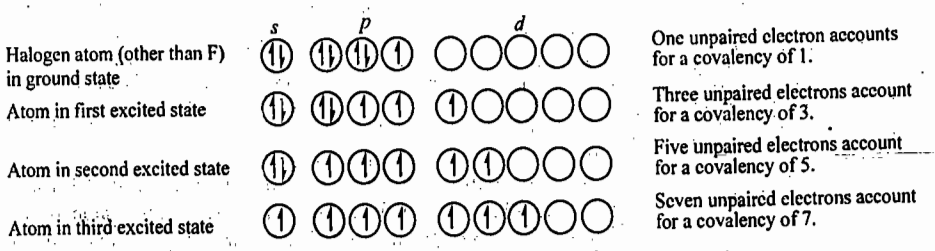

Fig. 9. Variable covalency exhibited by the halogens other than fluorine.

In the ground state, there is only one unpaired electron in the outer electronic configuration of each halogen. Hence, the halogens exhibit covalency of 1, as in the formation of HF, HCl, HBr and HI. In the *first excited state*, of halogens other than fluorine, one pair of *p* electrons gets unpaired providing three

unpaired electrons. This accounts for covalency of 3. Thus, in the interhalogen compounds such as ClF_3, BrF_3 and IF_3, chlorine, bromine and iodine exhibit covalency of 3. In the *second excited state*, both the pairs of *p* electrons get unpaired providing five unpaired electrons which account for covalency of 5. Thus, in $HClO_3$, $HBrO_3$ and HIO_3, all the three halogens exhibit covalency of 5. Similarly, in BrF_5 and IF_5, bromine and iodine exhibit covalency of 5. In the *third excited state*, all the pairs of *p* as well as *s* electrons get unpaired, providing seven unpaired electrons which account for covalency of 7. Thus, in $HClO_4$ and Cl_2O_7, chlorine exhibits covalency of 7.

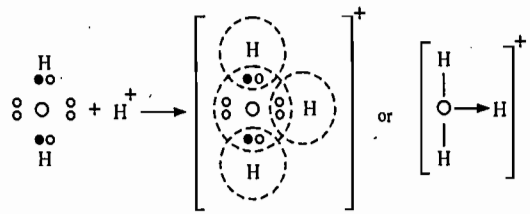
It is evident from the above discussion that elements *whose atoms contain vacant d orbitals* in their valency shells, can, on account of unpairing of *s* and *p* electrons, exhibit variable covalency in forming covalent bonds with more electronegative elements. The **maximum covalency** is generally *equal to the total number of s and p electrons present in the valency shell.* Thus, sulphur having six *s* and *p* electrons (s^2p^4 configuration) exhibits a maximum covalency of 6. The halgoens (Cl, Br, I) having seven *s* and *p* electrons (s^2p^5 configuration) exhibit maximum covalency of 7. Phosphorus having five *s* and *p* electrons (s^2p^3 configuration) exhibits maximum covalency of 5, and so on.

COORDINATE COVALENT BOND OR DATIVE BOND

Lewis proposed that a different type of covalent bond can be formed when both the electrons for sharing between the atoms are contributed by one atom only. This type of bond is known as **coordinate covalent bond or dative bond.**

A coordinate covalent bond is established between two atoms one of which has a complete octet and at the same time possesses at least one pair of unshared electrons while the other is short of the two electrons. The former atom contributes one such pair of electrons for mutual sharing between the two atoms as a result of which the second atom also completes its octet and acquires a stable noble gas configuration. The atom which contributes the pair of electrons is known as the **donor** and the atom which accepts these electrons is called the **acceptor**. The unshared pair of electrons is known as the **lone pair.**

In the formation of hydronium ion, for example, the oxygen atom in water molecule is the donor whereas the hydrogen ion is the acceptor. The coordinate covalent bond is conventionally represened by an arrow pointing from the donor to the acceptor, as shown below in the formation of hydronium ion.



It is important to note that *the coordinate covalent bond once formed is indistinguishable from a covalent bond.*

According to the atomic orbital overlap concept of covalency, a coordinate covalent bond results when an orbital containing a lone pair of electrons in one atom overlaps with an empty orbital present in the other atom. The central atom, oxygen, in water molecule has four orbitals. Two of these orbitals contain bond pairs of electrons while the other two (shaded ones) contain lone pairs of electrons, as shown in Fig. 10. The H^+ ion has an empty *s* orbital which overlaps with one of the orbitals of oxygen atom containing a lone pair of electrons forming hydronium ion, H_3O^+, as illustrated in Fig. 10.

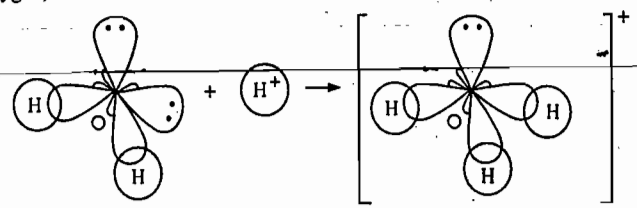


Fig. 10. Formation of hydronium ion.

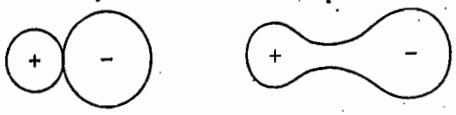
Polarity in Covalent Bonds. A covalent bond formed between two *identical* or *similar atoms* is said to be a **non-polar covalent bond** but if formed between two *dissimilar atoms*, the bond formed is said to be a **polar covalent bond.** The reason is that in the former case the shared electron pair is attracted equally by both atoms and lies exactly midway between them, as in hydrogen molecule, H : H. The molecule formed is said to be a **non-polar molecule.**

In the case of a covalent bond formed between two dissimilar atoms, one of the atoms generally has a greater tendency to attract the electrons towards itself (*i.e.*, it is more electronegative). The electron pair is, therefore, pulled closer to that atom, as in hydrogen fluoride molecule (H :$\ddot{\underset{..}{F}}$:) in which the electron pair shared between hydrogen and fluorine atoms remains closer to the fluorine atom. This unsymmetric distribution of electrons leads to partial charge separation, *i.e.*, development of partial negative charge near fluorine end and partial positive charge near hydrogen end. This is represented in HF and HCl molecules as follows :

$$\overset{+\delta}{H} - \overset{-\delta}{F} \qquad \overset{+\delta}{H} - \overset{-\delta}{Cl}$$

The molecules formed are said to be **polar molecules.** The polar covalent bond, therefore, has *partial ionic character.* The two opposite charges at the ends are called *electrical poles* and the molecules are called ***dipoles.***

Covalent Character of Ionic Bond. Polarisation of Ions. It is a common experience that many times an ionic bond has some covalent character and a covalent bond has some ionic character. The formation of a bond intermediate between an ionic and a covalent bond occurs through a phenomenon known as **polarisation of Ions.** When oppositely charged ions approach each other, the attraction between the positive charge of cation and negative charge of anion and also the simultaneous repulsion between their nuclei and between their electrons results in the *distortion, deformation* or **polarisation** *of the electron charge cloud of the anion.* The electron charge cloud of the anion no longer remains spherical but gets distorted, *i.e.*, polarised towards the cation, as shown in Fig. 11. The electron charge cloud of the cation also gets distorted, *i.e.*, polarised by the anion through a similar process but the polarisation of the cation is far less pronounced because of its small size. The polarisation of ions results in a high electron charge concentration between the two nuclei. This results in the formation of a bond which is intermediate between an ionic and a covalent bond. This type of bond is called **polar covalent bond.** A polar covalent bond is more stable than a pure covalent bond. The higher the degree of polarisation, the greater is the stability of the polar covalent bond. The extent of polarisation depends, evidently, on the polarising power of the cation and the polarisability of the anion.



No polarisation Polarisation of anion

Fig. 11. Polarisation of electron charge cloud of an anion by a cation.

The rules regarding polarisation are known as *Fajan's rules.* These are given below.

Fajan's Rules. 1. The cations with smaller size have higher polarising power, *i.e.*, they cause polarisation of electron charge cloud of an anion to a greater extent. Such cations have positive charge concentrated over a small surface area, *i.e.*, they have a **high charge density** and thus distort the electron charge cloud of the anion highly efficiently. The cations with large size have low polarizing power.

2. The anions with large size have high polarizability, *i.e.*, their electron charge cloud can be deformed easily. The grip of the nucleus on the orbital electrons in large anions will be weak and hence such anions will get polarised by a cation relatively easily.

3. For effective polarisation, there should be a high charge on the cation or the anion or both. The electrostatic forces which cause polarisation, would increase with increase in the charge on the ions.

4. Cations with pseudo inert gas configuration, *viz.*, $ns^2p^6d^{10}$ or with inert pair configuration, *viz.*, $d^{10}(n+1)s^2$, have high polarising power while cations with noble gas configuration, *viz.*, ns^2p^6, have low polarising power. This is due to greater effective nuclear charge in the former cases and smaller effective nuclear charge in the latter cases.

Effects of Polarisation. 1. Bromides and iodides have higher lattice energies (and hence higher stabilities) than expected from theoretical calculations. The extra stability is due to polarisation of the anions resulting in the formation of a polar covalent bond which is more stable than a pure ionic bond.

2. The solubility of ionic compounds in polar solvents decreases with increase in the degree of polarisation, *i.e.*, with increase in the degree of covalent bonding.

3. The hardness of ionic compounds decreases with increase in the degree of polarisation, *i.e.*, with increase in the covalent character.

Per cent Ionic Character of a Polar Covalent Bond. The per cent ionic character of a polar covalent bond depends upon two factors : *1. The Electronegativity Difference of the Bonded Atoms* and *2. Dipole Moment of the Compound Formed.*

1. Electronegativity Difference and Per cent Ionic Character. A pure covalent bond is formed between atoms A and B when the electronegativities of the two atoms are the same. If A and B have different electronegativities, the resulting bond would be a polar covalent bond since the bonding electron pair is pulled more towards the more electronegative atom thereby bringing some excess negative charge on the latter. As a result, some excess positive charge is developed on the less electronegative atom. If A is more electronegative than B, a polar covalent bond $\overset{-\delta}{A} - \overset{+\delta}{B}$ would be formed between A and B. The larger the differece in the electronegativities of A and B, the greater would be the magnitude of δ and the higher would be the polarity of the bond.

Several empirical equations have been proposed to calculate the per cent ionic character of a covalent bond from the electronegativities of the bonding atoms. Two of these equations are the Pauling equation and the Hannay-Smith equation.

The Pauling Equation. Pauling proposed the following empirical equation for determining the per cent ionic character of a covalent bond :

$$\text{Per cent ionic character} = 1 - e^{-\frac{1}{4}(\chi_A - \chi_B)} \qquad ...(1)$$

where χ_A and χ_B are the electronegativities of A and B. He established the following empirical relationship between $\chi_A - \chi_B$ and the per cent ionic character :

$\chi_A - \chi_B$	0·6	1·0	1·4	2·0	2·4	3·0
Per cent ionic character	9	22	39	63	76	89

The Hannay-Smith Equation. Hannay and Smith proposed the following equation for the purpose :

$$\text{Per cent ionic character} = 16\,(\chi_A - \chi_B) + 3{\cdot}5\,(\chi_A - \chi_B)^2 \qquad ...(2)$$

Both the equations, however, give only approximate values.

2. Dipole Moment and Per cent Ionic Character. Consider the bond H – X where X is a halogen atom. If the bond is purely covalent, its dipole moment would be negligibly small. If the bond is ionic, H^+X^-, it implies that complete transfer of an electron has taken place from H to X and the bond would have an appreciable dipole moment which is determined by the product of the electronic charges and the internuclear distance between H and X. For a polar covalent bond which is intermediate between a pure covalent and a pure ionic bond, the dipole moment would be given by the product of the charge (δ) separated due to polarisation and the internuclear distance. The magnitude of δ will depend upon the

extent of the ionic character developed in the bond. Thus,

$$\text{Per cent ionic character} = \frac{\text{Actual dipole moment of the bond}}{\text{Dipole moment of pure ionic bond}} \times 100$$

For example, in **HF molecule**, the internuclear distance is 0·92 Å and the dipole moment for the ionic structure H^+F^- when an electron is completely transferred from hydrogen atom to fluorine atom is given by $4{\cdot}8\times10^{-10}$ esu $\times$ $0{\cdot}92\times10^{-8}$ cm, *i.e.*, 4·42 D. The actual dipole moment of HF molecule is found to be 1·98 D. (1 Debye = 1×10^{-18} esu cm)

$$\therefore \quad \text{Per cent ionic character} = \frac{1{\cdot}98\,\text{D}\times100}{4{\cdot}42\,\text{D}} = 44{\cdot}8 \approx \mathbf{45}$$

Similarly, **for HCl molecule,** using SI units,

$$\text{Internuclear distance} = 127\,\text{pm} = 127\times10^{-12}\,\text{m}$$

$$\text{Actual dipole moment} = 3{\cdot}44\times10^{-30}\ \text{coulomb metre}$$

$$\left.\begin{array}{l}\text{Dipole moment when an electron is}\\ \text{completely transferred from H to Cl}\end{array}\right\} = 1{\cdot}6\times10^{-19}\,\text{C}\times127\times10^{-12}\,\text{m}$$

$$= 2{\cdot}03\times10^{-29}\,\text{C m}$$

$$\therefore \quad \text{Per cent ionic character} = \frac{3{\cdot}44\times10^{-30}\,\text{C m}}{2{\cdot}03\times10^{-29}\,\text{C m}}\times100 = 16{\cdot}9 \approx 17$$

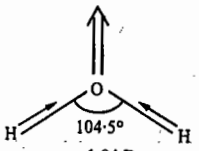
It may be mentioned, however, that dipole moment calculated from the ionic structure of the compound alone contributes only partly towards the total molecular dipole moment. Other factors such as the differences in the sizes of the two atoms, the hybridisation of orbitals involved and the directions of the lone pairs of electrons with respect to the nucleus also contribute towards the total molecular dipole moment. Hence, the per cent ionic character calculated on the basis of dipole moment obtained from the ionic structure of the compound alone, without considering other factors, is only *approximate*.

Dipole Moment and Structure of Molecules. A diatomic molecule is polar if the bond formed between the atoms is polar. In such a molecule, the dipole moment of the bond gives the dipole moment of the molecule. For example, the dipole moment of HCl molecule is the same as the dipole moment of HCl bond and is known to be 1·03 D. However, in the case of molecules containing more than two atoms, the dipole moment not only depends upon the individual dipole moments of the bonds but also on the spatial arrangement of various bonds in the molecule. In such cases, the dipole moment of the molecule is the vector sum of the dipole moments of the various bonds. Obviously, the polar or non-polar nature of molecule will depend upon the spatial arrangement of atoms in the molecule. The bonds may be polar yet the molecule may be non-polar.

For example, carbon dioxide (CO_2) and water (H_2O) molecules are both triatomic molecules but the dipole moment of carbon dioxide is zero while that of water is 1·84 D. This can be easily explained on the basis of their structures as illustrated below :

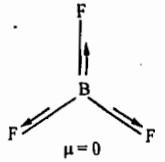
In carbon dioxide molecule, both the carbon–oxygen bonds are polar. But since the molecule is linear, the dipole moment of C = Q bond (2·3 D) on one side of the molecule is cancelled by that on the other side of the molecule giving net zero dipole moment. On the other hand, water molecule is not linear but has a *bent structure* as shown. Therefore, the dipole moment of water molecule is not zero. It is the resultant of the dipole moments of the two O – H bonds inclined at an angle of 104·5° and the contribution of the two lone pairs of electrons on oxygen atom. It has been found to be 1·84 D.

μ = 0

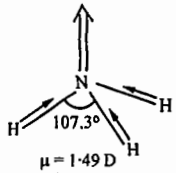


μ = 1·84 D

Likewise, the dipole moment of BF_3 is zero while that of NH_3 is 1·49 D, although both the molecules are tetra-atomic. This is because BF_3 has symmetrical structure in which the three B–F bonds are oriented at an angle of 120° to one another. The three bonds lie in one plane and the dipole moments of these bonds cancel one another giving net dipole moment equal to zero. On the other hand, the ammonia molecule has *pyramidal structure*. The individual dipole moments of three N – H bonds and the contribution of the lone pair of electrons on nitrogen atom to dipole moment give the resultant dipole moment of NH_3 molecule as 1·49 D, as shown.

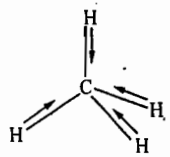


μ = 0

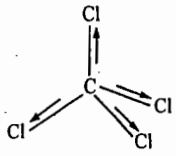


μ = 1·49 D

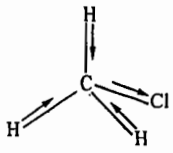
CH_4 and CCl_4 molecules have symmetrical tetrahedral structures and their resultant dipole moments are *zero*. CH_3Cl molecule has also tetrahedral structure but its dipole moment is not *zero* because its structure is not symmetrical and the dipole moments of C – Cl and H– C bonds are not equal. This is illustrated below :



μ = 0



μ = 0



μ ≠ 0

Some Important Characteristics of Covalent Bond. The important characteristics of a covalent bond are its bond length, bond angle and bond energy. These are discussed below.

TABLE 2

Bond Lengths (Å) of Some Common Bonds

Bond	Bond length	Bond	Bond length
H – H	0·74	H – F	0·92
C – H	1·00	H – Cl	1·27
O – H	0·96	H – Br	1·41
F – F	1·42	H – I	1·61
Cl – Cl	1·99	C – C	1·54
Br – Br	2·28	C = C	1·34
I – I	2·67	C ≡ C	1·20

Bond Length. Let us consider a diatomic molecule. The atoms in this molecule are always vibrating with respect to each other. The question of any *fixed* distance between them, therefore, does not arise. We can, however, think of an average distance between the nuclei of the two atoms bonded to each other. This is called bond length or bond distance. Thus, **bond length** is defined as the average distance between the nuclei of two bonded atoms in a molecule. We have already seen that in the formation of hydrogen molecule, when two hydrogen atoms approach each other, a stage is reached when there is maximum electrostatic attraction and minimum repulsion between the two atoms. At this point the potential energy of the system becomes minimum and the atoms get bonded together. The distance between the nuclei of the bonded hydrogen atoms is called the length of the H – H bond. For hydrogen molecule, this length has been found to be 0·74 Å.

The bond lengths have been determined, fairly accurately, in the case of crystals by X-ray diffraction and in the case of gases by spectroscopy. The values obtained for some common diatomic molecules are given in Table 2.

It may be noted that bond length decreases with multiplicity of the bond formed between the two atoms. Thus, C ≡ C bond is shorter than C = C bond which, in turn, is shorter than C – C bond.

Bond Angle. Bond angle may be defined as the angle between two bonds of the atom in a molecule or the internal angle between the orbitals containing bonding electron pairs in the valency shell of the atom in a molecule. For example, the bond angles in H_2O, NH_3 and CH_4 molecules are 104·5°, 107·3° and 109·5°, respectively.

The bond angle gives an idea of the distribution of the orbitals in three-dimensional space around the central atom in the molecule and thus gives an idea of the shape of the molecule.

Bond Strength or Bond Energy. Energy is required invariably to break a chemical bond. For instance, in the breaking of one mole of hydrogen gas into atoms, 458 kJ of energy is required. The bond strength in this case is said to be 458 kJ per mole, *i.e.*, per Avogadro's number of bonds. **Bond strength** or **bond energy** of a particular type of bond is defined as *the energy required to break one mole of bonds of that type in a substance in gaseous state.* The bond energies of some common bonds are given in Table 3.

TABLE 3

Bond Energies of Some Common Bonds

Bond	Bond energy (kJ mol^{-1})	Bond	Bond energy (kJ mol^{-1})
H – H	458·0	O = O	494·6
F – F	154·8	N ≡ N	945·6
Cl – Cl	242·7	C – C	347·0
H – Cl	430·0	C = C	619·0
I – Cl	209·2	C ≡ C	836·8

The strength of the bond indicates the stability of the bond. Thus, N ≡ N bond is more stable than O = O bond. Hence, nitrogen molecule is more stable than oxygen molecule. Consequently, nitrogen is much less reactive than oxygen. The strength of F – F bond is lower than that of Cl – Cl bond. Hence, fluorine is more reactive than chlorine. Similarly, ICl is more reactive than Cl_2.

WAVE MECHANICAL TREATMENT OF COVALENT BOND

The Lewis concept of covalent bond based on sharing of electrons satisfactorily explains the bonding between atoms all of which have a tendency to gain electrons in order to acquire the stable noble gas configurations. It also explains adequately the polarity of molecules. However, the concept remains *purely qualitative* and it cannot answer a number of questions such as

1. Why a covalent bond is formed at all ?
2. How do the electrons distribute themselves in space around the central atom in a molecule ?
3. What are the forces of attractive interaction in a covalent molecule ?
4. What is the concept of bond energy in a covalent bond ?
5. How are the compounds such as PF_5, IF_7, SF_6, BF_3, with central atoms having more than or less than 8 valence shell electrons so stable ?

Wave mechanics has provided satisfactory answers to most of these questions and has led ultimately to the development of more comprehensive theories of covalent bonding. These theories are : 1. *The Valence Bond Theory.* 2. *The Molecular Orbital Theory.*

But, before we discuss the two theories, it would be worthwhile to elucidate the **wave mechanical principles** which are involved in their treatment. These principles are :

1. If ψ_1 is a solution of the wave equation $\hat{H}\psi = E\psi$, then $c_1\psi_1$ is also the solution of the same wave equation where c_1 is a constant known as *coefficient of the wave function.* This means that ψ_1 and $c_1\psi_1$ give the same value of energy E.

2. If ψ_1 and ψ_2 are separately the solutions of the wave equation $\hat{H}\psi = E\psi$, then $c_1\psi_1$, $c_2\psi_2$ and $c_1\psi_1 \pm c_2\psi_2$ are also the solutions of the same wave equation. This means that ψ_1, ψ_2, $c_1\psi_1$, $c_2\psi_2$ and $c_1\psi_1 \pm c_2\psi_2$ would give the same value of energy E. The squares of the coefficients, *viz.*, c_1^2 and c_2^2 give the contributions of ψ_1 and ψ_2, respectively, to the total wave function.

Approximate Solution of Schrodinger Wave Equation. We have already discussed in the first chapter that the Schrodinger wave equation can be solved only for hydrogen and hydrogen-like systems, such as He^+ in which a single electron moves under the influence of a single nucleus. The wave equation cannot be solved for systems containing more than one electron or more than one nucleus. Nevertheless, methods have been devised for finding out approximate ψ closest to the true ψ and the corresponding approximate energy closest to the true energy of multi-electron and multi-nucleus systems. One such method is based on the *variation principle.*

The Variation Principle. Consider the wave equation $\hat{H}\psi = E\psi$. Multiplying each side of the wave equation by ψ and integrating it throughout the space, we get

$$\int_{-\infty}^{+\infty} \psi \hat{H} \psi \, d\tau = \int_{-\infty}^{+\infty} \psi E \psi \, d\tau \qquad ...(3)$$

$$= E \int_{-\infty}^{+\infty} \psi^2 d\tau \qquad (\because E \text{ is constant}) \qquad ...(4)$$

where $d\tau$ is a small space element.

From Eqs. 3 and 4,

$$E = \int_{-\infty}^{+\infty} \psi \hat{H} \psi d\tau \Big/ \int_{-\infty}^{+\infty} \psi^2 d\tau \qquad ...(5)$$

We can, thus, calculate energy E of the system if we know true ψ. If we do not know true ψ, even then we can guess a wave function which is close to the true wave function ψ by using our chemical intuition. If this approximate wave function is ψ_1, then Eq. 5 takes the form

$$\varepsilon = \int_{-\infty}^{+\infty} \psi_1 \hat{H} \psi_1 d\tau \Big/ \int_{-\infty}^{+\infty} \psi_1^2 d\tau \qquad ...(6)$$

where ε, known as **energy function,** will have the dimensions of energy but will *not be equal* to the true energy of the system.

In case ψ and ψ_1 are complex wave functions, then Eq. 3 is written as

$$\int_{-\infty}^{+\infty} \psi^* \hat{H} \psi \, d\tau = \int_{-\infty}^{+\infty} \psi^* E \psi \, d\tau$$

and Eq. 6 is written as

$$\varepsilon = \int_{-\infty}^{+\infty} \psi_1^* \hat{H} \psi_1 d\tau \Big/ \int_{-\infty}^{+\infty} \psi^* \psi_1 d\tau$$

where ψ_1^* is the complex component of ψ_1. In case ψ and ψ_1 are real, then ψ^* is the same as ψ and ψ_1^* is the same as ψ_1. *For the sake of simplicity we have assumed ψ to be real.*

According to the variation principle, if we are able to guess at a number of wave functions ψ_1, ψ_2, ψ_3, etc., which are thought to be close approximations of the true wave function ψ, then we can calculate the energy functions, ε_1, ε_2, ε_3, etc., with the help of Eq. 6. In such a case

1. All the energy functions calculated as above would have *higher values* than the true energy of the system.

2. Out of ε_1, ε_2, ε_3, etc., the energy function with the *minimum value would be closest to the true* energy E.

3. The wave function which gives the minimum value of energy function is the closest approximation of the true wave function ψ.

One may question, why we cannot calculate E directly from the relation

$$E = \hat{H}\psi/\psi \qquad ...(7)$$

The answer is as follows : Eq. 7 can be employed for calculating E only if ψ is a true wave function. If ψ is an approximate wave function (as is usually the case in multi-electron systems), then, $\hat{H}\psi/\psi$ would be a function of x, y, z and would vary from place to place in a three-dimensional space. The value of E would also vary accordingly. In other words, if E is calculated with the help of Eq. 7, it would not be a constant parameter.

The approximate ψ can also be calculated with the help of **Ritz linear combination method** which too is based on the variation principle. Suppose we have reasons to believe that the wave function ψ has some charactristics of a known wave function ψ_1 and some characterisitics of another known wave function ψ_2. The wave function ψ can then be written as a *linear combination of* ψ_1 *and* ψ_2, *i.e.*, as $\psi = c_1\psi_1 + c_2\psi_2$. Accordingly,

$$\text{Energy function,} \quad \varepsilon = \int_{-\infty}^{+\infty} \psi \hat{H} \psi d\tau \Big/ \int_{-\infty}^{+\infty} \psi^2 d\tau \qquad ...(8)$$

$$= \int_{-\infty}^{+\infty} (c_1\psi_1 + c_2\psi_2)\hat{H}(c_1\psi_1 + c_2\psi_2)d\tau \Big/ \int_{-\infty}^{+\infty} (c_1\psi_1 + c_2\psi_2)^2 d\tau \qquad ...(9)$$

The coefficients c_1 and c_2 are so adjusted in the total wave function ψ as to yield a *minimum value* of ε. This is done by differentiating Eq. 9 with respect to c_1 and also with respect to c_2 and then putting $\partial\varepsilon/\partial c_1$ and also $\partial\varepsilon/\partial c_2 = 0$ as these are the conditions for minimization of ε. By doing so we get two equations containing ε, c_1 and c_2. From these equations, we can derive a quadratic equation in ε. The solution of this quadratic equation gives ε, c_1 and c_2. Similarly, if we have reasons to believe that the true wave function ψ has characteristics of known wave functions ψ_1, ψ_2, ψ_3, etc., the actual ψ can then be written as $\psi = c_1\psi_1 + c_2\psi_2 + c_3\psi_3 + \cdots\cdots$ The coefficients c_1, c_2, c_3, etc., are so adjusted as to yield minimum value of the energy function.

This method has an advantage that if we guess at a wrong wave function (ψ_i), its coefficient (c_i) would automatically come out to be zero.

With the help of the wave mechanical principles elucidated above, it is possible to discuss at length the Valence Bond and the Molecular Orbital theories of covalent bonding.

VALENCE BOND THEORY

The valence bond theory was first put forward by W. Heitler and F. London, in 1927, to explain the stability of a covalently bonded hydrogen molcule. It was extended further by J. C. Slater and L. Pauling. The theory utilises the following wave mechanical principles :

1. If ψ_A and ψ_B are the wave functions for any two completely independent (non-interacting) systems A and B, then the total wave function ψ for these independent systems, taken together, would be given by

$$\psi = \psi_A \psi_B \qquad ...(10)$$

and the total energy E of these non-interacting systems would be equal to the sum of the energies of systems A and B. The total hamiltonian is also equal to the sum of the hamiltonians for the systems A and B, *i.e.*,

$$E = E_A + E_B \text{ and } \hat{H} = \hat{H}_A + \hat{H}_B$$

2. If the wave function for a many-electron system has characteristics of several wave functions $\psi_1, \psi_2, \psi_3 \ldots\ldots \psi_n$, then according to the Ritz principle of linear combination, the wave function ψ closest to the true wave function of the system is given by

$$\psi = c_1\psi_1 + c_2\psi_2 + c_3\psi_3 + \cdots\cdots c_n\psi_n \qquad ...(11)$$

where $c_1, c_2 \ldots c_n$ are the various coefficients. As already mentioned, the square of the coefficient of a particular wave function gives the contribution of that wave function, generally called the *weightage* of that wave function, to the total wave function. The coefficients c_1, c_2, etc., are so adjusted as to give a *state of lowest energy, i.e., a state of maximum stability*. Further, the wave function ψ should be *normalised* (cf. Chapter 1) so that

$$c_1^2 + c_2^2 + c_3^2 + \ldots\ldots = 1 \qquad ...(12)$$

We will elucidate the Valence Bond theory by taking into consideration the formation of H_2 molecule.

Formation of Hydrogen Molecule. Consider two hydrogen atoms lying far apart from each other so that no interaction between them is possible. Let A and B represent the nuclei and e_1 and e_2 the two electrons. The two atoms of hydrogen may thus be represented as $H_A(e_1)$ and $H_B(e_2)$.

Let the wave functions for the electrons in separated atoms be represented by $\psi_A(1)$ and $\psi_B(2)$. The wave function $\psi_A(1)$ is also called the wave function of the atomic orbital containing electron (1) and the wave function $\psi_B(2)$ is called the wave function of the atomic orbital containing electron (2). According to Eq. 10, the combined wave function ψ for the two separated atoms of hydrogen can be written as

$$\psi = \psi_A(1)\psi_B(2) \qquad ...(13)$$

When the two atoms are brought closer together, their energy changes and, consequently, the energy operator $\hat{H}$ also changes. Assuming that the combined wave function ψ, as represented by Eq. 13, still describes the wave function for H_2 molecule, the energy of the hydrogen molecule, following Eqs. 3 and 4, would be given by

$$E = \int_{-\infty}^{+\infty} \psi_A(1)\,\psi_B(2)\hat{H}\,\psi_A(1)\,\psi_B(2)\,d\tau \Big/ \int_{-\infty}^{+\infty} [\psi_A(1)\psi_B(2)]^2 d\tau \qquad ...(14)$$

The energy changes that take place as the two H atoms are gradually brought closer to each other are shown graphically in Fig. 12.

When the two atoms are far removed from each other, *i.e.*, when the internuclear distance r_{AB} is infinity, the total energy of the system is taken as zero*. As the atoms are brought closer in a region in which the electric field due to one can influence that of the other, the energy of the system starts decreasing till a certain minimum value is reached. This stage corresponds to the formation of H_2 molecule. The internuclear distance at this stage is designated as r_0.

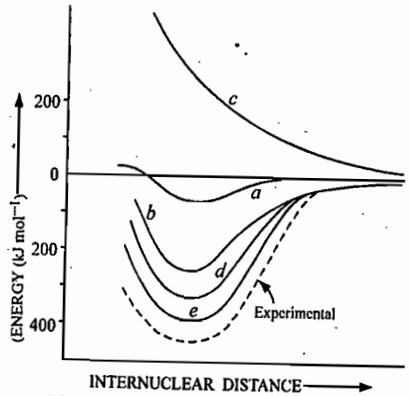


Fig. 12. Variation of energy with internuclear distance in the formation of hydrogen molecule.

When we calculate the enegy of the system of the two hydrogen atoms by using Eq. 14 and plot these energies as a function of internuclear distance, the *curve a* is obtained. The bonding energy given by the minimum in potential energy *curve a* is only 24 kJ mol^{-1}. This is too far below the experimental value of 458 kJ mol^{-1} (represented by the minimum in the *experimental curve*). Moreover, the minimum is found at an internuclear distance of about 0·90 Å (*curve a*) whereas the experimental bond distance in hydrogen molecule is 0·74 Å. Evidently, the wave function $\psi_A(1)\psi_B(2)$, as applied to H_2 system, is not a good approximation. Apparently, some other interactions between the two hydrogen atoms are required to be

*Since we are interested in finding out only the *change in energy* when the two atoms A and B come close to each other from infinite distance to form a bond, the sum of energies of the *two isolated* atoms A and B, when they are at infinite distance from each other, is taken as zero.

taken into consideration to arrive at the correct wave function for the combined H_2 system. Some of these interactions are as follows.

1. Exchange of Electrons. In arriving at Eq. 14, we had assumed that the electrons of the two hydrogen atoms could be distinguished from each other and, therefore, the electron around nucleus A was labelled as e_1 and that around nucleus B was labelled as e_2. This assumption, however, is not correct because when a bond is formed, *the two atomic orbitals overlap* and the two electrons become *indistinguishable* from each other. We can no longer be sure that electron 1 will always be near the nucleus A and electron 2 will always be near the nucleus B. The system of two hydrogen atoms may then be represented by two different states, I and II, as shown below :

$$H_A(e_1)\,H_B(e_2) \qquad\qquad H_A(e_2)\,H_B(e_1)$$
$$\text{(I)} \qquad\qquad\qquad \text{(II)}$$

In state I, nucleus A is associated with electron 1 and nucleus B is associated with electron 2. In state II, nucleus A is associated with electron 2 and nucleus B is associated with electron 1. Both the states I and II are equally probable.

If ψ_I and ψ_{II} are the wave functions representing states I and II, respectively, then, according to Eq. 10, we can write

$$\psi_I = \psi_A(1)\,\psi_B(2) \quad \text{and} \quad \psi_{II} = \psi_A(2)\psi_B(1)$$

A linear combination of ψ_I and ψ_{II} (and not ψ_I or ψ_{II} alone) should be employed for calculating the energy of H_2 molecule. There are evidently two possible modes of linear combination, *viz.*, additive and subtractive according to which there are two wave functions, *viz.*, ψ_+ and ψ_-, given by

$$\psi_+ = \psi_I + \psi_{II} = \psi_A(1)\psi_B(2) + \psi_A(2)\psi_B(1) \qquad ...(15)$$

and

$$\psi_- = \psi_I - \psi_{II} = \psi_A(1)\psi_B(2) - \psi_A(2)\psi_B(1) \qquad ...(16)$$

The actual normalised ψ_+ and ψ_- are $1/\sqrt{2}(\psi_I + \psi_{II})$ and $1/\sqrt{2}(\psi_I - \psi_{II})$, resectively. However, since the normalising constant $1/\sqrt{2}$ does not enter into the calculation of energy, it is not written in the expression for ψ_+ and ψ_-.

The energy of the system, calculated by using ψ_+ in the wave equation is shown by the *curve b* while that calculated from ψ_- is shown by the *curve c* in Fig. 12**. It is evident that ψ_- leads to *increase of energy*. Thus, *bonding is not possible in* ψ_-. We may, therefore, regard ψ_- as a **repulsive state.** The wave function ψ_+, however, leads to *fall of energy*. Thus, *bonding is possible in this state.* We may, therefore, regard ψ_+ as a **bonding state.**

The wave function ψ_+ (Eq. 15) which represents the *bonding state* is also referred to as **covalent wave function.** Therefore, it may be written as $\psi_{covalent}$. The reason for this terminology is that in state I as well as in state II, there is equal distribution of charge on both the nuclei A and B.

As mentioned above, the bonding energy calculated from Eq. 14 is only 24 kJ mol^{-1}. The bonding energy corresponding to ψ_+ (Eq. 15) is 303 kJ mol^{-1} and the internuclear distance is 0·80 Å. *The additional energy resulting from the exchange of electrons between the two hydrogen atoms is called* the **exchange energy.** Thus, 303 − 24 = 279 kJ mol^{-1} is the exchange energy for H_2 molecule.

2. Screening Effect of Electrons. The wave function given by Eq. 15 is further improved by considering the screening effect of the electrons. When the two atoms come close to each other, the electron of one atom shields the electron of the other atom from the nucleus so that the electrons do not feel the full charge of the nucleus. The actual charge felt by an electron is termed as its *effective nuclear charge*. This will be, evidently, less than the actual nuclear charge. If we use the effective nuclear charge

**Since both the states I and II are equally probable, a linear combination having equal contributions from ψ_I and ψ_{II} is employed to calculate the energy of H_2 molecule.

and improve the wave function given by Eq. 15, bonding energy of 365 kJ mol^{-1} is obtained. This is depicted by the minimum in the *curve d.*

3. Ionic Character of H – H Bond. The bond energy of 365 kJ mol^{-1} is still appreciably smaller than the experimental value of 458 kJ mol^{-1}. This shows that ψ_+ still does not give the *true wave function* for H_2 molecule. Evidently, further improvement of wave function is needed. Since the calculated value of bond energy is smaller than the experimental value, it is necessary to provide in our model of H_2 molecule an additional factor which will tend to enhance the binding force between the two hydrogen atoms because increase in such a force will lead to increase in the bond energy. The additional factor that has been suggested is the possibility that *momentarily both the electrons may simultaneously be present close to one nucleus or the other. This gives rise to ionic configurations* represented by states III and IV :

$$(e_2\,e_1)\,H_AH_B \qquad\qquad H_AH_B(e_1\,e_2)$$
$$\text{(III)} \qquad\qquad\qquad \text{(IV)}$$

These two ionic structures may be represented as $H_A^-\,H_B^+$ and $H_A^+\,H_B^-$, respectively. However, the coulombic repulsion between the two electrons present so close to each other would far exceed the coulombic attraction between H_A^- and H_B^+ or between H_A^+ and H_B^-. This reduces the probability of the existence of these additional structures to a bare minimum. Nevertheless, the incorporation of these structures as resonance structures does increase the stability of the hydrogen molecule and hence its bond energy.

The states III and IV are, amongst themselves, equally probable and the wave functions corresponding to state III (ψ_{III}) and state IV (ψ_{IV}) may be expressed as

$$\psi_{III} = \psi_A(1)\psi_A(2) \quad \text{and} \qquad ...(17)$$

$$\psi_{IV} = \psi_B(1)\psi_B(2) \qquad ...(18)$$

The total ionic wave function ψ_{ionic} may be expressed as a linear combination of ψ_{III} and ψ_{IV}, as

$$\psi_{ionic} = \psi_A(1)\psi_A(2) + \psi_B(1)\psi_B(2) \qquad ...(19)$$

Since both the states III and IV are equally probable, hence there is equal contribution from ψ_{III} and ψ_{IV}, towards ψ_{ionic}.

However, states III and IV are less probable than states I and II as the two electrons present on the same H atom would repel each other and make states III and IV less likely compared to states I and II.

Considering the possibilities of covalent as well as ionic structures, the combined wave function for H_2 molecule is written as

$$\psi = \psi_{covalent} + \lambda\psi_{ionic}$$
$$= [\psi_A(1)\psi_B(2) + \psi_A(2)\psi_B(1)] + \lambda\,[\psi_A(1)\psi_A(2) + \psi_B(1)\psi_B(2)] \qquad ...(20)^*$$

where λ gives the extent to which the ionic structures contribute to the bonding. For H_2, λ is calculated to be 0·17. Knowing λ, we can find out *the extent of the contribution of the ionic structures.* The fraction λ is called the **mixing coefficient.**

With all these modifications, the calculated bond energy comes out to be about 388 kJ mol^{-1} which can be considered as reasonably close to the experimental value of 458 kJ mol^{-1}. The internuclear

*The actual normalised wave function is $\frac{1}{\sqrt{(1+\lambda^2)}}[(\psi_{A(1)}\psi_{B(2)} + \psi_{A(2)}\psi_{B(1)}) + \lambda(\psi_{A(1)}\psi_{A(2)} + \psi_{B(1)}\psi_{B(2)})]$. However, $\left(\frac{1}{\sqrt{1+\lambda^2}}\right)$ is omitted since it does not enter into the calculation of energy.

distance between hydrogen atoms now comes out to be 0·75 Å which is quite close to the experimental value of 0·74 Å. The differences which still persist are considered to be due to some complicated electronic interactions, the discussion of which is beyond the scope of this book.

Bond energies and bond lengths for H_2 molecule corresponding to various wave functions are summed up in Table 4.

Table 4

Bond Energies and Bond Lengths for H_2 Molecule Corresponding to Various Wave Functions

Wave Function	Bond Energy (kJ mol^{-1})	Bond Length (Å)
$\psi = \psi_A(1)\psi_B(2)$	24	0·90
$\psi_{covalent} = \psi_A(1)\psi_B(2) + \psi_A(2)\psi_B(1)$	303	0·80
$\psi_{covalent}$ with screening effect	365	0·76
$\psi = \psi_{covalent} + \lambda\psi_{ionic} = [\psi_A(1)\psi_B(2) + \psi_A(2)\psi_B(1)] + \lambda[\psi_A(1)\psi_A(2) + \psi_B(1)\psi_B(2)]$	388	0·75
Experimental values	**458**	**0·74**

Singlet and Triplet Wave Functions. In the valence bond treatment of H_2 molecule, the linear combination of the two approriate wave functions yields the following two space covalent wave functions :

$$\psi_+ = \psi_A(1)\psi_B(2) + \psi_A(2)\psi_B(1) \quad \text{...(Eq. 15)}$$

$$\psi_- = \psi_A(1)\psi_B(2) - \psi_A(2)\psi_B(1) \quad \text{...(Eq. 16)}$$

where ψ_+ is the wave function for the bonding state and ψ_- is the wave function for the repulsive state.

If we exchange the coordinates of electron (1) with those of electron (2) in ψ_+ and ψ_-, the sign of ψ_+ does not change whereas the sign of ψ_- changes from plus to minus so that the wave function changes from ψ_- to $-\psi_-$. Therefore, while ψ_+ is designated as $\psi_{symmetric}$, ψ_- is designated as $\psi_{asymmetric}$.

The complete wave function for the system which includes both the space as well as the spin part of the wave function is written by assuming that these two parts of the wave function do not influence each other, that is, there is no 'spin-orbit' interaction. Accordingly, the complete wave functions for the two states are written as

$$\psi_{+(complete)} = \psi_+ \times \psi_{spin} = \psi_+\alpha_1\alpha_2,\ \psi_+\beta_1\beta_2,\ \psi_+(\alpha_1\beta_2 + \alpha_2\beta_1),\ \psi_+(\alpha_1\beta_2 - \alpha_2\beta_1)$$

$$\psi_{-(complete)} = \psi_- \times \psi_{spin} = \psi_-\alpha_1\alpha_2,\ \psi_-\beta_1\beta_2,\ \psi_-(\alpha_1\beta_2 + \alpha_2\beta_1),\ \psi_-(\alpha_1\beta_2 - \alpha_2\beta_1)$$

where α_1, α_2 are the spin wave functions representing $+\frac{1}{2}$ spin states of electrons 1 and 2, respectively and β_1, β_2 are the spin wave functions representing $-\frac{1}{2}$ spin states of electrons 1 and 2, respectively. As discussed in Chapter 1, the complete wave function of a system is acceptable if it is asymmetric with respect to the exchange of the coordinates of electrons, that is, if the sign of the complete wave function changes on changing the coordinates of electrons.

As can be seen, of the four expressions which can be written for $\psi_{+(complete)}$, there is only a **single** expression for $\psi_{+(complete)}$ which is asymmetric and hence acceptable. Therefore, $\psi_{+(complete)}$ is called a **singlet state.**

Thus, the single asymmetric and hence acceptable $\psi_{+(complete)}$ is $(\psi_{A(1)}\psi_{B(2)} + \psi_{A(2)}\psi_{B(1)})(\alpha_1\beta_2 - \alpha_2\beta_1)$.

However, there are **three** asymmetric and hence acceptable wave functions for $\psi_{-(complete)}$, namely, $(\psi_{A(1)}\psi_{B(2)} - \psi_{A(2)}\psi_{B(1)})\alpha_1\alpha_2$, $(\psi_{A(1)}\psi_{B(2)} - \psi_{A(2)}\psi_{B(1)})\beta_1\beta_2$ and $\psi_{A(1)}\psi_{B(2)} - \psi_{A(2)}\psi_{B(1)})(\alpha_1\beta_2 + \alpha_2\beta_1)$ in which the exchange of coordinates of electrons yields a change of sign of ψ_-. Hence, $\psi_{-(complete)}$ is called a **triplet state.**

Consider again, the singlet state, *viz.*, $\psi_{+(complete)} = (\psi_A(1)\psi_B(2) + \psi_A(2)\psi_B(1))(\alpha_1\beta_2 - \alpha_2\beta_1)$ which is responsible in forming a chemical bond according to VB theory. The spin part of the wave function is the contribution of the product $\alpha\beta$ of opposite spins of electrons 1 and 2. It does not have any contribution from the parallel spin functions $\alpha\alpha$ and $\beta\beta$ of electrons 1 and 2. It follows from the above that in a chemical bond, the two participating electrons must be of opposite spins.

CONCEPT OF RESONANCE

The physical interpretation of Eq. 20 is that H_2 molecule can neither be represented adequately by the pure covalent bond H – H nor by the ionic structures $H_A^+H_B^-$ and $H_A^-H_B^+$. The true structure lies somewhere in between these three structures.

When a molecule cannot be completely represented by a single structure but its characteristic properties can be described by two or more different structures, then the true structure is said to be a **resonance hybrid** *of these structures.* In such a case we say that there is **resonance** between the various possible structures. The possible structures are called **resonating structures.** As a result of resonance, the energy of the molecule becomes lower than the energy of any of the resonating structures. The molecule with a *lower energy* has *higher stability* and also *higher bond energy.* Thus, *resonance imparts extra stability to the molecule.*

The resonance between two or more structures is represented by drawing double-headed arrows between the various structures, as shown below in the case of hydrogen :

$$\overset{+}{H}_A\overset{-}{H}_B \leftrightarrow H_A - H_B \leftrightarrow \overset{-}{H}_A\overset{+}{H}_B$$

The molecule is said to *resonate* between the three resonance structures.

It may be emphasised here that the various postulated resonating structures of a molecule have *no real existence.* Also, it does not mean that the actual molecule exists for a certain fraction of time in one form and for another fraction of time in another form. In fact, *the actual structure has no pictorial representation.* The resonating structures are only a covenient way of picturing a molecule to account for all the properties of a molecule.

Resonance Energy. As mentioned above, the resonance hybrid is more stable than any of the contributing structures. The extra stability of the resonance hybrid over and above the stability of the most stable of the various resonating structures is reflected through an extra decrease in the energy of the molecule. This extra decrease in energy which results from the extra stabilisation of the molecule because of resonance, is called resonance energy. **Resonance energy** *is thus the difference between the actual energy of the molecule and that of the most stable of the resonating structures.* For example, the resonance energy of carbon dioxide is 138 kJ mol^{-1}. This means that the molecule of CO_2 is about 138 kJ more stable than the most stable contributing structure of the molecule.

Let us assume that E_1, E_2 and E_3 are the energies of the three resonating structures for a molecule and among these E_3 is the lowest energy corresponding to the most stable contributing structure. If E_0 is the actual energy of the molecule (determined experimentally), then, resonance energy is $E_3 - E_0$.

There are certain **rules** which permit the **selection of the structures** which contribute towards resonance. These are given below.

1. The contributing structures should have the same atomic positions. They should differ only in the positions of electrons.

2. The contributing structures should have the same number of unpaired electrons.

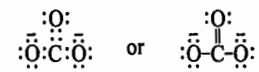
3. The contributing structures should not differ much in energy.

4. Contributing structures should be such that negative charge resides on an electronegative element and positive charge resides on an electropositive element.

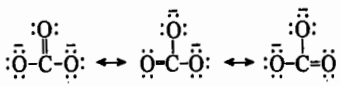
5. In contributing structures, like charges should not reside on atoms close to each other and unlike charges should not be widely separated.

As an illustration, we may consider resonance structures of CO_3^{2-} ion and CO molecule.

Carbonate ion (CO_3^{2-}). According to the octet rule, the electronic structure of carbonate ion (CO_3^{2-}) carrying two negative charges (*i.e.*, with two additional electrons) may be represented as follows :



In this structure, there are three carbon-to-oxygen bonds, two of which are single bonds while the third is a double bond. Evidently, a carbon-to-oxygen double bond should be shorter than a carbon-to-oxygen single bond. But it is known from X-ray studies that all the three carbon-to-oxygen bonds in carbonate ion are of equal length which lies in between the usual single and double bond lengths. Pauling explained this observation on the basis of resonance between the three possible structures, as shown below :



This implies that the double bond resulting from the sharing of four electrons is *not localised* between carbon and any one particular oxygen atom. It is spread over all the three oxygen atoms.

Carbon monoxide molecule, CO. Carbon monoxide is a resonance hybrid of the following three resonating structures :

(I) (II) (III)

The carbon – oxygen bond length determined by X-ray diffraction is 1·13 Å which is close to the calculated C ≡ O bond length. This suggests that the bond between carbon and oxygen atoms in CO molecule is *closer to a triple bond*. Hence, structure II predominates.

Structures II and III have dipole moments in the opposite direction. Therefore, as expected, carbon monoxide has very low dipole moment (0·12 D).

LINNET'S DOUBLE QUARTET APPROACH

The valence bond theory, however, could not explain the unexpected paramagnetic behaviour of certain molecules such as O_2. In order to explain this behaviour, Linnet introduced the **concept of double quartet** according to which the 8 electrons (completed octet) around an atom, instead of constituting four pairs of 2 electrons each, constitute *two groups of four electrons each* (hence the name double quartet). The *spins of all the electrons in a quartet are the same*. But the spins of electrons in one quartet is opposite to the spin of electrons in the other quartet. Because of the effects of like charge (*charge correlation*) and same spin (*spin correlation*) of the four electrons in each quartet, each set of four electrons in a quartet has a high probability of occurring in a regular tetrahedral arrangement around the nucleus of the atom.

The charge correlation effect which tends to keep all the electrons of the two quartets apart and Pauli exclusion principle (*i.e.*, spin correlation), which tends to keep electrons of opposite spins together, oppose each other and roughly cancel each other so that the two tetrahedra *are spacially uncorrelated to each other*. This results in a spherical symmetry of electronic charge in free atoms and ions as in Ne, Na^+, F^-, O^{2-}, etc. *The most probable positions* for the electrons of a double quartet of a free ion or atom, which will result in spherical symmetry of electronic charge, are shown in Fig. 13*a*. These tetrahedra become strongly correlated to one another because of the localisation of electron pairs which form the covalent bonds. Since the two electrons in a bond pair have to be of opposite spin, each bond pair shall bind one

corner of one tetrahedron of electrons *having one type of spin* with one corner of the other tetrahedron of electrons *having opposite type of spin*. This is shown below in the case of H_2O, NH_3 and CH_4 molecules (Figs. 13*b*, *c* and *d*).

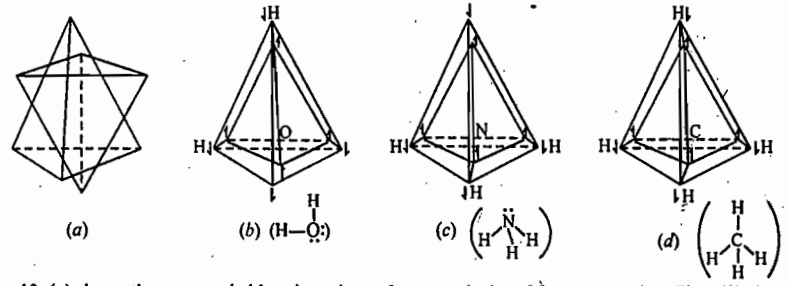


Fig. 13. (*a*) shows the most probable orientations of two tetrahedra of free atom or ion. Figs. (*b*), (*c*) and (*d*) indicate the fixation of tetrahedra around O, N and C nuclei in H_2O, NH_3 and CH_4 molecules respectively.

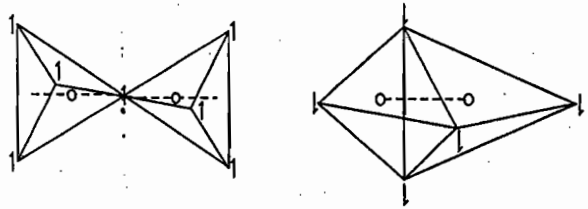
As is clear from the above figures, the bond pairs of electrons (as in H_2O, NH_3 and CH_4 molecules) fix the spacial orientation of the two tetrahedra of electrons with respect to each other.

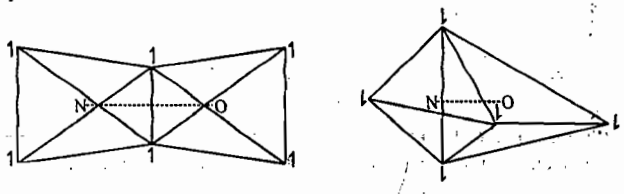
In order to **explain the paramagnetic behaviour of O_2**, seven electrons are assigned one type of spin and five electrons are assigned the opposite spin. Each set of electrons is arranged in two tetrahedra around the oxygen nuclei in the following manner :



If the two figures are superimposed on each other in such a way that the O-nuclei of two figures coincide, then each O nucleus will be surrounded by eight electrons arranged in two tetrahedra. The resulting situation can be represented as :

The circles represent electrons with one type of spin and dots represent electrons with the other type of spin. The short line represents an electron pair. The molecule is obviously paramagnetic with a resultant spin equivalent to *two unpaired electrons*. (Four unpaired electrons are having *one type of spin* and the other two unpaired electrons are having the *opposite type of spin*).

The structure of NO molecule can also be explained by the double quartet approach. The IR, X-ray and thermodynamic studies of this molecule reveal that its bond order is intermediate between those of N_2 and O_2 (which contain 6 and 4 electrons, respectively, in the internuclear region). The double quartet approach explains it by means of the following two structures, each consisting of two tetrahedra of electrons one of which contains 6 electrons of one type of spin and the other contains 5 electrons of the other type of spin.



If the two figures are superimposed in such a way that N and O nuclei of the figures coincide and that each nucleus is surrounded by 8 electrons arranged in two tetrahedra, the structure obtained can be written as :

The molecule apparently contains a bond order of $2\frac{1}{2}$ (*i.e.*, it has 5 electrons in the internuclear region). The molecule is paramagnetic because of the resultant one electron unpaired spin, as is experimentally observed.

However, the quartet approach, being entirely empirical, failed to receive any recognition.

MOLECULAR ORBITAL THEORY (MOT)

The wave mechanical treatment of a covalent bond based on the valence bond theory has been discussed above. The second approach to the problem is through another theory known as the **molecular orbital theory**. The two theories reflect distinctly different conceptual approaches to the basic structural model of a molecule. For instance, according to VBT, the two atoms in a diatomic molecule lie close to each other with their completely filled atomic orbitals remaining intact. *Only the half-filled orbital of one atom overlaps with the half-filled orbital of the same symmetry of the other atom* resulting in the formation of a covalent bond. According to MOT, on the other hand, the nuclei of the two atoms lie at appropriate distance and *all the atomic orbitals of one atom overlap with all the atomic orbitals of the other atom provided the overlapping orbitals are of the same symmetry and of similar energy*. The resulting polynuclear molecular orbitals contain all the electrons of the molecule.

The molecular orbital theory was put forth by F. Hund and R.S. Mulliken in 1930s and later further developed by I.E. Lennard-Jones and Charles Coulson.

The **basic principles of molecular orbital theory** are as follows :

1. When nuclei of two atoms come close to each other, *their atomic orbitals interact leading to the formation of* **molecular orbitals.** The atomic orbitals of the atoms in a molecule completely lose their identity after the formation of molecular orbitals.

2. Each molecular orbital is described by a wave function ψ, known as molecular orbital wave function.

3. The molecular orbital wave function ψ is such that ψ^2 represents the probability density or electron charge density.

4. Each molecular orbital wave function (ψ) is associated with a set of quantum numbers which determine the energy and the shape of the molecular orbital.

5. Each ψ is associated with a definite energy value and the total energy of the molecule is the sum of the energies of occupied molecular orbitals.

6. Electrons fill the molecular orbitals in the same way as they fill the atomic orbitals following the aufbau principle, Pauli's exclusion principle and the Hund's rule of maximum multiplicity.

7. Each electron in a molecular orbital belongs to all the nuclei present in the molecule.

8. Each electron moving in a molecular orbital has a spin of $+\frac{1}{2}$ or $-\frac{1}{2}$.

The **basic difference** *between an atomic orbital and a molecular orbital* is that while an electron in an atomic orbital is influenced by *one positive nucleus* only, an electron in a molecular orbital is influenced *by all the nuclei* of atoms contained in a molecule.

If we have a simple molecular system comprising of two electrons described by two *one-electron molecular orbital wave functions* ψ_1 and ψ_2, then the *combined configurational wave function for the system, i.e., the molecule*, would be given by

$$\psi = \psi_1\psi_2 \qquad ...(21)$$

If, in general, there are n electrons, then the configurational wave function for the system would be given by

$$\psi = \psi_1\psi_2\psi_3...\psi_n \qquad ...(22)$$

where ψ_1, ψ_2, ψ_3, etc., are one-electron molecular orbital wave functions*.

The individual one-electron molecular orbital wave functions such as ψ_1, ψ_2, ψ_3,.....can be determined with the application of the wave mechanical principles, especially the Ritz method of linear combination of atomic orbitals.

Linear Combination of Atomic Orbitals (LCAO). Molecular Orbital Treatment of Hydrogen Molecule Ion, H_2^+. Linear combination of atomic orbitals which has been described earlier in this chapter, is also employed in the treatment of molecular orbital theory. We shall apply this principle in the molecular orbital treatment of a simple species, *viz.*, H_2^+ **ion**, containing only one electron and then extend the treatment to more complicated systems.

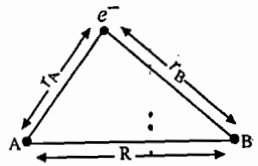


Fig. 14. Representation of H_2^+ ion.

Consider a H_2^+ ion consisting of two H nuclei designated as A and B (Fig. 14). The single electron is supposed to be moving in a molecular orbital formed by the interaction of atomic orbitals of the two hydrogen atoms, H_A and H_B. The potential energy of the H_2^+ system would evidently, be given by

$$V = -\frac{e^2}{r_A} - \frac{e^2}{r_B} + \frac{e^2}{R} \qquad ...(23)$$

where r_A, r_B and R are the appropriate distances, as shown in Fig. 14.

As shown in Chapter 1, the energy operator (*i.e.*, the Hamiltonian operator) $\hat{H}$ for H_2^+ ion is represented as

$$\hat{H} = -\frac{h^2}{8\pi^2 m}\nabla^2 + V \qquad ...(24)$$

$$= -\frac{h^2}{8\pi^2 m}\nabla^2 - \frac{e^2}{r_A} - \frac{e^2}{r_B} + \frac{e^2}{R} \qquad ...(25)$$

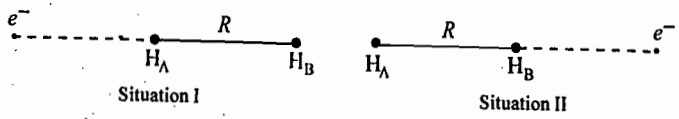
*Strictly speaking, expressions (21) and (22) are true only if we assume ψ_1, ψ_2, and ψ_3, etc., to be totally independent of one another. This is not exactly true since the electrons in the molecular orbitals of a multi-electron system repel one another and, therefore, ψ_1, ψ_2, ψ_3, etc., are dependent on one another to some extent. Hence, the expressions (21) and (22) are only approximations.

Accordingly, the wave equation $\hat{H}\psi = E\psi$ becomes

$$\left(-\frac{h^2}{8\pi^2 m}\nabla^2 - \frac{e^2}{r_A} - \frac{e^2}{r_B} + \frac{e^2}{R}\right)\psi = E\psi \qquad ...(26)$$

If we know ψ, we can find the energy E of the molecular orbital with the help of Eq. 26. But, it is not possible to ascertain the true ψ for such a system due to reasons already discussed in Chapter 1. However, we can find a wave function which is close to the true ψ, as discussed below.

The electron in H_2^+ ion is moving in molecular orbital under the influence of both the nuclei A and B. When, at some instant, it comes nearer to nucleus A (situation I), the electron would behave as if it was moving in the atomic orbital of H_A. The motion of the electron would then be described by ψ_A (the unmixed atomic orbital of H_A). Similarly, when the electron is nearer to nucleus B (situation II), its motion would be described by ψ_B (the unmixed atomic orbital of H_B).



In between these two situations, the electron would be under the influence of both the nuclei and its motion would be described by a wave function *which is a linear combination of* ψ_A and ψ_B. Thus,

$$\psi = c_A\psi_A + c_B\psi_B \qquad ...(27)$$

where c_A and c_B are the coefficients of the atomic orbital wave functions ψ_A and ψ_B, respectively. The squares of the coefficients, *viz.*, c_A^2 and c_B^2, give, respectively, the contributions of ψ_A and ψ_B to the wave function ψ.

The energy function ε corresponding to this wave function is given by

$$\varepsilon = \int_{-\infty}^{+\infty}\psi\hat{H}\psi\,d\tau \Big/ \int_{-\infty}^{+\infty}\psi^2 d\tau \qquad \text{(cf. Eq. 8.)} \qquad ...(28)$$

$$= \int_{-\infty}^{+\infty}(c_A\psi_A + c_B\psi_B)\hat{H}(c_A\psi_A + c_B\psi_B)d\tau \Big/ \int_{-\infty}^{+\infty}(c_A\psi_A + c_B\psi_B)^2 d\tau \qquad ...(29)$$

Differentiating Eq. 29 with respect to c_A only and then with respect to c_B only and applying the conditions of minimisation of energy, *viz.*, $\partial\varepsilon/\partial c_A = 0$, and $\partial\varepsilon/\partial c_B = 0$, we get a quadratic equation in ε whose solution gives two values of energy function ε. Since these energy functions being of minimum energy, are closest approximations of energy E, we may designate these two values of ε as E_+ and E_-.

Since the probability of occurrence of situation I and situation II, described above, is the same, therefore, the weightages of ψ_A and ψ_B in overall ψ would be the same. Thus, $c_A^2 = c_B^2$.

In order that ψ is an acceptable wave function, it must be normalised, *i.e.*, it must satisfy the condition that $\int_{-\infty}^{+\infty}\psi^2 d\tau = 1$. The atomic orbital wave functions taken for the combination are already normalised, *i.e.*,

$$\int_{-\infty}^{+\infty}\psi_A^2 d\tau = 1 \quad \text{and} \quad \int_{-\infty}^{+\infty}\psi_B^2 d\tau = 1$$

The above conditions give the relation

$$c_A^2 + c_B^2 = 1$$

But, as shown above, $c_A^2 = c_B^2$

$$c_A = \pm c_B = \pm(1/\sqrt{2}) \qquad ...(30)$$

Thus, we get two sets of values for c_A and c_B, *viz.*, $(+1/\sqrt{2}, +1/\sqrt{2})$ and $(+1/\sqrt{2}, -1/\sqrt{2})$ and hence two linear combinations of ψ_A and ψ_B corresponding to each set of the values of c_A and c_B. Accordingly, we have

$$\psi_+ = +(1/\sqrt{2})\psi_A + (1/\sqrt{2})\psi_B = (1/\sqrt{2})(\psi_A + \psi_B) \qquad ...(31)$$

$$\psi_- = +(1/\sqrt{2})\psi_A - (1/\sqrt{2})\psi_B = (1/\sqrt{2})(\psi_A - \psi_B) \qquad ...(32)$$

In the above equations, ψ_+ corresponds to energy E_+ and ψ_- corresponds to energy E_-. The lower value of energy E_+ is lower than either of E_A and E_B (*viz.*, the energies of isolated H_A and H_B). The higher value of energy E_- is higher than either of E_A and E_B. Thus, we see that in the case of H_2^+ ion :

1. A linear combination of two atomic orbitals ψ_A and ψ_B leads to the formation of two molecular orbitals ψ_+ and ψ_-.

2. The energy E_+ of molecular orbital ψ_+ is *lower* than either of E_A and E_B. It is, therefore, designated as **bonding molecular orbital** (BMO).

3. The energy E_- of molecular orbital ψ_- is higher than either of E_A and E_B. It is, therefore, designated as **antibonding molecular orbital** (ABMO).

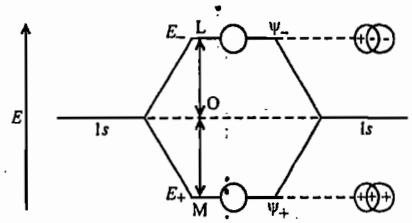


Fig. 15. Energies of bonding and antibonding molecular orbitals.

4. The extent of lowering of energy of the bonding molecular orbital is equal to the extent of increase of energy of the antibonding molecular orbital, as shown in Fig. 15.

5. Detailed LCAO calculations show that the greater the overlap of the two combining atomic orbitals ψ_A and ψ_B, the lower would be the energy of the bonding molecular orbital (ψ_+) formed.

6. The combining atomic orbitals ψ_A and ψ_B are completely used up during the formation of the molecular orbitals ψ_+ and ψ_-. The electron occupying originally the 1*s* atomic orbital of H_A or H_B, now occupies the lower level molecular orbital ψ_+, losing energy = OM and thus gaining in stability.

The molecular orbital treatment for H_2^+ ion, discussed above, can be extended to other homonuclear and heteronuclear systems. In general, whenever atomic orbitals ψ_A and ψ_B, of the same symmetry and of similar energies, of two atoms A and B, overlap, two molecular orbitals ψ_+ and ψ_- would be formed by the linear combination of these atomic orbitals so that the equations for molecular orbitals would be

$$\psi_+ = N_+(\psi_A + \lambda\psi_B) \qquad ...(33)$$

$$\psi_- = N_-(\lambda\psi_A - \psi_B) \qquad ...(34)$$

where λ is called the **mixing coefficient** and N_+ and N_- are called **normalising constants**. The values of these constants are adjusted in such a way that the normalising conditions, *viz.*, $\int_{-\infty}^{+\infty}\psi_+^2 d\tau = 1$ and $\int_{-\infty}^{+\infty}\psi_-^2 d\tau = 1$ are satisfied.

If the molecule AB is homonuclear, the weightages of ψ_A and ψ_B in both ψ_+ and ψ_- would be the same, *i.e.*, $N_+^2 = \lambda^2 N_+^2$ and $N_-^2\lambda^2 = N_-^2$ (weightage or contribution of a wave function is related to square of its coefficient). It readily follows from above that $\lambda^2 = 1$ so that $\lambda = \pm 1$. In such a case, Eqs. 33 and 34 for molecular orbitals would reduce to Eqs. 31 and 32, respectively because $N_+ = N_- = 1/\sqrt{2}$ and $\lambda = \pm 1$.

If, however, the molecule AB is heteronuclear, the weightages of ψ_A and ψ_B would not be the same, *i.e.*, $N_-^2\ \lambda^2 \neq N_-^2$ and $N_+^2 \neq \lambda^2 N_+^2$ so that $\lambda^2 \neq 1$ and the equations for molecular orbitals would remain as Eqs. 33 and 34.

Construction of Molecular Orbital Wave Functions and Valence Bond Wave Functions

In the preceding pages, the wave mechanical treatment of covalent bond has been discussed on the basis of valence bond and molecular orbital theories. The following **typical solved examples** illustrate how the above theories can be made use of for constructing molecular orbital wave functions and valence bond wave functions.

Example 1. Construct a molecular orbital wave function for the bond between H and Cl in HCl assuming that the bond is formed from the 1s electron of H atom and a 3p electron of Cl atom.

Solution : Let H atom be designated by A and Cl atom by B. Let the 1*s* electron of H atom be labelled as electron 1 and 3*p* electron of Cl atom be labelled as electron 2.

According to Eq. 21, $\psi_{MO} = \psi_1\psi_2$ where

$$\psi_1 = c_1\psi_A(1) + c_2\psi_B(1)$$

and

$$\psi_2 = c_1\psi_A(2) + c_2\psi_B(2)$$

$$\therefore \quad \psi_{MO} = [c_1\psi_A(1) + c_2\psi_B(1)][c_1\psi_A(2) + c_2\psi_B(2)]$$

$$= c_1^2[\psi_A(1)\psi_A(2)] + c_1c_2[\psi_A(1)\psi_B(2) + \psi_A(2)\ \psi_B(1)] + c_2^2\ [\psi_B(1)\psi_B(2)]$$

As can be seen, the first and the last terms are *ionic* whereas the middle terms are *covalent*. Also, the covalent terms have *equal weightage* but the ionic terms have *different weightage* from the covalent terms and also from each other.

Example 2. Write down the molecular orbital wave function for H_2^- molecule anion.

Solution : H_2^- molecule anion contains three electrons which may be labelled as 1, 2 and 3. It contains two nuclei which may be designated as A and B. According to Eq. 22,

$$\psi_{MO} = \psi_1\psi_2\psi_3$$

where

$$\psi_1 = c_1\psi_A(1) + c_2\psi_B(1)$$

$$\psi_2 = c_3\psi_A(2) + c_4\psi_B(2)$$

$$\psi_3 = c_5\psi_A(3) + c_6\psi_B(3)$$

Example 3. Using the principle of LCAO for the wave function for H_2^+ ion, obtain the normalised wave functions for the BMO and the ABMO.

Solution : Using the principle of LCAO, the wave function for H_2^+ ion is written as

$$\psi = N(c_1\psi_A + c_2\psi_B) \qquad ...(i)$$

where N is the normalisation constant.

According to the normalization condition, for real ψ

$$\int_{-\infty}^{+\infty} \psi^2 d\tau \equiv <\psi\,|\,\psi>^{**} = 1 \qquad ...(ii)$$

Incorporating the value of ψ from Eq. (*i*) in Eq. (*ii*), we have

$$N^2 <(c_1\psi_A + c_2\psi_B)\,|\,(c_1\psi_A + c_2\psi_B)> = 1$$

or

$$c_1^2[<\psi_A\,|\,\psi_A>] + c_2^2[<\psi_B\,|\,\psi_B>] + 2c_1c_2[<\psi_A\,|\,\psi_B>] = 1/N^2 \qquad ...(iii)$$

It can be shown that $<\psi_A\,|\,\psi_B> = <\psi_B\,|\,\psi_A>$

Assuming that ψ_A and ψ_B are normalised, *i.e.*,

$$<\psi_A\,|\,\psi_A> \equiv \int \psi_A^2 d\tau \quad \text{and} \quad <\psi_B\,|\,\psi_B> \equiv \int \psi_B^2\ d\tau = 1, \text{ we have}$$

$$c_1^2 + c_2^2 + 2c_1c_2S = 1/N^2 \qquad ...(iv)$$

where S is the *overlap integral* defined as

$$S = <\psi_A\,|\,\psi_B> \equiv \int \psi_A\psi_B d\tau \qquad ...(v)$$

From Eq. (*iv*),

$$N = (c_1^2 + c_2^2 + 2c_1c_2S)^{-1/2} \qquad ...(vi)$$

Hence, from Eq. (*i*),

$$\psi = (c_1^2 + c_2^2 + 2c_1c_2S)^{-1/2}(c_1\psi_A + c_2\psi_B) \qquad ...(vii)$$

We know that for BMO of H_2^+ ion, $c_1 = c_2$ and for ABMO, $c_1 = -c_2$.

Hence, from Eq. (*vii*),

$$\psi_{BMO} = (1/\sqrt{2(1+S)})\ (\psi_A + \psi_B)$$

and

$$\psi_{ABMO} = (1/\sqrt{2(1-S)})\,(\psi_A - \psi_B)$$

Example 4. Write down the normalised VB wave functions and normalised MO wave functions for H_2 molecule and comment on the expressions obtained.

Solution : H_2 molecule contains two electrons (labelled 1 and 2) and two hydrogen nuclei (labelled A and B). The pairing of electrons leads to the formation of a covalent bond. In the VB approach, if electron 1 is on nucleus A, then electron 2 would be on nucleus B and vice-versa. Since, however, the two electrons are indistinguishable, therefore, the VB wave function for H_2 molecule can be written as

$$\psi_{VB} = (1/\sqrt{2})\,[\psi_{A(1)}\psi_{B(2)} + \psi_{A(2)}\psi_{B(1)}] \qquad ...(i)$$

where $1/\sqrt{2}$ is the *normalization constant* obtained by normalizing ψ_{VB}.

In the MO theory, the MO wave function for H_2 molecule is given by

$$\psi_{MO} = \psi_1\psi_2 \qquad ...(ii)$$

where ψ_1 and ψ_2 are the *normalised* wave functions for MOs of H_2 given by

$$\psi_1 = (1/\sqrt{2})\,[\psi_A(1) + \psi_B(1)] \qquad ...(iii)$$

and

$$\psi_2 = (1/\sqrt{2})\,[\psi_A(2) + \psi_B(2)] \qquad ...(iv)$$

Multiplying ψ_1 and ψ_2, we get the ψ_{MO} as

$$\psi_{MO} = (1/2)[\psi_A(1) + \psi_B(1)][\psi_A(2) + \psi_B(2)] \qquad ...(v)$$

$$= (1/2)[\psi_A(1)\psi_A(2) + \psi_B(1)\psi_B(2)] + 1/2[\psi_A(1)\psi_B(2) + \psi_A(2)\psi_B(1)] \qquad ...(vi)$$

**This type of notation is known as 'bra' and 'ket' notation. In this notation, $\int_{-\infty}^{+\infty} \psi_1\psi_2 d\tau$ and $\int_{-\infty}^{+\infty} \psi_1\hat{H}\psi_2 d\tau$ are written as $<\psi_1\,|\,\psi_2>$ and $<\psi_1\,|\,\hat{H}\,|\,\psi_2>$, respectively.

In Eq. (*vi*), the first two terms represent the probability of finding *both the electrons on the same atom at the same time*. In other words, these terms represent the *ionic structures* of H_2 molecule which may be written as $\overset{-}{H}_A\overset{+}{H}_B$ and $\overset{+}{H}_A\overset{-}{H}_B$.

The last two terms in Eq. (*vi*) represent the *covalent structure* of the H_2 molecule.

Comparing ψ_{VB} and ψ_{MO}, we observe that while the wave function in VBT does not give any weightage to ionic structures, the MOT gives equal weightage to covalent and ionic structures.

Example 5. Write down the wave function for the BMO for a hetero-nuclear diatomic molecule AB assuming that the electron on an average spends 90% of its time on nucleus A and 10% of its time on nulceus B.

Solution : In the LCAO – MO scheme, $\psi_{MO} = c_A\psi_A + c_B\psi_B$

where the coefficients c_A and c_B are such that $[c_A]^2$ and $[c_B]^2$ determine the probability of finding the electron in atomic orbitals ψ_A and ψ_B, respectively. Then, clearly,

$$[c_A]^2 = 90\% = 0{\cdot}9 \text{ and}$$

$$[c_B]^2 = 10\% = 0{\cdot}1$$

Hence,

$$c_A = \pm\sqrt{0{\cdot}9} = \pm\, 0{\cdot}95$$

and

$$c_B = \pm\sqrt{0{\cdot}1} = \pm\, 0{\cdot}32$$

Thus,

$$\psi_{MO} = 0{\cdot}95\,\psi_A + 0{\cdot}32\,\psi_B$$

Example 6. Write down the valence bond wave function for the HF molecule (assuming that it is formed from 1*s* orbital of H and 2p_z orbital of F) in the following three cases : (*a*) HF is purely covalent (*b*) HF is purely ionic and (*c*) HF is 80% covalent and 20% ionic.

Solution : Let the H atom be represented by A and F atom by B. Let the electron numbered 1 be the 1*s* electron of H atom and the electron numbered 2 be the 2p_z electron of F atom.

(*a*) For purely covalent structure of HF, the wave function is written as

$$\psi_{covalent} = \psi_A(1)\psi_B(2) + \psi_A(2)\psi_A(1)$$

(*b*) For the purely ionic structure H^+F^-, both the electrons are on the F atom so that

$$\psi_{ionic} = \psi_B(1)\psi_B(2)$$

(*c*) HF is a resonance hybrid shown as

$$H - F \longleftrightarrow H^+F^-$$

$\therefore$

$$\psi_{VB} = c_1\psi_{covalent} + c_2\psi_{ionic} \text{ with } c_1^2 + c_2^2 = 1$$

Since

$$c_1^2 = 0{\cdot}80 \text{ and } c_2^2 = 0{\cdot}20 \text{ (given), hence,}$$

$$c_1 = \sqrt{0{\cdot}80} = 0{\cdot}89$$

and

$$c_2 = \sqrt{0{\cdot}20} = 0{\cdot}45$$

$\therefore$

$$\psi_{VB} = 0{\cdot}89\,[\psi_A(1)\psi_B(2) + \psi_A(2)\psi_B(1)] + 0{\cdot}45\,[\psi_B(1)\psi_B(2)]$$

Electron Charge Densities in Molecular Orbitals of H_2^+ ion

Consider once again a H_2^+ ion. The square of the wave function, *viz.*, ψ^2, *is a measure of the probability density, i.e.*, the probability of finding an electron *in a given volume* of space. Since probability density is directly related to **electron charge density**, hence, ψ_+^2 and ψ_-^2 give electron charge densities in the two molecular orbitals ψ_+ and ψ_- of H_2^+ ion formed in accordance with Eqs. 31 and 32. According to these equations

$$\psi_+^2 = [1/\sqrt{2}\,(\psi_A + \psi_B)]^2 = 1/2\,(\psi_A^2 + \psi_B^2 + 2\psi_A\psi_B) \quad ...(35)$$

and

$$\psi_-^2 = [1/\sqrt{2}\,(\psi_A - \psi_B)]^2 = 1/2\,(\psi_A^2 + \psi_B^2 - 2\psi_A\psi_B) \quad ...(36)$$

If the atomic orbitals ψ_A and ψ_B had not combined, there would have been no overlap between ψ_A and ψ_B. In that case, the overlap density, given by $\psi_A\psi_B$, would have been zero and ψ_+^2 would have been equal to $1/2(\psi_A^2 + \psi_B^2)$. This means that $1/2(\psi_A^2 + \psi_B^2)$ gives the electron charge density in between the nuclei *A* and *B* in the *uncombined atomic orbitals* ψ_A and ψ_B. When the two atomic orbitals *combine to form the molecular orbital* ψ_+, the overlap density $\psi_A\psi_B$ between the two atomic orbitals is non-zero and the electron charge density ψ_+^2 in between the two nuclei is given by $1/2\psi_A^2 + 1/2\psi_B^2 + \psi_A\psi_B$ (Eq. 35). This means that the electron charge density in between the nuclei A and B in the molecular orbital ψ_+ *increases by* $\psi_A\psi_B$.

The increased electron charge density shields the two similarly charged nuclei very effectively and decreases the energy of the molecular orbital in the event of its being occupied by electrons. In other words, the molecular orbital ψ_+ has *lower energy* than the energy of either of the uncombined atomic orbitals ψ_A and ψ_B. This orbital, therefore, leads to the formation of a stable chemical bond and is called **bonding molecular orbital.**

The electron charge density in between the nuclei A and B in molecular orbital ψ_- is given by $1/2\psi_A^2 + 1/2\psi_B^2 - \psi_A\psi_B$ (Eq.36). Evidently, the electron charge density in between the two nuclei in the molecular orbital ψ_- now *decreases by* $\psi_A\psi_B$. Because of the decrease in the electron charge density, the two similarly charged nuclei in this molecular orbital would be screened to a much smaller extent. As a result, the two nuclei would repel each other to a greater extent. This would lead to an increase of energy of the molecular orbital in the event of its being occupied by electrons. In other words, the molecular orbital ψ_- has *higher energy* than the energy of either of the uncombined atomic orbitals ψ_A and ψ_B. Such an orbital, evidently, opposes the formation of a chemical bond and is called **antibonding molecular orbital.**

It is evident that a filled BMO has high electron charge density in the overlap region whereas a filled ABMO has no electron charge density in between the nuclei. This may be illustrated by plotting ψ^2 for the bonding as well as the antibonding molecular orbitals against the internuclear distance of H_2^+ ion. When the electron probability density $(\psi_+)^2$ of the BMO, *i.e.*, $1/2(\psi_A + \psi_B)^2$, is plotted against the internuclear distance, a curve represented by the *solid line* in Fig. 16. is obtained. The plots for the electron charge densities in between the two nuclei in the uncombined atomic orbitals of H atoms for the same internuclear distance are also shown in the figure *by dotted lines*. As mentioned above, the electron charge density in between the nuclei in the uncombined atomic orbitals ψ_A and ψ_B is $1/2\psi_A^2 + 1/2\psi_B^2$. It is clear from the figure that there is greater probability of finding electron between the two nuclei in BMO than in the uncombined AOs.

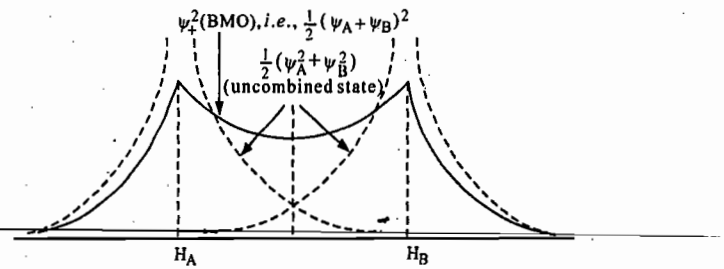

Fig. 16. The plot of electron probability density *vs* internuclear distnace for a BMO shown by a solid line and for the separate uncombined atomic orbitals of hydrogen atoms shown by the dotted lines.

For an ABMO, the picture is quite different. When the electron probability density (ψ_-^2) of an ABMO, *i.e.*, $1/2(\psi_A - \psi_B)^2$, is plotted against the internuclear distance, a curve represented by the *solid line* in Fig. 17 is obtained. This curve indicates that the electron charge density in the middle of

internuclear distance becomes almost zero. As a result, the two nuclei repel each other more effectively than the nuclei of the uncombined atoms A and B at that internuclear distance.

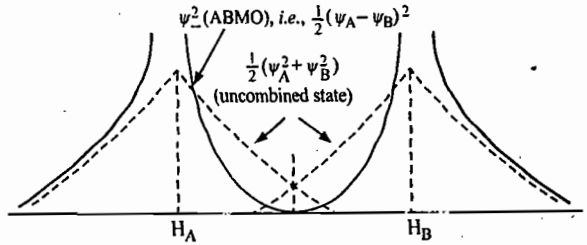

Fig. 17. The plot of electron probability density *vs* internuclear distance for an ABMO shown by solid line and for separate uncombined atomic orbitals of hydrogen atoms shown by dotted lines.

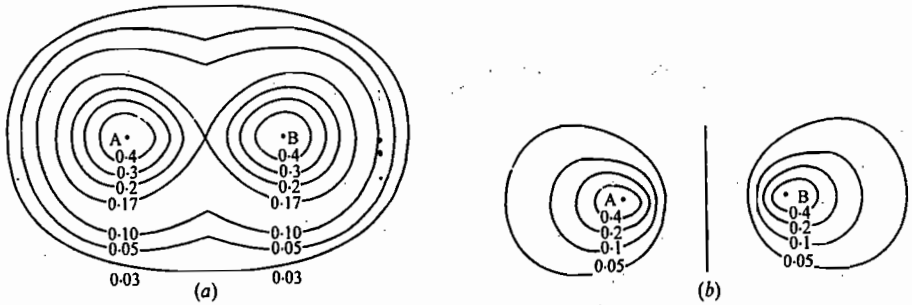
The distinction between bonding and antibonding molecular orbitals can be made more clear by showing the **contours** of electron charge densities or probability densities around the two nuclei A and B for these orbitals, as illustrated in Figs. 18 (*a*) and (*b*).

In a **bonding MO**, the high probability density contours are localised on the two nuclei but tend to polarise *towards the space* located in between the two nuclei. The low probability density contours are, however, *spread over both the nuclei*. This implies enhancement of electronic charge in the space in between the two nuclei.



(*a*) σ(1*s*) Bonding Molecular Orbital (*b*) σ*(1*s*) Antibonding Molecular Orbital

Fig.18. Contours of electron charge densities in bonding and antibonding molecular orbitals.

In an **antibonding MO**, the high as well as low probability density contours are *localised on two nuclei* and tend to polarise away from the space falling in between the two nuclei. This implies depletion of electronic charge from the space in between the two nuclei.

Pictorial Representation of Combination of Atomic Orbitals to form Molecular Orbitals

1. Combination of *s* atomic orbitals. To begin with, we consider a simple case of combination of 1*s* atomic orbital of one hydrogen atom with 1*s* atomic orbital of another hydrogen atom to give *two* MOs. As discussed earlier, there are two ways of linearly combining AOs. One is by the *additive combination* while the second is by the *subtractive combination* of atomic orbitals. The overlapping of two 1*s* atomic orbitals by linear additive combination to form a bonding molecular orbital is shown in Fig. 19. In such a combination, the region between the two nuclei has a (+) × (+), *i.e.*, algebraic + sign. This implies that *the electron charge density in the region between the two nuclei would get intensified.*

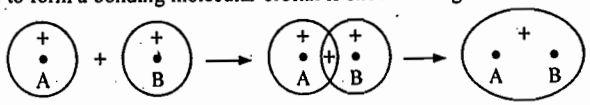


Fig. 19. Formation of a bonding molecular orbital by overlapping of two 1*s* atomic orbitals by linear additive combination.

The high electron charge density in between the two positive nuclei shields them from mutual repulsion and holds them together at the observed distance from each other. Such a linear additive combination gives a BMO. It is designated as σ(1*s*) orbital. The sign σ signifies that the molecular orbital is symmetrical about the molecular axis and the script (1*s*) indicates that it is formed by the combination of 1*s* atomic orbitals.

The overlapping of two 1*s* atomic orbitals by linear subtractive combination is shown in Fig. 20. The region of overlap between the two nuclei has (+) × (–), *i.e.*, algebraic – sign. This implies that *the electron charge density would get removed from the middle of the two nuclei.* It may be noted that a negative overlap means removal of electron charge from the region in between the nuclei. Thus, there will be *no shielding of the nuclei.* The repulsion between the two nuclei would, therefore, increase thereby increasing the energy of the molecular orbital formed (Fig. 20). Such a molecular orbital is termed as ABMO and is designated as σ*(1*s*).

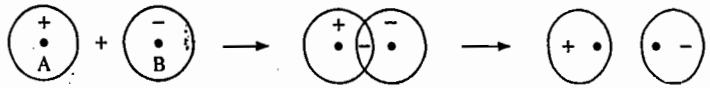

Fig. 20. Formation of antibonding molecular orbital by overlapping of two 1*s* atomic orbitals by linear subtractive combination. The thick dots represent the nuclei.

It may be noted that the positive and negative signs shown above in atomic and molecular orbitals are only algebraic signs of wave functions and *should not be confused with charges.*

Just like the combination of 1*s* atomic orbitals, 2*s* atomic orbitals also combine to form bonding and antibonding molecular orbitals. These are designated as σ(2s) and σ*(2*s*), respectively. They differ from σ(1*s*) and σ*(1*s*) MOs with regard to their size only.

2. Combination of p_z atomic orbitals. There are three *p* atomic orbitals designated as p_x, p_y and p_z. As a convention, the Z-axis is taken as the internuclear axis. The *X* and *Y* axes would then be perpendicular to the nuclear line. The combination of two p_z atomic orbitals belonging to different nuclei would, evidently, give a sigma BMO represented as σ($2p_z$) and a sigma ABMO represented as σ*($2p_z$).

The formation of a σ($2p_z$) BMO by the linear additive combination of two p_z atomic orbitals is represented in Fig. 21. The thick dots represent the nuclei. In this combination, the positive lobes of the two AOs overlap so that *the electron charge density between the two nuclei is enhanced.* The nuclei are thus well shielded from each other. Since the repulsion between the nuclei in such a case is minimum, the energy of this MO is lower than the energy of the atomic orbitals which have gone into its formation.

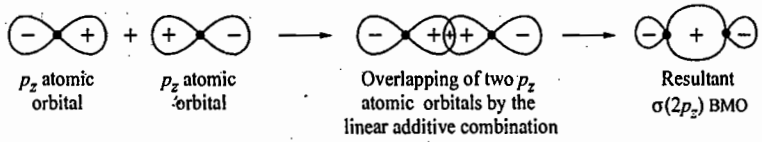

Fig. 21. Formation of a σ($2p_z$) BMO by the linear additive combinatioin of two p_z atomic orbitals.

The corresponding ABMO is obtained by the linear subtractive combination of two p_z atomic orbitals, as represented in Fig. 22.

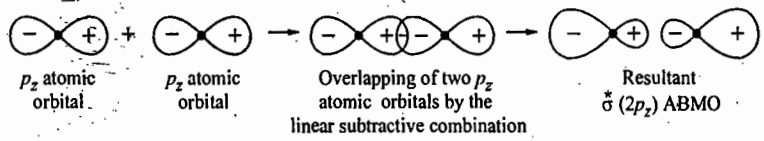

Fig. 22. Formation of a σ* ($2p_z$) ABMO by the linear subtractive combination of two p_z atomic orbitals.

The positive lobe of one p_z AO overlaps with the negative lobe of the other p_z AO resulting in the negative overlapping region. *The electron charge density between the nuclei, therefore, gets depleted.* The similarly charged nuclei are, thus, exposed to each other and hence tend to repel each other. This orbital, being antibonding, is designated as $\overset{*}{\sigma}$ $(2p_z)$. The energy of this ABMO is *higher* than the energy of either of the AOs which have gone into its formation.

3. Combination of p_x and p_y atomic orbitals. Suppose a p_x orbital of an atom overlaps with a p_x orbital of another atom. The overlap would be positive but it would be *side to side* and not end to end as in the case of p_z orbitals. The resulting molecular orbitals will, thus, be called **pi molecular orbitals.** The formation of the BMO, designated as π $(2p_x)$, is shown in Fig. 23.

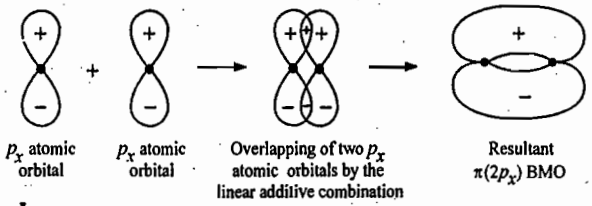

Fig. 23. Overlapping of two p_x atomic orbitals by linear additive combination to give π $(2p_x)$ BMO orbital.

The corresponding ABMO formed by linear subtractive combination of p_x AOs, designated as $\overset{*}{\pi}(2p_x)$, is shown in Fig. 24.

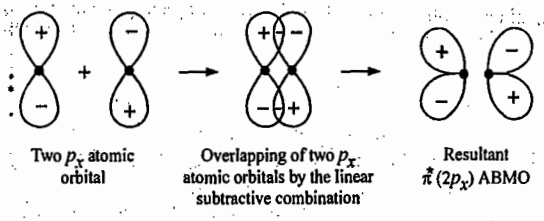

Fig. 24. Overlapping of two p_x atomic orbitals by the linear subtractive combination to form $\overset{*}{\pi}(2p_x)$ ABMO.

The energy of the antibonding molecular orbital would be high because the similarly charged nuclei are not effectively screened by the electronic charge and, therefore, repel each other considerably.

The formation of $\pi(2p_y)$ and $\overset{*}{\pi}(2p_y)$ MOs is similar to the formation of π $(2p_x)$ and $\overset{*}{\pi}(2p_x)$ MOs discussed above. The only difference is that the AOs which combine and MOs which are formed now lie perpendicular to the plane of the paper.

Difference Between Bonding and Antibonding Molecular Orbitals. The difference between bonding and antibonding molecular orbitals has been summed up in Table 5.

TABLE 5
Difference Between Bonding and Antibonding Molecular Orbitals

BMO	ABMO
1. A BMO is formed *by the addition overlap of atomic orbitals.*	An ABMO is formed *by the subtraction overlap of atomic orbitals.*
2. It has *lower energy* than the AOs from which it is formed.	It has *higher energy* than the AOs from which it is formed.
3. The electron charge density in between the nuclei is *high* and hence the repulsion between the nuclei is very low. This results in stabilisation of the BMO. In other words, the electrons in the BMO favour stable bond formation.	The electron charge density in between the nuclei is *low* and hence the repulsion between the nuclei is high. This results in de-stabilisation of the ABMO. In other words,, the electrons in the ABMO oppose bond formation.

Conditions for the Combination of Atomic Orbitals. It should be noted that *any two* atomic orbitals will not essentially combine to form molecular orbitals. There are, in fact, **certain limitations** to the combination of atomic orbitals. These are discussed below :

1. *The energy of the AOs involved should not differ much from one another.* Thus, in the formation of a *homonuclear* diatomic molecule of the type A_2, 1*s* orbital of one atom does not combine with 2*s* orbital of another atom of the *same* element as the energy difference between them is quite high. Likewise, 2*s* orbital of one atom does not combine with 2*p* orbital of another atom of the same element as the energy difference between them is very high.

In the case of *heteronuclear* diatomic molecules of the type AB, however, such combinations may be possible.

2. *The AOs combine only if they overlap to a considerable extent.* This overlap increases the electron charge density in between the two nuclei thereby minimising their mutual repulsion.

3. *The AOs should have the same symmetry about the molecular axis.* Thus, a p_x (or p_y) orbital of one atom *does not* combine with an *s* orbital of another atom. This is illustrated in Fig. 25. The *s* orbital of an atom A is shown to overlap with the p_x orbital of another atom B. But, since the molecular axis is in the *Z*-direction and the p_x orbital is oriented at right angles to this axis, no combination is possible. Thus, no molecular orbital can result in spite of the overlap. In fact, the + overlap is cancelled by the – overlap, as shown in the figure.

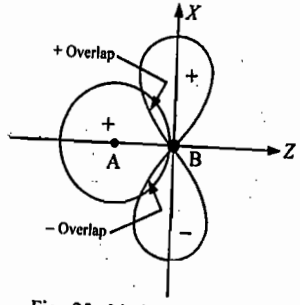

Fig. 25. Limitation of a p_x atomic orbital to combine with an *s* atomic orbital due to lack of symmetry about the molecular axis.

Similarly, a p_y orbital does not combine with an *s* orbital as they have different symmetry.

A p_z orbital, however, is able to combine with an *s* orbital since they have the same symmetry, as shown in Fig. 26.

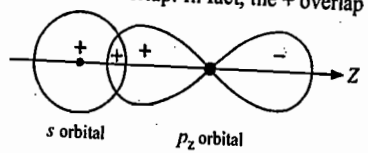

Fig. 26. Freedom of p_z atomic orbital to combine with an *s* orbital because of the same symmetry about the axial line.

The s and *p* atomic orbitals which can combine with each other to form molecular orbitals (assuming *Z*-axis as the internuclear axis) are as shown below :

First orbital	*Second orbital*	*Type of molecular orbital formed*
s	*s*, p_z	σ
p_z	*s*, p_z	σ
p_x	p_x	π
p_y	p_y	π

Energy Level Diagram for Molecular Orbitals. We have seen that 1*s* atomic orbitals of two atoms give two MOs designated as $\sigma(1s)$ and $\overset{*}{\sigma}(1s)$. The 2*s* and 2*p* atomic orbitals (eight AOs on two atoms) give rise to the following eight MOs :

Bonding MOs : $\sigma(2s)$ $\sigma(2p_z)$ $\pi(2p_x)$ $\pi(2p_y)$

Antibonding MOs : $\overset{*}{\sigma}(2s)$ $\overset{*}{\sigma}(2p_z)$ $\overset{*}{\pi}(2p_x)$ $\overset{*}{\pi}(2p_y)$

The energy levels of these molecular orbitals have been determined experimentally from spectroscopic data. The energy generally increases as we move from left to right in the following list :

$$\sigma(1s),\ \overset{*}{\sigma}(1s),\ \sigma(2s),\ \overset{*}{\sigma}(2s),\ \sigma(2p_z),\ \pi(2p_x) = \pi(2p_y),\ \overset{*}{\pi}(2p_x) = \overset{*}{\pi}(2p_y),\ \overset{*}{\sigma}(2p_z)$$

— Energy increases ⟶

The energy levels of different molecular orbitals are shown diagrammatically in Fig. 27*. In this diagram, the molecular orbitals are shown in the centre and the atomic orbitals which combine are shown on the two extremes. The atomic orbitals of same energy are shown at the same level while the BMOs are shown lower and the ABMOs are shown higher than the corresponding atomic orbitals. This indicates that while the BMOs are more stable, the ABMOs are less stable than the AOs from which they are formed. It is clear from the figure that the extent of stabilization for a BMO is always equal to the extent of destabilization of the corresponding ABMO.

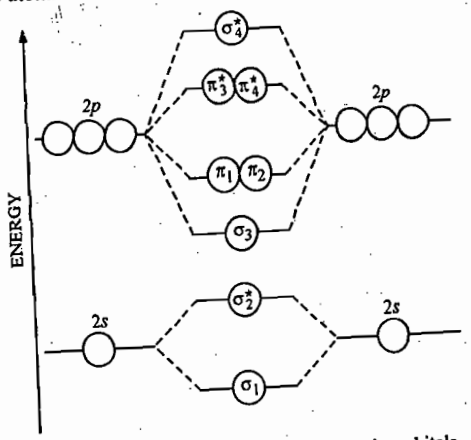

Fig. 27*. Energy levels of different molecular orbitals.

According to a **recent convention**, the molecular orbitals $\sigma(2s)$, $\overset{*}{\sigma}(2s)$, $\sigma(2p_z)$, $\overset{*}{\sigma}(2p_z)$, etc., are written as σ_1, $\overset{*}{\sigma}_2$, σ_3, $\overset{*}{\sigma}_4$, etc., and molecular orbitals $\pi(2p_x)$, $\pi(2p_y)$, $\overset{*}{\pi}(2p_x)$, $\overset{*}{\pi}(2p_y)$, etc., are written as π_1, π_2, $\overset{*}{\pi}_3$, $\overset{*}{\pi}_4$, etc., as shown in Fig. 27. This new nomenclature, which is quite convenient, is particularly useful for heteronuclear molecules.

Spectroscopic studies have revealed that the above sequence of energy levels of MOs is not correct for all molecules. It has been observed that in the case of homonuclear diatomic molecules of Second row elements of the periodic table upto N_2 (*viz.*, Li_2, Be_2, B_2, C_2, N_2), the $\sigma(2p_z)$ MO *is higher in energy than the* $\pi(2p_x)$ *and* $\pi(2p_y)$ MOs. The reversal in the sequence of energy levels of MOs is due to the *mixing of 2s and $2p_z$ orbitals*, as discussed below.

Mixing of Orbitals. We have seen that $\sigma(2s)$ and $\overset{*}{\sigma}(2s)$ MOs are formed by the combination of 2s atomic orbitals of two atoms while $\sigma(2p_z)$ and $\overset{*}{\sigma}(2p_z)$ MOs are formed by the combination of $2p_z$ atomic orbitals of the two atoms. However, if the energy differences between 2s and 2p atomic orbitals are small, there is a possibility of **mixing** of molecular orbitals $\sigma(2s)$ with $\sigma(2p_z)$ as they are of the same symmetry and $\overset{*}{\sigma}(2s)$ with $\overset{*}{\sigma}(2p_z)$ as they are also of the same symmetry with the result that the $\sigma(2s)$ and $\overset{*}{\sigma}(2s)$ MOs do not retain the pure *s* character and the $\sigma(2p_z)$ and $\overset{*}{\sigma}(2p_z)$ MOs do not retain the pure *p* character. In fact, *all the four MOs acquire a mixed sp character*. Due to this *s–p* mixing,

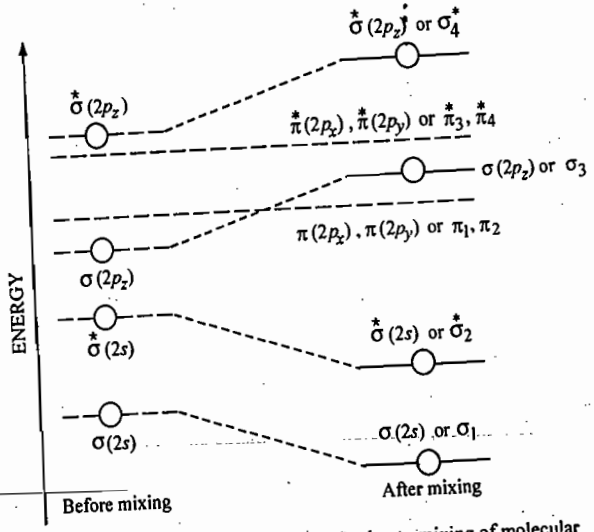

Fig. 28. The change in energies of MOs due to mixing of molecular orbitals of the same symmetry.

*The *d* orbitals are not included in the present discussion since the purpose is to consider the formation of simple diatomic molecules only.

the energies of all the four orbitals change in such a way that the resulting MOs $\sigma(2s)$ and $\overset{*}{\sigma}(2s)$, which also contain some *p* character, become more stable and are thus lowered in energy whereas the MOs $\sigma(2p_z)$ and $\overset{*}{\sigma}(2p_z)$ which contain some *s* character also now become less stable and are thus raised in energy, as illustrated in Fig. 28.

Since $\pi(2p)$ orbitals are not involved in mixing, the energies of $\pi(2p_x)$ and $\pi(2p_y)$ MOs remain unchanged, as shown in the figure.

As can be seen from Fig. 28, *$\sigma(2p_z)$ MO is raised to such an extent that it becomes higher in energy than $\pi(2p_x)$ and $\pi(2p_y)$* MOs. The new sequence of energy of MOs, therefore, becomes

$$\sigma(1s),\ \overset{*}{\sigma}(1s),\ \sigma(2s),\ \overset{*}{\sigma}(2s),\ \pi(2p_x) = \pi(2p_y),\ \sigma(2p_z),\ \overset{*}{\pi}(2p_x) = \overset{*}{\pi}(2p_y),\ \overset{*}{\sigma}(2p_z)$$

—— Energy increases ⟶

or

$$\sigma_1,\ \overset{*}{\sigma}_2,\ \sigma_3,\ \pi_1 = \pi_2,\ \overset{*}{\pi}_3 = \overset{*}{\pi}_4,\ \overset{*}{\sigma}_4$$

—— Energy increases ⟶

Now, a question arises : How is it that the mixing of $\sigma(2s)$ with $\sigma(2p_z)$ and of $\overset{*}{\sigma}(2s)$ with $\overset{*}{\sigma}(2p_z)$ occurs in the case of second row elements upto nitrogen only and not in the case of oxygen and fluorine. The answer lies in the differences in energies of 2s and 2p atomic orbitals of atoms of second row elements, as shown in Table 9.

TABLE 9

Differences in the Energies of 2s and $2p_z$ AOs of Atoms of Second Row Elements

Atoms	Li	Be	B	C	N	O	F
Difference in energies of 2s and $2p_z$ AOs (kJ mol^{-1})	178	262	449	510	570	1430	1970

It is clear from the above table that the differences in energies of 2s and $2p_z$ atomic orbitals of atoms up to nitrogen are small. Therefore, the energy differences between BMOs $\sigma(2s)$ and $\sigma(2p_z)$ [and between ABMOs $\overset{*}{\sigma}(2s)$ and $\overset{*}{\sigma}(2p_z)$] is also small upto N_2. Since $\sigma(2s)$ and $\sigma(2p_z)$ are of the same symmetry, these would mix effectively with each other and energies of the resulting *mixed molecular orbitals* would be considerably different from the energies of pure $\sigma(2s)$ and pure $\sigma(2p_z)$ molecular orbitals. A similar situation occurs in the case of molecular orbitals obtained by mixing of $\overset{*}{\sigma}(2s)$ with $\overset{*}{\sigma}(2p_z)$ molecular orbitals of molecules upto N_2.

In the case of O_2 and F_2, however, the energy differences between 2s and 2p atomic orbitals are quite large. Consequently, the energy differences between $\sigma(2s)$ and $\sigma(2p_z)$ or between $\overset{*}{\sigma}(2s)$ and $\overset{*}{\sigma}(2p_z)$ molecular orbitals in case of O_2 and F_2 are also quite large with the result that neither $\sigma(2s)$ and $\sigma(2p_z)$ nor $\overset{*}{\sigma}(2s)$ and $\overset{*}{\sigma}(2p_z)$ can mix to any significant extent in these molecules. Hence the energies of $\sigma(2s)$, $\sigma(2p_z)$, $\overset{*}{\sigma}(2s)$ and $\overset{*}{\sigma}(2p_z)$ molecular orbitals practically remain unaltered so that the energy of $\sigma(2p_z)$ molecular orbital continues to remain lower than the energies of $\pi(2p_x)$ and $\pi(2p_z)$ molecular orbitals.

Mixing of Orbitals. An Alternative Explanation. The 2s and $2p_z$ atomic orbitals of each atom are of the same symmetry and if the energy difference between the 2s and 2p orbitals of each atom is small, there is a possibility of mixing of these atomic orbitals to produce two mixed sp_z atomic orbitals on *each atom*. The two mixed orbitals, *viz.*, $\psi_{sp_z} = \frac{1}{\sqrt{1+\lambda^2}}\left(\psi_{2s} + \lambda\psi_{2p_z}\right)$ and $\frac{1}{\sqrt{1+\lambda^2}}\left(\lambda\psi_{2s} - \psi_{2p_z}\right)\left(\lambda^2 \neq 1\right)$, on each atom will be of unequal energy. Since the 2s atomic orbital was of lower

energy than the $2p_z$ atomic orbital of the atom, the lower energy mixed sp_z atomic orbital thus formed on each atom will have more contribution from $2s$ atomic orbital and less contribution from the $2p_z$ atomic orbital. Similarly, the higher energy mixed sp_z atomic orbital will have more contribution from the $2p_z$ atomic orbital and less contribution from the $2s$ atomic orbital of the atom. Since all the four mixed sp_z atomic orbitals of both the atoms are of the same symmetry, they linearly combine with one another to give four σ MOs. (The number of molecular orbitals obtained is always equal to the number of atomic orbitals combined). Each such σ MO contains contributions from all the four sp_z atomic orbitals. But, the greater the contribution of an sp_z atomic orbital, the closer to it will be the resulting molecular orbital. Because of the formation of molecular orbitals (σ type) having contributions from s as well as p_z orbitals, it has been calculated that the energy of σ_1 is lower than the energy of $\sigma(2s)$ orbital of Fig. 27 and the energy of σ_3 orbital is higher than the energy of pure $\sigma(2p_z)$ orbital of Fig. 27. While drawing Fig. 27, it was assumed that $\sigma(2s)$ and $\sigma^*(2s)$ molecular orbitals are formed from $2s$ atomic orbitals of the atoms whereas $\sigma(2p_z)$ and $\sigma^*(2p_z)$ molecular orbitals are formed from $2p_z$ atomic orbitals of the atoms.

The modified molecular orbital energy levels for homonuclear diatomic molecules, where $2s$ and $2p$ atomic orbitals are comparable in energy, are shown in Fig. 29. This order of energy levels has been confirmed spectroscopically.

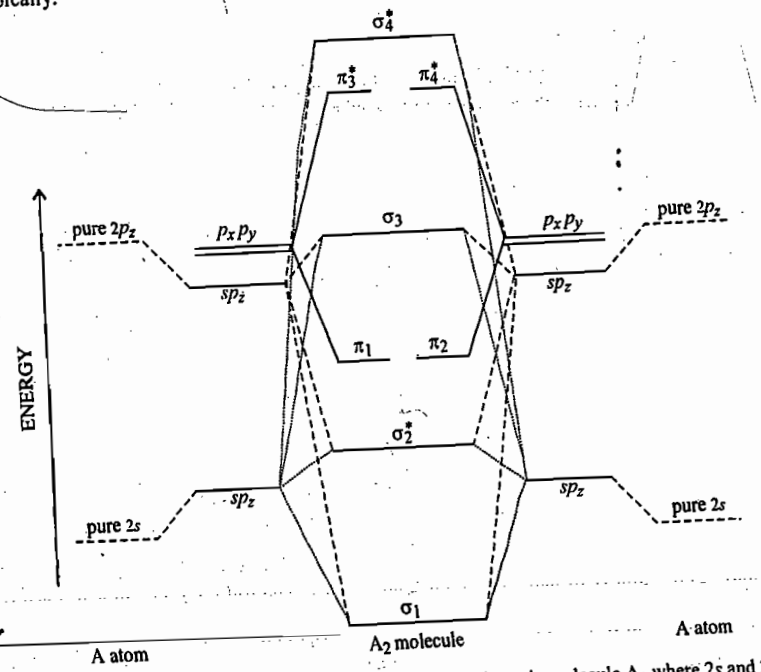

Fig. 29. Modified molecular orbital energy levels of homonuclear diatomic molecule A_2 where $2s$ and $2p$ orbitals are of comparable energy.

In the atoms where the energy difference between $2s$ and $2p$ atomic orbitals is very high, the mixing of $2s$ and $2p_z$ atomic orbitals of an atom is insignificant, even though they are of the same symmetry. Therefore, the atomic orbitals of such atoms as O and F remain almost pure $2s$ and pure $2p_z$ orbitals so that the order of energies of the resulting molecular orbitals of O_2 and F_2 remains the same as shown in Fig. 27. This order has also been confirmed from spectroscopic techniques for O_2 and F_2.

Rules for Adding Electrons to MOs. The molecules are built up by adding electrons to molecular orbitals in the same way as the atoms are built up by adding electrons to atomic orbitals. The principles involved are the same in both cases. These may be summed up as follows :

1. The molecular orbital with lowest energy is filled first.

2. The maximum number of electrons in a molecular orbital cannot exceed two and the two electrons must be of opposite spin.

3. If there are two or more molecular orbitals at the same energy level, pairing of electrons will occur only after each orbital of the same energy has one electron.

Electronic Configurations of Molecules. While discussing the electronic configurations of molecules, we shall frequently make use of a term called **bond order.** This is calculated from the number of electrons in bonding and antibonding molecular orbitals as follows :

$$\textit{Bond order} = \tfrac{1}{2}[\text{ Number of electrons in BMOs} - \text{Number of electrons in ABMOs}]$$

If the number of electrons in bonding and antibonding MOs is the same, the bond order is zero, *i.e.*, no bond is formed. The bond order of 1, 2 or 3 corresponds to single, double or triple bond.

The bond order of a molecule is directly proportional to its bond dissociation energy and inversely proportional to its bond length. This means that the higher the bond order, the larger is the bond dissociation energy of the molecule and the smaller is the bond length.

As would be discussed at appropriate places, the electronic configuration of a molecule helps to predict the magnetic character of the molecule. If all the electrons in a molecule are paired, the substance is *diamagnetic*. On the other hand, if some of the electrons are unpaired, the substance is *paramagnetic*.

Electronic Configurations of Homonuclear Diatomic Molecules. The electronic configurations of some simple diatomic molecules may now be considered.

Hydrogen molecule, H_2. It is formed by the combination of two hydrogen atoms. Each hydrogen atom has one electron in $1s$ orbital and, therefore, there are two electrons to be accommodated in MOs. Both these electrons would be accommodated in the $\sigma(1s)$ BMO. In accordance with Pauli's exclusion principle, these two electrons should have opposite spins. The molecular orbital energy level diagram for H_2 molecule is presented in Fig. 30.

The electronic configuration of H_2 molecule is, thus, $H_2 : \sigma(1s)$ and its **bond order** = 1/2(2 – 0) = 1.

This means that two hydrogen atoms are bonded together by a single bond. The bond dissociation energy of H_2 molecule has been found to be 458 kJ mol^{-1} and bond length equal to 0·74 Å.

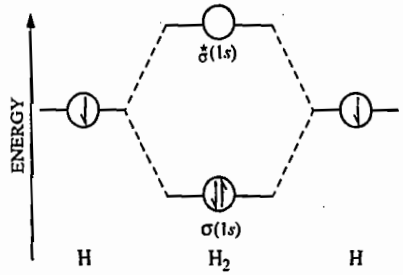

Fig. 30. Molecular orbital energy level diagram of H_2 molecule.

Hydrogen molecule ion, H_2^+. This molecule has been detected spectroscopically when electric discharge is passed through hydrogen gas under reduced pressure. The molecule has only one electron and its electronic configuration is $H_2^+ : \sigma(1s)^2$ and **bond order** = 1/2(1 – 0) = 1/2.

The positive value of bond order indicates that the bond does get formed and the molecule is stable. However, the bond in H_2^+ ion is weaker than that in H_2 molecule. The bond dissociation energy of H_2^+ ion (269 kJ mol^{-1}) is less than that of H_2 molecule (458 kJ mol^{-1}). The bond length in H_2^+ ion (1·04 Å) is larger than that in H_2 molecule (0·74 Å).

Helium molecule, He_2. Each helium atom has two $1s$ electrons and thus there are four electrons to be accommodated in He_2 molecule. Since each molecular orbital, just like atomic orbital, can accommodate only two electrons of opposite spins, only one pair can be accommodated in $\sigma(1s)$ BMO. The other pair will have to be accommodated in $\sigma^*(1s)$ ABMO.

The electronic configuration of He_2 is, thus,

$$He_2 : \sigma(1s)^2\ \overset{*}{\sigma}(1s^2) \text{ and its } \textbf{bond order} = \tfrac{1}{2}(2-2) = 0.$$

The zero bond order indicates that the molecule does not exist. Calculations have shown that the antibonding effect of a filled ABMO is slightly stronger than the bonding effect of a filled BMO. Consequently, there is no possibility whatsoever for the existence of He_2 molecule.

Diatomic Molecules of Second Row Elements. In these elements, the 1*s* orbitals are completely filled. In the formation of molecular orbitals, the electrons in the inner shells (*i.e.*, 1*s* electrons) of each atom remain essentially unperturbed in their respective atomic orbitals and may be kept out of consideration. In the formulation of electronic configurations of these molecules, the letters *KK* are generally used for denoting the fully filled inner shells (*K*-shells) in the two atoms.

Lithium molecule, Li_2. The electronic configuration of lithium (Z = 3) is $1s^2\ 2s^1$. There are six electrons in lithium molecule. The four electrons are present in *K*-shells and there are only two electrons to be accommodated in molecular orbitals. These two electrons go into $\sigma(2s)$ BMO which has lower energy and $\overset{*}{\sigma}(2s)$ ABMO remains empty.

The electronic configuration of Li_2 molecule is thus represented as

$$Li_2 : KK\,\sigma(2s)^2 \quad \text{or} \quad KK\,\sigma_1^2 \text{ and its } \textbf{bond order} = \tfrac{1}{2}(2-0) = 1$$

Thus, there is one Li – Li sigma bond. The bond dissociation energy of the molecule is quite low, being about 105 kJ mol^{-1}. The bond length of the molecule is 2·67 Å.

Beryllium molecule, Be_2. The next element beryllium (Z = 4) has electronic configuration $1s^2\ 2s^2$. In the formation of a diatomic molecule, evidently, two outer electrons of each atom, *i.e.*, four in all, have to be accommodated in molecular orbitals. Two of these (one pair) will go into $\sigma(2s)$ BMO while the other two (the second pair) will have to go into $\overset{*}{\sigma}(2s)$ ABMO.

The electronic configuration of Be_2 molecule is, thus,

$$Be_2 : KK\sigma(2s)^2\overset{*}{\sigma}(2s)^2 \quad \text{or} \quad KK\sigma_1^2\overset{*}{\sigma}{}_2^2 \text{ and its } \textbf{bond order} = \tfrac{1}{2}(2-2) = 0.$$

The zero bond order suggests that the existence of stable Be_2 molecule is not possible.

Boron molecule, B_2. The electronic configuration of boron (Z = 5) is $1s^2\ 2s^2p^1$. The outer shell (*i.e.*, the second shell) of each atom contains 3 electrons. When two boron atoms combine to form the molecule B_2, there are 6 electrons which need to be accommodated in the molecular orbitals of B_2. Two of these will be accommodated in $\sigma(2s)$ molecular orbital (*i.e.*, σ_1 MO) which has the lowest energy and the other two in $\overset{*}{\sigma}_2$ molecular orbital which comes next in the order of increasing energy. Due to the mixing of orbitals as discussed above, the energies of MOs would be as shown in Figs. 28 and 29. Accordingly, the $\pi(2p_x)$ and $\pi(2p_y)$ molecular orbitals (*i.e.*, π_1 and π_2 orbitals) lie at lower energy level than the σ_3 molecular orbital. Since $\pi(2p_x)$ and $\pi(2p_y)$ molecular orbitals (*i.e.*, π_1 and π_2 MOs) have equal energies, therefore, the two electrons distribute themselves between these two orbitals, one going to each orbital according to rule 3 above. As both these π molecular orbitals are bonding molecular orbitals, the B_2 molecule is expected to be stable. Further, since each bonding molecular orbital contains a single, *i.e.*, an unpaired electron, the molecule B_2 is *paramagnetic* as is experimentally observed. (Had there been no mixing of orbitals, the order of energy levels should have been as shown in Fig. 27 and the configuration of B_2 would have been $KK(\sigma(2s)^2\ \overset{*}{\sigma}(2s)^2\sigma 2p_z^2$, *i.e.*, the molecule B_2 should have been diamagnetic which is contrary to experimental observation). The electronic configuration of B_2 molecule is, thus,

$$B_2 : KK\sigma(2s)^2\overset{*}{\sigma}(2s)^2\pi(2p_x)^1\pi(2p_y)^1 \quad \text{or} \quad KK\sigma_1^2\overset{*}{\sigma}{}_2^2\,\pi_1\pi_2$$

and its **bond order** $= \tfrac{1}{2}(4-2) = 1$

The molecule has only one bond. The bond dissociation energy of B_2 molecule has been found to be 289 kJ mol^{-1} and bond length equal to 1·59 Å.

Carbon molecule, C_2. The next element is carbon (Z = 6). Its electronic configuration is $1s^2\,2s^2 2p^2$. The outer shell of each atom contains 4 electrons. In the formation of C_2 molecule, there will be, evidently, 8 electrons to be accommodated in the molecular orbitals of C_2 in accordance with Figs. 28 and 29. The electronic configuration of C_2 molecule is

$$C_2 : KK(2s)^2\overset{*}{\sigma}(2s)^2\pi(2p_x)^2\pi(2p_y)^2 \quad \text{or} \quad KK\sigma_1^2\overset{*}{\sigma}{}_2^2\,\pi_1^2\pi_2^2$$

and its **bond order** = 1/2(6 – 2) = 2

Since, C_2 molecule does not have any unpaired electron, it is *diamagnetic*, as observed experimentally.

The bond dissociation energy of C_2 molecule has been found to be 627·9 kJ mol^{-1} and bond length equal to 1·31 Å.

It may be noted that in this case also, the $\sigma(2p_z)$ or σ_3 molecular orbital is left vacant indicating that it is at a higher energy level than the π_1 and π_2 molecular orbitals. If, in accordance with the energy level diagram shown in Fig. 27, six electrons had gone into $\sigma(2s)$, $\overset{*}{\sigma}(2s)$ and $\sigma(2p_z)$ molecular orbitals, the remaining two electrons would have distributed themselves equally between the two $\pi(2p)$ molecular orbitals which are of equal energy. In that case, the molecule C_2, having two unpaired electrons, would have been paramagnetic. But actually the molecule is diamagnetic. This can be explained only on the basis of the reversal of energies of $\sigma(2p_z)$, *i.e.*, σ_3 and $\pi(2p_x)$, and $\pi(2p_y)$, *i.e.*, π_1 and π_2, molecular orbitals as a result of mixing of molecular orbitals, as discused earlier.

Nitrogen molecule, N_2. Consider, next, the formation of N_2 molecule. The electronic configuration of nitrogen (Z = 7) is $1s^2\ 2s^2\ p^3$. The outer shell in this case contains 5 electrons. Thus, there are 10 electrons to be accommodated in the molecular orbitals of N_2. The electronic configuration of nitrogen molecule is, thus,

$$N_2 : KK\,\sigma(2s)^2\,\overset{*}{\sigma}(2s)^2\pi(2p_x)^2\,\pi(2p_y)^2\,\sigma(2p_z)^2 \text{ or } KK\,\sigma_1^2\,\overset{*}{\sigma}{}_2^2\,\pi_1^2\,\pi_2^2\,\sigma_3^2$$

and its **Bond order** $= \tfrac{1}{2}(8-2) = 3$

Thus, nitrogen molecule contains a **triple bond.**

It is evident that in the formation of N_2 molecule, only one antibonding molecular orbital is involved (the remaining four being all bonding molecular orbitals). Hence, the nitrogen molecule is highly stable. This is confirmed by its high bond dissociation energy, *viz.*, 945·6 kJ mol^{-1} and small bond length equal to 1·10 Å. Also, since there are no unpaired electrons in any orbital, N_2 molecule is *diamagnetic.*

Oxygen molecule, O_2. As already explained, there is negligible mixing of 2*s* and 2*p* atomic orbitals on each O atom. Therefore, the order of energy levels in O_2 is as given in Fig. 27. The electronic configuration of oxygen (Z = 8) is $1s^2\,2s^2p^4$. In the formation of O_2 molecule, 12 outer electrons are to be accommodated in MOs. Four of these electrons fill the $\sigma(2s)$ and $\overset{*}{\sigma}(2s)$ molecular orbitals. Six of them (*i.e.*, 3 pairs) go into the three bonding MOs, *viz.*, $\sigma(2p_z)$, $\pi(2p_x)$ and $\pi(2p_y)$ and the remaining two electrons go into the antibonding MOs. The lowest ones are $\overset{*}{\pi}(2p_x)$ and $\overset{*}{\pi}(2p_y)$. Since both these orbitals are of equal energy, the electrons will distribute themselves one in each orbital. Since there are now two unpaired electrons, the oxygen molecule is *paramagnetic.*

The electronic configuration of oxygen molecule is, thus

$$O_2 : KK\sigma(2s)^2\overset{*}{\sigma}(2s)^2\sigma(2p_z)^2\pi(2p_x)^2\pi(2p_y)^2\overset{*}{\pi}(2p_x)^1\overset{*}{\pi}(2p_y)^1 \text{ or } KK\,\sigma_1^2\,\overset{*}{\sigma}{}_2^2\,\sigma_3^2\,\pi_1^2\,\pi_2^2\,\overset{*}{\pi}{}_3^1\,\overset{*}{\pi}{}_4^1$$

Bond order in this case is $= \tfrac{1}{2}(8-4) = 2$. Oxygen molecule, thus, contains a double bond.

Because of the presence of 4 electrons in ABMOs, oxygen molecule is less stable than nitrogen molecule. Its bond dissociation energy is much less, being 494·6 kJ mol^{-1} and bond length is larger being 1·21 Å.

Fluorine molecule, F_2. Because of large energy difference in 2*s* and 2*p*, orbitals on each F atom, the mixing of these orbitals is negligible and the order of MO energy levels will be as shown in Fig. 27. The electronic configuration of fluorine (Z = 9) is $1s^2 2s^2 p^5$. In the formation of F_2 molecule by the combination of two fluorine atoms, there would be 14 outer electrons to be accommodated in molecular orbitals.

The electronic configuration of fluorine molecule is, thus,

$$F_2 : KK\sigma(2s)^2\, \overset{*}{\sigma}(2s)^2\, \sigma(2p_z)^2\, \pi(2p_x)^2\, \pi(2p_y)^2\, \overset{*}{\pi}(2p_x)^2\, \overset{*}{\pi}(2p_y)^2 \quad \text{or} \quad KK\ \sigma_1^2\ \sigma_2^{*2}\ \sigma_3^2\ \pi_1^2\ \pi_2^2\ \pi_3^{*2}\ \pi_4^{*2}$$

Bond order in this case is $= \frac{1}{2}(8-6) = 1$. The F_2 molecule, thus, contains a single bond. Because of the presence of as many as 6 electrons in ABMOs, the bonding in F_2 is weaker than that in O_2. Therefore, bond dissociation energy of F_2 is very low being 155 kJ mol^{-1} and bond length is 1·42 Å.

Since there are no unpaired electrons, the molecule is *diamagnetic*.

Neon molecule, Ne_2. The order of energy levels in hypothetical Ne_2 should be as given in Fig. 27 because the energy gap between 2*s* and 2*p* orbitals on Ne is very high and the extent of their mixing will be negligible. The electronic configuration of neon (Z = 10), is $1s^2 2s^2 p^6$. In the formation of Ne_2, if possible, 16 outer electrons have to be accommodated in molecular orbitals.

The electronic configuration of *hypothetical* neon molecule is

$$Ne_2 : \quad KK\ \sigma(2s)^2\, \overset{*}{\sigma}(2s)^2\, \sigma(2p_z)^2 \pi(2p_x)^2 \pi(2p_y)^2\, \overset{*}{\pi}(2p_x)^2\, \overset{*}{\pi}(2p_y)^2\, \overset{*}{\sigma}(2p_z)^2$$

or

$$KK\ \sigma_1^2\ \sigma_2^{*2}\ \sigma_3^2\ \pi_1^2\ \pi_2^2\ \pi_3^{*2}\ \pi_4^{*2}\ \sigma_4^{*2}$$

Bond order in this case is equal to $= \frac{1}{2}(8-8) = 0$. Since antibonding MOs slightly dominate over the bonding MOs, Ne_2 molecule would be incapable of existence.

Problem 1. Write the electronic configurations of H_2, H_2^+ and the H_2^- in terms of molecular orbital theory.

Answer. H_2, H_2^+ and H_2^- have 2, 1 and 3 electrons, respectively. Hence, their electronic configurations would be as follows :

H_2 : $\sigma(1s)^2$

H_2^+ : $\sigma(1s)^1$

H_2^- : $\sigma(1s)^2\, \overset{*}{\sigma}(1s)^1$

Problem 2. Why does He_2^+ exist whereas He_2 does not ?

Answer : Electronic configuration of He_2 is : $\sigma(1s)^2\, \overset{*}{\sigma}(1s)^1$

$\therefore$ **Bond order** $= 1/2\,(2-2) = 0$

Electronic configuration of He_2^+ is : $\sigma(1s)^2\, \overset{*}{\sigma}(1s)^1$

$\therefore$ **Bond order** $= 1/2\,(2-1) = 1/2$

Thus, while the bond order of He_2 is zero, that of He_2^+ is 1/2. Hence, He_2^+ exists while He_2 does not.

Problem 3. Of the species O_2, O_2^+ O_2^-, O_2^{2-}, which would have the maximum bond strength ?

Answer : Higher bond orders are associated with shorter bond lengths and higher bond strengths. We will first calculate the bond orders for the various species from their electronic configurations :

$$O_2 : KK\ \sigma(2s)^2\, \overset{*}{\sigma}(2s^2)\, \sigma(2p_z)^2\, \pi(2p_x)^2\, \pi(2p_y)^2\, \overset{*}{\pi}(2p_x)^1\, \overset{*}{\pi}(2p_y)^1$$

$\therefore$ **Bond order** $= 1/2\,(8-4) = 2$

O_2^+ : One electron is removed from $\overset{*}{\pi}(2p_y)$ ABMO.

$\therefore$ **Bond order** $= 1/2\,(8-3) = 2\frac{1}{2}$

O_2^- : One electron is added to $\overset{*}{\pi}(2p_x)$ ABMO.

$\therefore$ **Bond order** $= 1/2\,(8-5) = 1\frac{1}{2}$

O_2^{2-} : Two electrons are added to the outermost ABMO.

$\therefore$ **Bond order** $= 1/2\,(8-6) = 1$

Since O_2^+ has the highest bond order, it has the shortest bond length and hence the maximum bond strength.

Electronic Configurations of Heteronuclear Diatomic Molecules

The cases of heteronuclear diatomic molecules, in which the two atoms constituting a molecule are different, may now be considered. The principles involved in the distribution of electrons are the same as discussed before.

However, the molecular orbital diagrams will not be symmetrical as in the case of homonuclear diatomic molecules. Due to the difference in the electronegativities of the atoms, the electrons in a bonding molecular orbital spend more time near the more electronegative atom. On the other hand, electrons in an antibonding molecular orbital are closer to the less electronegative atom.

While discussing the molecular orbital energy level diagrams of heteronuclear diatomic molecules, it should be kept in mind that all the atomic orbitals of same symmetry will contribute in the formation of an equal number of molecular orbitals. Any molecular orbital thus formed will have greatest contribution from that combining atomic orbital which is nearest to it in energy and least contribution from that combining atomic orbital which is farthest to it in energy.

Let us discuss the electronic configurations and molecular orbital diagrams for some common heteronuclear diatomic molecules.

Carbon Monoxide Molecule, CO. The electronic configurations of C and O atoms are $1s^2 2s^2 p^2$ and $1s^2 2s^2 p^4$, respectively. There are 4 electrons in the outer shell of carbon and 6 electrons in the outer shell of oxygen. Thus, a total of 10 outer electrons are to be accommodated in the molecular orbitals of CO molecule. Because of higher electronegativity of oxygen, its atomic orbitals would be of lower energy than the corresponding atomic orbitals of carbon. Due to this energy difference, the bonding and antibonding molecular orbitals receive different contributions from atomic orbitals of carbon and oxygen. The bonding molecular orbitals receive more contribution from atomic orbitals of lower energy, *i.e.*, the atomic orbitals of oxygen and would be closer to it in energy than the antibonding molecular orbitals which would be closer to the atomic orbitals of carbon in energy, as shown in Fig. 31. The bonding molecular orbitals would have more characteristics of atomic orbitals of oxygen and antibonding molecular orbitals would have more characteristics of atomic orbitals of carbon.

The $2s$ and $2p_z$ atomic orbitals of C atom mix to produce two atomic orbitals of mixed sp_z character. The higher energy mixed sp_z orbital of C atom is closer in energy to its pure $2p_z$ orbital and has major contribution from it whereas the lower energy mixed sp_z orbital of C is closer in energy to its pure $2s$ orbital and has major contribution from it. Similarly, $2s$ and $2p_z$ atomic orbitals of oxygen atom also mix with each other (though not to the same extent to which the orbitals of C atom mix because the energy difference between $2s$ and $2p_z$ atomic orbitals of oxygen atom is higher than that between the similar atomic orbitals of C atom) to form two atomic orbitals of mixed sp_z character. The higher energy mixed sp_z orbital of O is very close in energy to its pure $2p_z$ orbital and has contribution mostly from $2p_z$ orbital whereas the lower energy mixed sp_z orbital, being very close in energy to pure $2s$ orbital of oxygen atom, has contribution mostly from $2s$ orbital of oxygen atom.

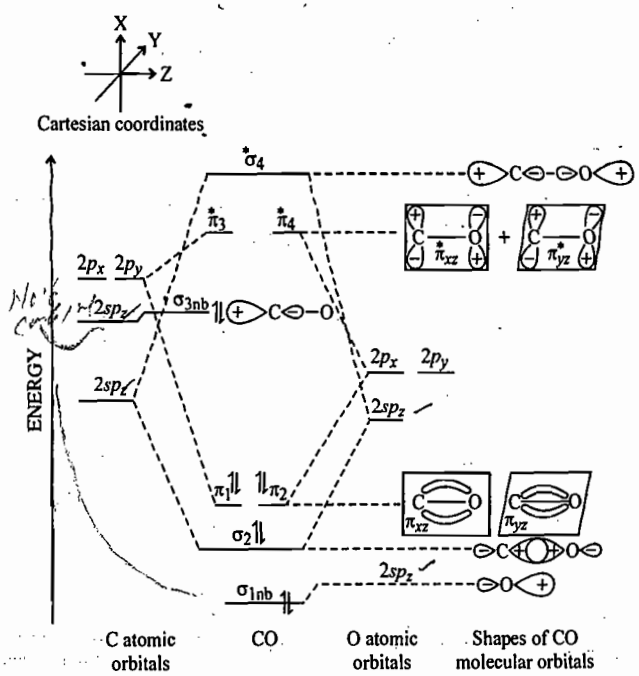

Fig. 31. Molecular orbital energy level diagram (with shapes of molecular orbitals) of CO molecule. Positions of pure $2s$ and $2p_z$ orbitals of C and O are not shown.

Since the orbital energies are lower for more electronegative O atom compared to the energies of similar orbitals of C atom, the lower energy mixed sp_z orbital of C atom is comparable in energy to the higher energy sp_z orbital of O atom, as shown in MOEL diagram of CO (Fig. 31). These two atomic orbitals of comparable energy and of same symmetry combine to give σ bonding and antibonding molecular orbitals. The lower energy sp_z orbital on O and the higher energy sp_z orbital on C atom are so far apart in energy that they *hardly* influence each other with the result that their energies remain almost unchanged. In other words, these orbitals remain *almost* non bonding. As already discussed above, the non bonding sp_z orbital on C (shown as σ_{3nb} in the figure) will have more characteristics of $2p_z$ orbital of C atom and the non bonding sp_z orbital on O atom (σ_{1nb} in the figure) will have more characteristics of $2s$ orbital of O atom. The degenerate set of $2p_x$, $2p_y$ orbitals of C and the similar degenerate set of $2p_x$, $2p_y$ orbitals of oxygen are of π symmetry to form a set of degenerate π_1, π_2 bonding molecular orbitals and another set of degenerate antibonding molecular orbitals. The electronic configuration of CO molecule is, therefore,

$$KK'\ \sigma_{1nb}^2\ \sigma_2^2\ \pi_1^2\ \pi_2^2\ \sigma_{3nb}^2$$

and the **bond order** of CO molecule is obviously 3 (due to two σ bonding and four π bonding electrons. The electrons in the non bonding orbitals do not contribute towards bonding.

Since σ_{3nb} is the highest placed occupied non bonding orbital localised on C atom, its electron pair can easily be donated for forming dative (or coordinate) bond.

Nitric Oxide Molecule, NO. The electronic configurations of N and O atoms are $1s^2 2s^2 p^3$ and $1s^2 2s^2 p^4$, respectively. There are 5 electrons in the outer shell of nitrogen and 6 electrons in the outer shell of oxygen. Thus, a total of 11 outer electrons are to be accommodated in the molecular orbitals of NO molecule.

The spectroscopic data reveal that the order of energy levels in NO molecule is similar to the order of energy levels in O_2 and F_2 molecules meaning that due to considerable energy difference between $2s$ and $2p_z$ atomic orbitals, the mixing of orbitals on each atom is insignificant.

The electronic configuration of NO molecule is, thus,

$$NO : KK\ \sigma(2s)^2\ \sigma^*(2s)^2\ \sigma(2p_z)^2\ \pi(2p_x)^2\ \pi(2p_y)^2\ \pi^*(2p_x)^1 \quad \text{or} \quad KK'\ \sigma_1^2\ \sigma_2^{*2}\ \sigma_3^2\ \pi_1^2\ \pi_2^2\ \pi_3^{*1}$$

The **bond order** in this case is $1/2(8-3) = 2\frac{1}{2}$. This represents one σ bond and two π bonds less the antibonding effect of one unpaired electron in the π_3^* molecular orbital. The presence of this antibonding electron makes the NO molecule less stable than the N_2 molecule. This is confirmed by the fact that the bond dissociation energy of nitric oxide, *viz.*, 667·8 kJ mol^{-1}, is less than that of nitrogen which is 945·6 kJ mol^{-1}. Since NO contains an unpaired electron, it is *paramagnetic*.

As in the case of CO molecule, the bonding molecular orbitals would have greater characteristics of atomic orbitals of oxygen and the antibonding molecular orbitals would have greater characteristics of atomic orbitals of nitrogen.

Hydrogen Flouride Molecule, HF. The valence shell atomic orbitals of the same symmetry are $1s$ atomic orbital of H and $2s$ and $2p_z$ atomic orbitals of F (the z-axis is assumed to be the internuclear axis). The two $2s$ and $2p_z$ of F, being of the same symmetry, can mix with each other. However, the extent of mixing of $2s$ and $2p_z$ orbitals will be *small* because the energy gap between these two orbitals is *high*. (For effective mixing of orbitals of same symmetry, the energy gap between them should be low).

The higher energy mixed orbital of F has predominantly p_z character with very little s character and will lie only a *little lower* in energy than the pure p_z orbital. Similarly, the lower energy mixed orbital has predominantly $2s$ character with only a little $2p_z$ character and lies *slightly higher* in energy than the pure $2s$ orbital. The $1s$ orbital of hydrogen atom is more comparable in energy to the higher energy mixed sp_z orbital (which is practically $2p_z$ orbital) of F. The two combine to give σ_1 bonding and σ_3^* antibonding molecular orbitals. The lower energy mixed sp_z orbital of F *cannot effectively combine* with $1s$ orbital of H atom due to large energy difference between this mixed orbital and $1s$ orbital of H atom and, therefore, remain *almost* non bonding (σ_{2nb}) orbital. The molecular orbital energy level diagram of HF is shown in Fig. 32.

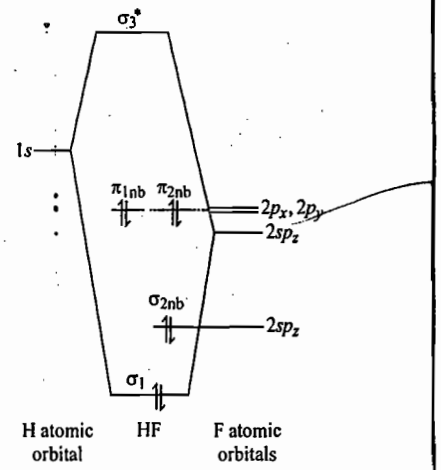

Fig. 32. Molecular orbital energy level diagram of HF molecule. The positions of pure $2p_z$ and $2s$ orbitals of F atom are not shown.

The $2p_x$ and $2p_y$ orbitals of F are suitable for forming only π bonding and antibonding molecular orbitals. Since there are no orbitals of the same symmetry as that of H atom, these remain non bonding and are designated in the figure as π_{1nb} and π_{2nb}. It is clear from the above discussion that σ_1 will have more contribution from $2p_z$ atomic orbital of F and less contribution from $1s$ atomic orbital of F atom whereas σ_3^* will have more contribution from $1s$ orbital of H atom and less contribution from $2p_z$ orbital of H atom. The electronic configuration of HF molecule is thus,

$$K\ \sigma_1^2\ \sigma_{2nb}^2\ \pi_{1nb}^2\ \pi_{2nb}^2$$

and the **bond order** is obviously 1 since only two electrons occupy the bonding molecular orbital σ_1 (the rest of the valence electrons are in non bonding orbitals).

As can be visualised, all the occupied orbitals are either pure F orbitals or have predominantly F orbital characteristics. Therefore, most of the electronic charge will be localised on F atom. This fact is corroborated by a considerably high dipole moment (1·9 D) observed for HF molecule.

Hydrogen Chloride Molecule, HCl. The treatment in this case is exactly similar to the one discussed for HF molecule except for the fact that the valence shell atomic orbitals of the same symmetry that are considered for the formation of molecular orbitals, are 1*s* atomic orbital of H atom and 3*s* and $3p_z$ orbitals of Cl atom. The electronic configuration of HCl molecule is :

$$KL\ \sigma_1^2\ \sigma_{2nb}^2\ \pi_{1nb}^2\ \pi_{2nb}^2$$

and the **bond order** is 1 due to two electrons in bonding molecular orbital. In the case of HCl molecule also, all the occupied orbitals are either pure Cl orbitals or have predominantly Cl orbital character. Therefore, most of the electronic charge gets accumulated on Cl atom of HCl making it considerably polar.

Term Symbols for Diatomic Molecules

Term symbols are used to designate electronic energy levels which arise out of an electronic configuration because of electrostatic repulsions amongst the electrons of a molecule. These terms are very helpful in understanding electronic spectra of molecules.

The term symbols employed for diatomic molecules are written in the following manner :

1. The symbols Σ, π and Δ are used to represent values 0, 1 and 2, respectively for $|M_L|$ or Σm_l of electrons in the diatomic molecules where m_l is the component of orbital angular momentum of a single electron along the nuclear axis and $|M_L|$ is the absolute value of similar overall component for all the electrons in the diatomic molecule. The m_l is 0, ±1 and ± 2 for an electron in σ, π and δ molecular orbitals, respectively.

2. Since all homonuclear diatomic molecules have a centre of symmetry in the middle of their nuclear axis, the overall symmetry to inversion is indicated by u or g and is written as a right subscript of Σ, π, Δ.

3. The electron spin multiplicity is indicated by 2*S* + 1 as the left superscript of Σ, π and Δ (*S* is the total spin of electrons in the system).

4. The term symbol is written as $^{2S+1}|M_L|_{g \text{ or } u}$.

For example, consider a H_2 molecule whose ground state electronic configuration is $\sigma^2(1s)$.

In this case, *S* (*i.e.*, $s_1 + s_2$) is 0 and $|M_L|$, *i.e.*, $(m_{l_1} + m_{l_2})$ is also 0. The σ_{1s} molecular orbital is symmetric with respect to the centre of inversion located in the middle of the nuclear axis, Therefore, the term symbol for σ_{1s}^2 should be $g \times g = g$ type. Hence, the term symbol $^{2S+1}M_{L_{g \text{ or } u}}$ for H_2 molecule in its ground state, is $^1\Sigma_g$.

Consider now hydrogen ion, H_2^+. Its ground state electronic configuration is σ_{1s}^1 so that $S = \frac{1}{2}$ and $2S + 1 = 2$. Since $|M_L| = 0$, hence the term symbol for its ground state. is $^2\Sigma_g$.

Let us now work out the term symbols for O_2 molecule. The ground state electronic configuration of O_2 is $\sigma_1^2\ \sigma_2^2\ \sigma_3^2\ \pi_1^2\ \pi_2^2\ \overset{*}{\pi}_3^1\ \overset{*}{\pi}_4^1$. The electrons in the filled sigma molecular orbitals and the completely filled degenerate set of pi orbitals contribute nothing to the overall component of angular momentum M_L along the nuclear axis. Since both the $\overset{*}{\pi}$ molecular orbitals are symmetric with respect to the centre of symmetry of the oxygen molecule, the term symbol will be $g \times g = g$ type.

Let us first consider the case when both the unpaired electrons in $\overset{*}{\pi}$ molecular orbitals have opposite spins. The m_l for each electron in $\overset{*}{\pi}$ molecular orbital will be +1 or −1 so that $|M_L| = 0$ or 2 and $2S + 1 = 1$ (because *S* is $\frac{1}{2} - \frac{1}{2} = 0$). The term symbols which arise from this situation are $^1\Sigma_g$ and $^1\Delta_g$.

Now consider the case when the spins of both the electrons are in the same direction so that $S = \frac{1}{2} + \frac{1}{2} = 1$ and the spin multiplicity is 3. Since spins of both the electrons in $\overset{*}{\pi}$ orbitals are in the same

direction, their m_l values *have* to be different (Paulis' exclusion principle). That is, m_l for one electron is +1 and for the other electron it is −1 (The + and − signs indicate whether the component of angular momentum m_l is parallel or antiparallel to the nuclear axis). Therefore, $|M_L|$ can only be 0 so that the term is $^3\Sigma_g$.

Out of $^3\Sigma_g$, $^1\Sigma_g$ and $^1\Delta_g$, the first term, *i.e.*, $^3\Sigma_g$, having maximum multiplicity will evidently represent the ground state term of the molecule.

The student is advised to work out the terms for Li_2, Be_2, N_2, F_2, F_2^+ molecules himself.

The term symbols for heteronuclear diatomic molecules are derived in a similar manner. Since a heteronuclear diatomic molecule has no centre of symmetry, we do not write the subscript *g* or *u* in the term symbols of such molecules.

The Σ terms are sometimes further codified by writting + or − as a right superscript depending upon whether the system is symmetric or asymmetric with respect to a plane of symmetry passing through the nuclear axis.

Molecular Orbitals of Polyatomic Species

H_3^+ Ion. The three 1*s* orbitals of H_A, H_B and H_C atoms can overlap with one another to produce an equal number of molecular orbitals. The H_3^+ ion thus formed can either have a linear geometry or a triangular planar geometry leading to two different sets of sigma overlaps. But, in both cases the linear combinations of three 1*s* atomic orbitals can be represented by the same three ψ_{MOs} in the following manner :

Various Combinations of AOs of H_A, H_B and H_C	Diagrammatic Representation for	
	Linear Geometry	Triangular Geometry
$\sigma_1 = \psi_{1MO} = \frac{1}{\sqrt{3}}\left[(\psi_{1s(A)} + \psi_{1s(B)} + \psi_{1s(C)})\right]$		$\sigma_2 = \psi_{2MO} = \frac{1}{\sqrt{2}}\left[(\psi_{1s(A)} - \psi_{1s(C)})\right]$		$\sigma_3 = \psi_{3MO} = \frac{1}{\sqrt{6}}\left[(\psi_{1s(A)} - 2\psi_{1s(B)} + \psi_{1s(C)})\right]$		
It is to be noted that each of the σ_1, σ_{2sp} and σ_3 is a normalised function and that each ψ_{1s} is completely utilised while writting σ_1, σ_2 and σ_3. The sum of the squares of the coefficients of each of ψ_{1s} in σ_1, σ_2 and σ_3 is 1.

For H_3^+ ion having linear geometry, σ_1, which has positive overlaps between the three 1*s* orbitals, is obviously a bonding molecular orbital. The molecular orbital σ_2 in a linear geometry cannot have any

overlap and is, therefore, nonbonding while σ_3, having a negative overlap in this geometry is obviously antibonding. The two electrons of H_3^+ will occupy the bonding molecular orbital σ_1 if its geometry is linear.

For H_3^+ ion having triangular geometry, σ_1 is bonding molecular orbital having positive overlaps as is obvious from the figure but σ_2, in which H_A and H_C orbitals form a negative overlap, is antibonding and is thus of higher energy than σ_2 of linear geometry. The molecular orbital σ_3 of triangular geometry is bonding between H_A and H_C involving positive overlaps but is antibonding between H_A and H_B as also between H_B and H_C involving negative overlaps. Therefore, σ_3 of triangular geometry, though antibonding, is of lower energy than σ_3 of linear geometry (why ?). Further it can be shown with the application of group theory that σ_2 and σ_3 of triangular geometry are of equal energy. It can be easily visualised that the triangular planar geometry can be obtained from linear geometry by bending ∠ABC from 180° to 60°. The energies of σ_1, σ_2, σ_3 as a function of ∠ABC can be *calculated*. If a correlation diagram is drawn in the case of H_3^+, it would clearly indicate that a triangular geometry of H_3^+ is more stable than the linear geometry. This is because σ_1 bonding molecular orbital which contains both the bonding electrons is of lower energy in the triangular geometry of H_3^+ because of greater overlaps amongst H_A, H_B and H_c than in its linear geometry, as shown in Fig. 33.

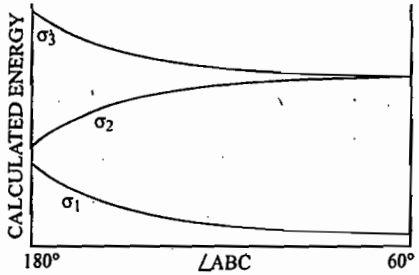

Fig. 33. Plot of calculated energies of molecular orbitals as a function of bond angle.

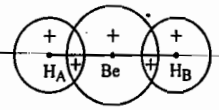
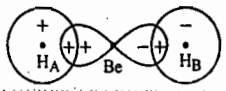
Walsh Diagrams. Normally, we explain the experimentally observed geometries of molecules by certain devised theories and concepts such as VSEPR theory, hybridisation, etc. But Walsh actually calculated the energies of molecular orbitals of a reference geometry and its several distortions for simple triatomic molecules. He correctly predicted the actual geometries of a number of simple triatomic molecules like H_3^+, H_2O, BeH_2, etc., by plotting a graph between the calculated energies of molecular orbitals of the reference geometry and those of the distorted geometries of a molecule *vs* the distortion parameter, *i.e.*, bond angle. The position of minimum energy of the filled molecular orbitals in the graph indicates the most stable geometry of the molecule. Such graphs are known as **Walsh diagrams.** Fig.33 discussed above, in one such diagram.

Beryllium Hydride Molecule, BeH_2. The BeH_2 molecule in gaseous state is linear. It has $D_{\infty h}$ symmetry and contains σ bonds only. From symmetry considerations, the atomic orbitals of Be capable of forming σ bonds in BeH_2 molecule are 2*s* and $2p_z$ orbitals. The p_x and p_y orbitals of Be are not suited for forming σ bonds. The orbitals of the two H atoms which are capable of forming σ bonds are 1*s* atomic orbitals. The two linear combinations of 1*s* atomic orbitals of H which are capable of forming σ bonds with 2*s* and $2p_z$ orbitals of Be are $(\psi_{1s(H_A)} + \psi_{1s(H_B)})$ and $(\psi_{1s(H_A)} - \psi_{1s(H_B)})$. The bonding and antibonding linear combinations of these orbitals are shown below. The bonding combinations have a net positive overlap of orbitals whereas antibonding combinations have a net negative overlap.

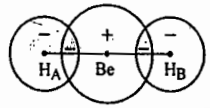
$$\sigma_1 \text{ (bonding)} = a\psi_{2s}(\text{Be}) + b[(\psi_{1s}(H_A) + (\psi_{1s}(H_B)] \quad \ldots$$



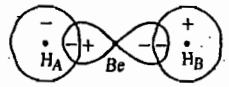
$$\sigma_2 \text{ (bonding)} = c\psi_{2p_z}(\text{Be}) + d[\psi_{1s}(H_A) - (\psi_{1s}(H_B)] \quad \ldots$$



$$\sigma_3 \text{ (antibonding)} = b\psi_{2s}(\text{Be}) - a[\psi_{1s}(H_A) + (\psi_{1s}(H_B)] \quad \ldots$$



$$\sigma_4 \text{ (antibonding)} = d\psi_{2p_z}(\text{Be}) - c[(\psi_{1s}(H_A) - (\psi_{1s}(H_B)] \quad \ldots$$



The molecular orbital energy level diagram of BeH_2 is shown in Fig. 34.

The four valence electrons occupy σ_1 and σ_2 bonding molecular orbitals.

The above simple molecular orbital treatment does not explain the equivalence of the two Be → H bonds which is experimentally established. For explaining this, the concept of hybridisation has to be introduced which is discussed in detail in the next chapter.

Although we began the discussion on BeH_2 by considering the actually observed linear geometry of the molecule, it will be shown with the help of Walsh diagram for AH_2 type of molecules (A belongs to the second period) that any nonlinear or bent geometry of the molecule AH_2 which has *only* 4 valence electrons to be accommodated in its molecular orbitals, will be of higher energy compared to the energy of linear geometry.

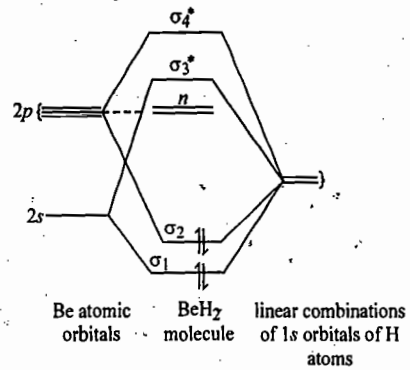


Fig. 34. Molecular orbital energy level diagram of BeH_2 molecule.

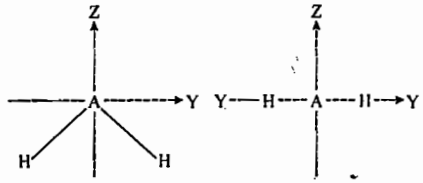
Walsh Diagrams for AH_2 Molecules

Consider a molecule AH_2 where the element A belongs to the second period of the periodic table. The molecule AH_2 can either have an angular geometry with c_{2v} symmetry or a linear geometry with $D_{\infty h}$ symmetry. The only orbital available with H atom for bonding is 1*s* orbital and the symmetry-adapted linear combinations of the two 1*s* orbitals of hydrogen atoms which are capable of forming bonds with orbitals of atom A in both the angular and the linear geometry are $\psi_{1s(H_A)} + \psi_{1s(H_B)}$ and $\psi_{1s(H_A)} - \psi_{1s(H_B)}$. These combinations are of a_1 and b_2 symmetry, respectively, in the angular AH_2 molecule and of a_{1g} and a_{1u} symmetry, respectively, in the linear AH_2 molecule.

In the angular AH_2 molecule, the two atomic orbitals of A of a_1 symmetry are 2*s* and $2p_z$ orbitals and the one with b_2 symmetry is the p_y orbital. In the linear AH_2 molecule, the atomic orbital of A which is of a_{1g} symmetry is 2*s* and the atomic orbital of A which is of a_{1u} symmetry is $2p_y$. Consider the axes Y and Z which pass through A and lie in the plane of paper as shown :



We shall first consider bonding in angular AH_2. The combination $(\psi_{1s(H_A)} + \psi_{1s(H_B)})$, which is of a_1 symmetry, combines with two mixed $2sp_z$ orbitals of *A* also of a_1 symmetry, to give three molecular orbitals $1a_1$, $2a_1$ and $3a_1$. The bonding $1a_1$ molecular orbital utilises the mixed sp_z orbital of A having predominant $2p_z$ character and the bonding $2a_1$ molecular orbital utilises the mixed sp_z orbital of A having predominant 2*s* character in the angular AH_2 molecule with ∠HAH of 90°. As the bond angle increases, the participation of $2p_z$ orbital in the mixed sp_z orbital in $1a_1$ decreases and that of 2*s* orbital increases with the result that in the linear geometry of AH_2, it is only the 2*s* orbital (of a_{1g} symmetry) which combines with the combination $\psi_{1s(H_A)} + \psi_{1s(H_B)}$ (also of a_{1g} symmetry) to give the bonding molecular orbital $1a_{1g}$. Since the $2p_z$ orbital of A is of higher energy than the 2*s* orbital, the lesser and lesser participating of $2p_z$ in molecular orbital $1a_1$, will cause a greater and greater decrease in the energy of the molecular orbital in going from the angular AH_2 molecule (∠HAH of 90°) to the linear AH_2 molecule (∠HAH of 180°).

Similarly, in the $2a_1$ molecular orbital in the angular AH_2 molecule, the contribution of $2s$ orbital goes on decreasing with increase in ∠HAH with the result that in the linear AH_2 molecule with ∠HAH = 180°, there is zero contribution of $2s$ orbital. The contribution of the $2p_z$ orbital, on the other hand, goes on increasing with increase in ∠HAH from 90° to 180°. However, $2p_z$ orbital in linear molecule is non-bonding because in the linear molecule ψ_{2pz} and the combination $(\psi_{1s(H_A)} + \psi_{1s(H_B)})$ are of different symmetry. (The decrease in the contribution of $2s$ orbital of A with increase in ∠HAH in $2a_1$ molecular orbital is understandably due to the increasing contribution of this orbital to the lowest energy bonding molecular orbital $1a_1$). In the angular AH_2 molecule, the $2a_1$ molecular orbital is of lower energy than in the linear AH_2 molecule because as can be seen from the Walsh diagram (Fig. 35), this molecular orbital has a positive overlap with the $1s$ orbitals of hydrogen whereas it has no overlap in the case of linear AH_2 molecule. The $3a_1$ molecular orbital is antibonding and this has not been shown in the figure.

The symmetry-adapted combination $(\psi_{1s(H_A)} - \psi_{1s(H_B)})$ of b_2 symmetry combines with p_y orbital of the same symmetry in the angular AH_2 molecule to give bonding and antibonding molecular orbitals of the same symmetry. Only the b_2 bonding orbital is shown in the Walsh diagram. It can be easily visualised that if we go on increasing ∠HOH in the angular AH_2 molecule, the overlap between $(\psi_{1s(H_A)} - \psi_{1s(H_B)})$ and p_y orbital in the bonding b_2 molecular orbital will go on increasing and hence the energy of this molecular orbital will go on decreasing with the result that the b_2 molecular orbital has lowest energy in the linear AH_2 molecule (∠HOH of 180°).

The p_x orbital of A in both the angular and the linear AH_2 molecules is non-bonding. In fact, in the linear geometry of AH_2 molecule, both the p_x and p_y orbitals are degenerate, non-bonding and are of e_{1u} symmetry.

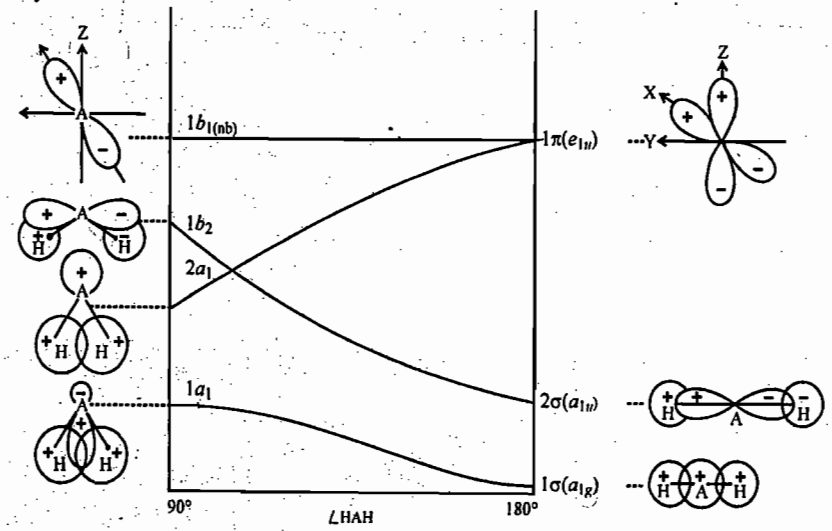


Fig. 35. Walsh diagram showing correlation between molecular orbital energy levels of angular and linear geometries of AH_2 molecule.

The various orbitals which take part in molecular orbital formation of AH_2 molecule are $2s$, $2p_x$, $2p_y$ and $2p_z$ orbitals of A and two $1s$ orbitals of hydrogen atoms. Thus, six molecular orbitals are formed out of which the four lower energy molecular orbitals are shown in Fig. 35. The four molecular orbitals can accommodate eight valence electrons which is the maximum number of electrons that are present in AH_2 molecule (A belongs to the second period).

It follows from the Walsh diagram of AH_2 molecules that a linear geometry of BeH_2 would be more favourable than the angular geometry. This is because the two filled lower energy molecular orbitals of linear geometry of BeH_2 are of lesser energy than the two lower energy molecular orbitals of angular geometry of BeH_2.

To sum up, if there are only 4 electrons to be accommdated in the molecular orbitals of the molecule AH_2 (as *e.g.*, BeH_2), the molecule would have a lower energy **linear geometry.**

If however, the number of electrons to be accommodated in molecular orbitals is more than four, as, for example, in H_2O, the third molecular orbital has to be occupied which is of much lower energy in angular AH_2 molecule than in linear AH_2 molecule. The filling of the fourth non-bonding molecular orbital is of no consequence in determining the geometry of AH_2 molecule since this non-bonding molecular orbital is of the same energy in linear as well as in angular geometry of AH_2 molecule. In such a case, the molecule will have an **angular geometry.**

Carbon Dioxide Molecule, CO_2. This molecule belongs to $D_{\infty h}$ symmetry. The orbitals of carbon and oxygen atoms which can form σ bonds in the direction of bond axis (taken as Z-axis) are $2s$ and $2p_z$ orbitals. The $2s$ orbital of carbon is of a_{1g} symmetry whereas its $2p_z$ orbital is of a_{1u} symmetry. The $2s$ orbital of carbon and $2s$ orbitals of oxygen atoms are of the same symmetry. However, they differ too much in energy. Hence, the $2s$ orbitals of oxygen atoms hardly take part in σ bonding. Therefore, the $2s$ orbitals of oxygen atoms are essentially non-bonding.

The two symmetry-adapted combinations of $2p_z$ orbitals of oxygen which can form σ bonds with atomic orbitals of carbon in the Z direction are $(\psi_{2p_z(O_1)} + \psi_{2p_z(O_2)})$ of a_{1g} symmetry and $(\psi_{2p_z(O_1)} - \psi_{2p_z(O_2)})$ of a_{1u} symmetry. The +Z coordinate of each oxygen atom is taken as pointing towards the carbon atom, as shown.

The various molecular orbitals formed from the combination of atomic orbitals of C and O atoms are shown in Fig. 37 on the next page and the molecular orbital energy level diagram of CO_2 molecule is shown in Fig. 36.

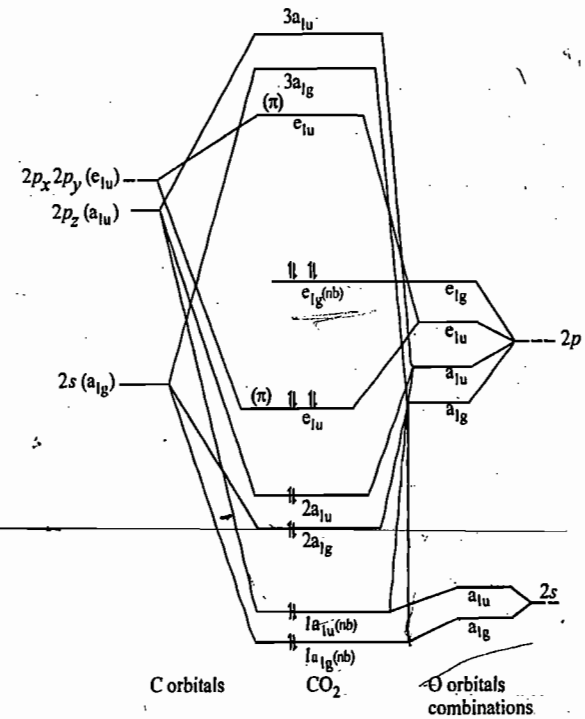

Fig. 36. Molecular orbital energy level diagram of CO_2 molecule.

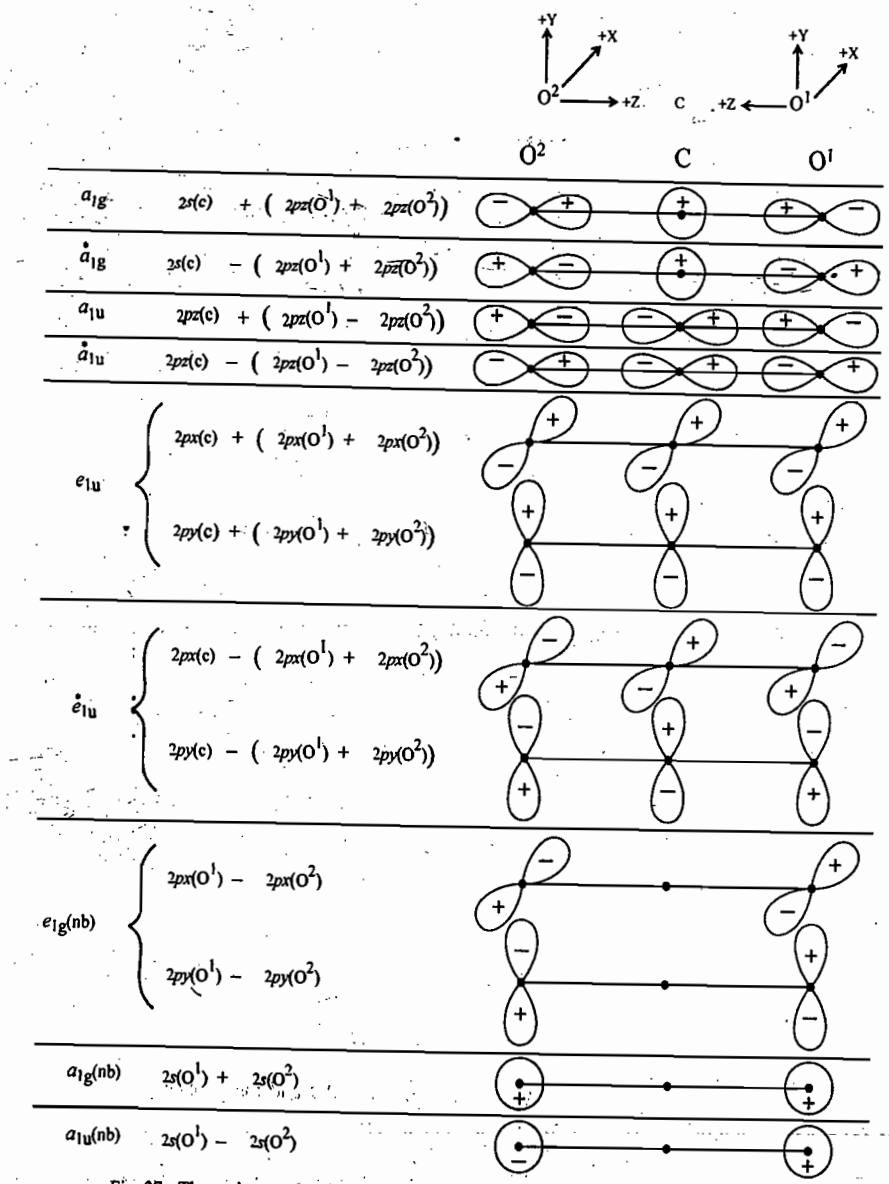

Fig. 37. The various molecular orbitals formed from the combination of atomic orbitals of C and O atom to form CO_2 molecule.

It is evident that CO_2 molecule has 16 valence electrons to be accommodated in its molecular orbitals so that its electronic configuration is written as :

$$CO_2 : 1a_{1g}^2(nb)\ 1a_{1u}^2(nb)\ 2a_{1g}^2\ 2a_{1u}^2\ e_{1u}^4(\pi)\ e_{1g}^4(nb)$$

Ammonia Molecule, NH_3. Each of the 2*s* and $2p_z$ orbitals of N is of the symmetry *a* in C_{3v} point group to which the molecule belongs. The $2p_x$ and $2p_y$ orbitals, *taken together*, are of the symmetry *e*. The three 1*s* orbitals of three H atoms can linearly combine with one another to give three combinations one of which is of the symmetry *a* and the rest of the two combinations, taken together, are of the symmetry *e*. The linear combination *a* of 1*s* atomic orbitals of H combine with 2*s*, $2p_z$ orbitals of N (each one having the symmetry *a*) to give an *equal number* of molecular orbitals (*i.e.*, three molecular orbitals). In the same way, the two linear combinations *e* of 1*s* atomic orbitals combine with p_x, p_y orbitals (also of the symmetry *e*) to give two sets of doubly degenerate molecular orbitals. It is possible to write the wave functions and draw the diagrams of all the seven molecular orbitals of NH_3 as was done in the above mentioned examples of H_3^+ ion and BeH_2. The molecular orbital energy level diagram of NH_3 is shown in Fig. 38.

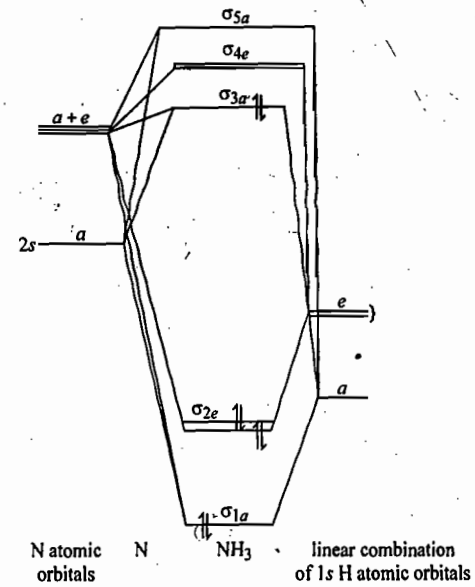

Fig.38. Molecular orbital energy level diagram of NH_3 molecule.

The electronic configuration of NH_3 is $\sigma_{1a}^2\ \sigma_{2e}^4\ \sigma_{3a}^2$. The two electrons in the highest occupied molecular orbital (HOMO), which is *almost non-bonding*, are practically localised on N atom. The remaining occupied molecular orbitals are of bonding type. This simple molecular orbital description of NH_3 tallies with the conventional picture of NH_3 having a lone pair of electrons on N atom and three N – H σ bonds. But it does not explain the equivalence of the three N – H bonds and the observed ∠ NHN. These are explained on the basis of the VSEPR theory and/or the concept of hybridisation as discussed in the next chapter on Hybridisation and Shapes of Molecules.

Problem 4. Of the following species, which has the shortest bond length : NO, NO^+, NO^{2+}, NO^-?

Answer : We shall first calculate the bond orders for the given species from their electronic configurations.

$$NO : KK\ \sigma(2s)^2\sigma(2s)^2\sigma(2p_z)^2\pi(2p_x)^2\pi(2p_y)^2\ \pi^*(2p_x)^1$$

$$\text{or} \quad KK'\sigma_1^2\sigma_2^{*2}\sigma_3^2\pi_1^2\pi_2^2\pi_3^{*1}$$

∴ **Bond order** $= 1/2\,(8-3) = 2\frac{1}{2}$

NO^+ : One electron is removed from the antibonding π_3^* MO.

Bond order $= 1/2(8-2) = 3$

NO^{2+} : One electron is removed from the antibonding π_3^* MO and the other electron is removed from the bonding π_1 (or π_2) MO.

Bond order $= 1/2\,(7-2) = 2\frac{1}{2}$

NO^-: One electron is added to the antibonding π_3^* MO.

Bond order $= 1/2\,(8-4) = 2$

Evidently, the species NO^+ has the highest bond order and thus has the shortest bond length.

Problem 5. Write the electronic configuration of CN^-. What is its bond order ?

Answer : The order of molecular orbitals is the same as in CO. Only the extent of mixing of 2*s* and $2p_z$ orbitals of N occurs to a greater extent in CN^- compared to a similar mixing of the orbitals of O in

CO. The electronic configuration is similar to CO. Thus,

$$CN^- : KK' \sigma^2_{1nb} \sigma^2_2 \pi^2_1 \pi^2 \sigma^2_{3nb}$$

and the **bond order** is 3 due to the presence of six electrons in the bonding orbitals and the rest in nonbonding orbitals. The nonbonding σ_{1nb} is localised on N atom and has predominantly s character whereas σ_{3nb} is localised on C atom and has predominantly p_z character.

Comparison Between Valence Bond Theory (VBT) and Molecular Orbital Theory (MOT)

Common Features. Valence bond and Molecular orbital theories have the following features in common :-

1. The basic principles involved in the distribution of electrons are similar. Thus, an orbital, whether atomic or molecular, cannot have more than two electrons. They are filled in the order of increasing energy. If there are more than one vacant orbitals having the same energy, they would first be filled *singly*.

2. In normal covalent bond formation, the essential interaction, according to both the theories, is the sharing of the bonding electron charge density by both nuclei and concentration of electron charge density between the nuclei.

3. In bond formation, the orbitals of the bonding atoms must overlap according to both the theories.

4. The energies of the overlapping orbitals, according to both the theories, must be comparable and their symmetries should be the same.

Differences

1. While VBT *starts with individual atoms* and considers the interaction between them, MOT *starts with the nuclei* of the constituent atoms.

2. In the valence bond theory, only the half-filled orbitals of the valence shell take part in bonding and the remaining orbitals retain their identity. In molecular orbital theory, however, all the atomic orbitals, whether filled or unfilled, would overlap to form molecular orbitals, provided they have proper symmetry and comparable energy.

3. The wave function in original VBT does not give any weightage to ionic structures (the concept of ionic contribution was incorporated later on as a modification to the original theory). The MOT inherently gives equal weightage to covalent and ionic structures. For example, ψ_{BMO} for H_2 molecule is given by

$$\psi_{BMO} = (\psi_A + \psi_B)_1(\psi_A + \psi_B)_2$$
$$= (\psi_A)_1(\psi_B)_2 + (\psi_A)_2(\psi_B)_1 + (\psi_A)_1(\psi_A)_2 + (\psi_B)_1(\psi_B)_2$$

In this equation, the first two expressions refer to covalent structures and the last two refer to ionic structures.

4. While VBT fails to account for the paramagnetic character of oxygen, MOT offers a satisfactory explanation.

5. While resonance plays an important role in VBT, this concept has no place in MOT.

6. MOT is more exact than the VBT. However, the calculations involved in MOT are much more tedious than those involved in VBT.

METALLIC BOND

Metals are characterised by high electrical and thermal conductivity, bright lustre, malleability, ductility and high tenstile strength. It has been observed that metals, generally, have low ionisation energies because the valency electrons can be taken out relatively easily.

The following three models have been proposed to account for the nature of bonding in metals :

1. *The Free Electron Model. The 'Electron Sea' Model.*
2. *The Valence Bond Model.*
3. *The Band Model : Molecular Orbital Approach.*

1. The Free Electron Model. The 'Electron Sea' Model

According to this model, a metal behaves as if *it is an assemblage of positive ions (kernels) immersed in a 'sea' of mobile electrons* (Fig. 38). *Thus, each electron belongs to a number of positive ions and each positive ion belongs to a number of electrons.*

The force of attraction which binds a metal atom kernel to a number of electrons within its sphere of influence is known as a **metallic bond.**

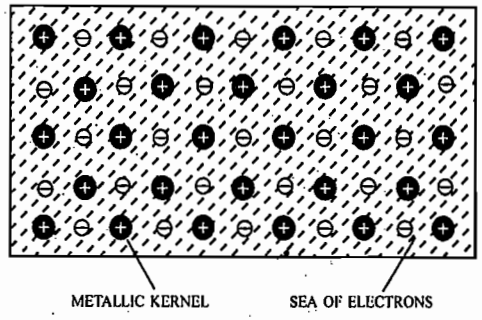

Fig. 38. The electron sea model for metals.

Explanation of Metallic Properties. All the metallic properties such as electrical and thermal conductivity, bright lustre, malleability, ductility, elasticity, etc., can be explained satisfactorily on the basis of the metallic structure described above.

1. The **high electrical conductivity** of metals, for example, is due to the presence of the mobile valency electrons. They move readily in an electric field and thus conduct electricity throughout the metal from one end to the other.

2. The **high thermal conductivity** is also due to the presence of these mobile electrons. If one part of a metal is heated, the electrons in that part acquire a large amount of kinetic energy. Being free, these electrons move rapidly through the crystal and convey heat (*i.e.*, conduct heat) to other parts of the metal.

3. The **bright metallic lustre** can also be explained as due to the presence of the highly mobile electrons. As a beam of light comprising of electromagnetic waves falls on the surface of a metal, the electric field associated with light waves sets the electrons present on the surface of the metal into to and fro oscillations. Now, a moving charge always emits electromagnetic energy. Hence, oscillating electrons emit electromagnetic energy in the form of light. Thus, when light falls on a metal surface, it appears as if light is being reflected. The surface, therefore, emits the typical metallic lustre.

4. The model of free valency electrons can also explain the **softness, malleability** and **ductility** associated with metals. The metallic bond holding the positive ions (say, M^+) and the valency electrons is *non-directional*. In other words, the force of attraction between the M^+ ions and the valency electrons is uniform in all directions. Also the bonds holding the crystal lattice in metals are not rigid unlike those in covalent solids, such as ice which are rigid. The result is that M^+ ions can be easily moved from one lattice site to another. In terms of the crystal, nothing has been changed. The environment of each metal ion remains the same as before since delocalized electrons are available everywhere.

The nearest neighbours can thus be changed easily and new metal bonds can be formed readily. This explains why metals are malleable, *i.e.*, they can be flattened out into thin sheets when hammered. A crystal of ice, on the other hand, is hard. It is neither malleable nor ductile. It is brittle, *i.e.*, it breaks into small pieces when hammered. This is obviously due to the fact that atoms in water (oxygen and hydrogen) are covalently bonded to each other. Covalent bond is thus *rigid* and *highly directional.*

The ease with which the metal ions can be moved from one lattice site to another is also responsible for the fact that the metals are *ductile*, *i.e.*, they can be drawn into wires by very little expenditure of energy. This also explains why metals like sodium and potassium are *soft* and can easily be cut with a knife.

5. Metals have **high tensile strength,** *i.e., they can resist stretching without breaking.* This is due to

the existence of strong electrostatic attraction between the positively charged metal ions and the 'sea' of negative electrons surrounding them. Substances which have covalent bonds, do not possess high tensile strength. This is due to the absence of electrostatic forces of attraction in the crystal, there being no oppositely charged units in the lattice.

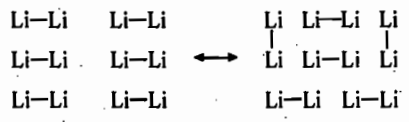
6. Metals possess **elasticity.** *Elasticity is a property by virtue of which a substance can resist a deforming force* or a property by virtue of which *a substance can recover its original form soon after the removal of the deforming force.* The elasticity of metals is also due to the ease with which metal ions can move from one lattice site to another.

7. The delocalized electron model can also explain the well known observation that *only a small force is needed to* **bend** *a straight copper wire sharply.* However, straightening of a bent wire is not so easy. It requires much more force to do so. Not only that ; a small kink always remains. The reason is that the formation of a sharp bend amounts to separation of some of the metal ions from their adjacent electrons and also from their nearest ion neighbours. The previous pattern of ions and electrons is disturbed and a new pattern is set up in the crystal giving rise to new planes and new edges. It is not so easy to restore the previous pattern because the new planes and edges formed during the bending do not ordinarily fit together to restore the original pattern once again.

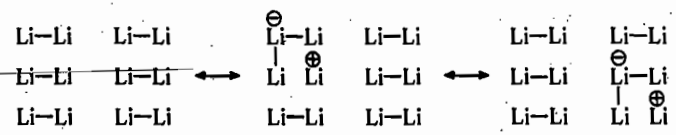
Limitations of the model. The free electron model, however, cannot explain vast variations in properties of certain metals. For example, while mercury melts at such a low temperature as – 39°C, tungsten melts at such a high temperature as 3300°C. While metals, in general, are good conductors of electricity, copper is more than 50 times better conductor than bismuth. Similarly, while metals like sodium and potassium are so soft that they can be cut easily with a knife, osmium is so hard that it can scratch even glass.

2. The Valence Bond Model

An examination of the crystal lattice of lithium atom reveals that each Li atom in this lattice is surrounded by eight nearest Li atoms and six next to nearest Li atoms. Because of the presence of only one valence electron, each Li atom is capable of forming only one normal covalent bond with one of its nearest Li atoms. This Li–Li covalent bond is assumed to resonate **mainly** between all the eight neighbours and **to some extent** between the six next to the nearest neighbours. In this way, each Li atom would bind all its neighbours. The resonance of the Li – Li bonds, which is similar to the resonance of the double bonds in benzene, stabilizes the metallic bond. The resonance of Li – Li bonds between a few Li atoms is shown below :



More stabilisation results from resonance of the following type :



Although the valence bond model does meet some success in explaining some of the characteristics of metals, yet it is only qualitative in nature. The cause of metallic bonding is best explained on the basis of the Band Model involving the concept of molecular orbitals.

As already discussed in this chapter, atomic orbitals overlap to produce molecular orbitals. For example, 1*s* atomic orbital of one H atom overlaps with the 1*s* atomic orbital of the other H atom to form two molecular orbitals of H_2 molecule. The energy of one of the resulting molecular orbitals is higher and of the other is lower than the energy of either of the combining atomic orbitals. The energies of the two molecular orbitals are represented in the form of two energy levels whose magnitudes vary with the internuclear distance between the two atoms, as shown in Fig. 39.

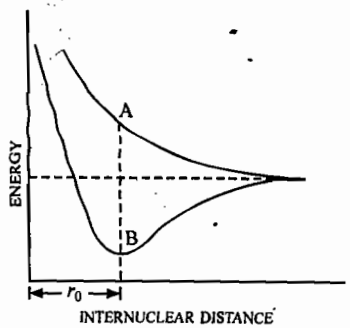


Fig. 39. Variation of the two molecular orbital energy levels with internuclear distance in the case of H_2 molecule. r_0 is the equilibrium internuclear distance.

The energy separation between the two molecular orbital energy levels at equilibrium internuclear distance r_0 is presented by AB.

In general, if there are *n* atomic orbitals, one on each atom, in a metallic crystal, they may overlap to give *n* molecular orbitals corresponding to *n* energy levels. It is essential, however, that the atomic orbitals have the same symmetry and are associated with the same or similar amount of energy. Thus, the larger the number of atomic orbitals satisfying the above conditions, the larger would be the number of molecular orbitals each of which can be represented by a separate energy level. The energy separation between any two adjacent energy levels would go on decreasing with increase in the number of overlapping orbitals. Consequently, if we have an exceedingly large number of overlapping orbitals, the energy separation between any two adjacent energy levels would be exceedingly small so that we get an almost *continuous energy band*, as shown in Fig. 40.

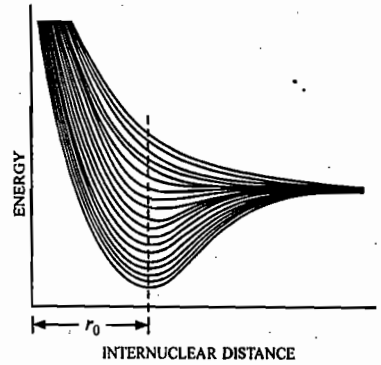

Fig. 40. An almost continuous energy band of energy levels of molecular orbitals obtained by overlapping of an exceedingly large number of atomic orbitals.

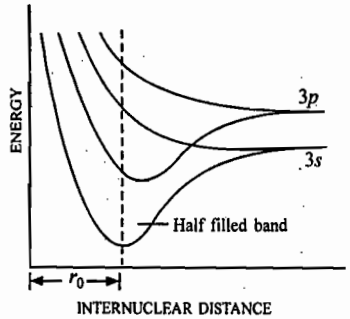

Fig. 41. The valence band of sodium metal. The dotted line indicates equilibrium internuclear distance.

A similar situation exists in case of metals. A metal lattice has an extremely large number of atoms. The atomic orbitals on these atoms with same symmetry and same energy overlap resulting in an almost continuous energy band of extremely large number of energy levels of molecular orbitals. Each energy level in this band is capable of holding two electrons. The overlaping of 3*s* and 3*p* orbitals (valence orbitals) in the crystal lattice of **sodium metal** is shown in Fig. 41.

The overlapping of inner orbitals of same symmetry and same energy produces molecular orbitals which are completely occupied by inner electrons. Also, there is considerable energy gap between the valence orbital energy bands and the inner orbital energy bands so that the electrons from the completely filled inner orbital energy band cannot be excited to the valence orbital energy bands. The fully filled inner orbital energy bands are not shown in the figure. Since the molecular orbitals are common to all

bands of atoms in the lattice, the electrons in the energy levels of these energy bands are common and belong to the whole lattice. In other words, they are completely delocalised.

Since sodium atom has only a single electron in the 3*s* orbital, therefore, in the case of sodium metal, only half of the 3*s* energy level band is occupied by electrons and even on slightest excitation, these electrons can move to the higher energy levels in this band. The mobility of these electrons makes the sodium metal a good conductor of electricity. A similar situation occurs in all the other alkali metals in which the valence energy level band is always half-filled.

The situation in the case of alkaline earth metals is, however, different. In these cases, the outermost valence orbital is fully filled with two electrons so that no vacant energy level of the energy band is available for the electrons to jump to. However, at the equilibrium internuclear distance, the 3*s* energy band and the 3*p* energy band overlap so that some of the vacant energy levels of 3*p* band and the filled energy levels of 3*s* band fall in the same energy range. Consequently, the 3*s* electrons can be easily excited to the 3*p* energy levels in this range. The resulting mobility of electrons makes the alkaline earth metals also good conductors of electricity.

In an **insulator,** there is a large energy gap between the lowest vacant energy band and the highest fully filled energy band even at the equilibrium internuclear distance (Fig. 41). As a result, the electrons cannot be easily excited from the fully filled energy band to the vacant energy band. This makes the material non-conducting.

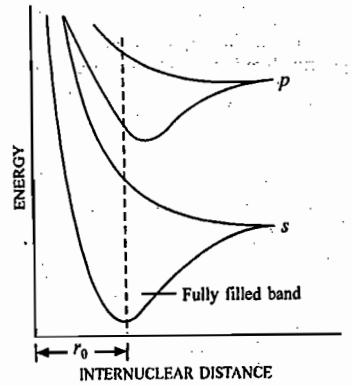

Fig. 42. The valence bands of an insulator.

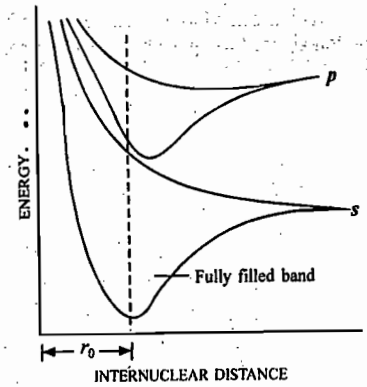

Fig. 43. The valence bands of a semi- conductor.

In a **semi-conductor,** there is a lesser energy gap between the two energy bands (Fig. 43). Although the electrons are not very easily excited from the filled to the vacant energy bands yet these can be excited if an appropriate amount of energy is made available.

HYDROGEN BOND

In compounds of hydrogen with *strongly electronegative* elements, such as fluorine, oxygen and nitrogen, the electron pair shared between the two atoms lies far away from the hydrogen atom. As a result, the hydrogen atom becomes *electropositive* with respect to the other atom. This phenomenon of charge separation in the case of hydrogen fluoride is represented as $\overset{+\delta}{H}-\overset{-\delta}{F}$. Such a molecule is said to be **polar,** as already discussed. The molecule behaves as a **dipole** because one end carries a positive charge and the other end a negative charge. The electrostatic force of attraction between such molecules should be very strong. This is because the *positive end of one molecule* attracts and is attracted by the *negative end of the other molecule.* Thus, *two or more molecules may associate together to form large clusters of*

molecules. This is illustrated below for the association of several molecules of hydrogen fluoride :

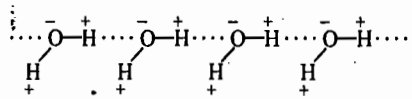
$$\cdots\overset{+\delta}{H}-\overset{-\delta}{F}\cdots\overset{+\delta}{H}-\overset{-\delta}{F}\cdots\overset{+\delta}{H}-\overset{-\delta}{F}\cdots\overset{+\delta}{H}-\overset{-\delta}{F}\cdots$$

The cluster of HF molecules may be described as $(HF)_n$.

The attractive force which binds hydrogen atom of one molecule with electronegative atom (such as fluorine) of another molecule, generally of the same substance, is known as **hydrogen bond.**

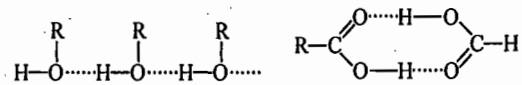
In this case, while the length of the covalent bond between F and H atoms is found to 1·00 Å, the length of the hydrogen bond between F and H atoms of neighbouring molecules has been found to be 1·55 Å.

Water molecule, because of its bent structure, is also a dipole, oxygen end carrying a negative charge and hydrogen end carrying a positive charge, as shown. Hydrogen bonding takes place in this case as well, as shown below :



The cluster of water molecules may be described as $(H_2O)_n$.

Alcohols and carboxylic acids also form associated molecules for the same reason, as illustrated below.



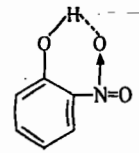
Alcohols Carboxylic acid

It is seen that in water and alcohols, the hydrogen bonding (or the association of molecules) may extend to several molecules as indicated above but in carboxylic acids, the hydrogen bonding is limited to the association of two molecules only.

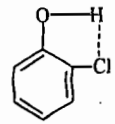
The nature of hydrogen bond. The hydrogen bond *is a class in itself.* It arises from electrostatic forces between the positive end (pole) of one molecule and the negative end (pole) of *another* molecule of the same or some other polar substance. For instance, extensive hydrogen bonding occurs between molecules of water, molecules of ethanol as also between molecules of water and molecules of ethanol. The strength of hydrogen bond has been found to vary between 10 – 40 kJ per mole (*i.e.,* per $6{\cdot}022\times10^{23}$ bonds) while that of a covalent bond has been found to be of the order of 400 kJ per mole. Thus, a hydrogen bond is very much weaker than a covalent bond.

Intramolecular Hydrogen Bonding. In addition to *intermolecular* hydrogen bonding resulting from electrostatic forces of attraction between the positive and negative ends of *different molecules* of the same substance, cases of **intramolecular hydrogen bonding** are also known. *These involve the electrostatic forces of attraction between hydrogen and an electronegative element both present in the* **same molecule.**

Interesting examples are provided by *o*-nitrophenol and *o*-chlorophenol :

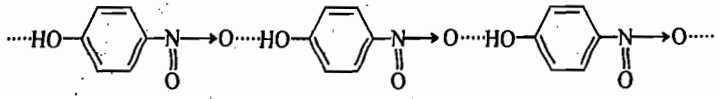


o-Nitrophenol showing intamolecular hydrogen bonding

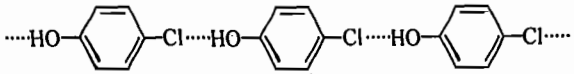


o-Chlorophenol showing intramolecular hydrogen bonding

Para nitrophenol and para chlorophenol, on account of larger distances between the two groups, do not show any intramolecular hydrogen bonding. On the other hand, they show the usual *intermolecular hydrogen bonding*, as illustrated below :



Intermolecular hydrogen bonding in *p*-nitrophenol



Intermolecular hydrogen bonding in *p*-chlorophenol

As a result of intermolecular hydrogen bonding, the para derivatives undergoes association as shown above, resulting in an increase in molar mass and hence an increase in boiling point. In ortho derivative, on account of *intramolecular hydrogen bonding*, no such association is possible. Consequently, the ortho derivatives are more volatile than the para derivatives.

Consequences of Hydrogen Bonding. 1. Boiling Points of Binary Hydrogen Compounds. Let us consider boiling points of binary compounds of hydrogen with various elements of Groups 15, 16 and 17, given in Table 10.

TABLE 10

Boiling Points of Binary Hydrogen Compounds with Elements of Groups 15, 16 and 17

Group 15			Group 16			Group17		
Formula	Molar mass	B.P. (°C)	Formula	Molar mass	B.P. (°C)	Formula	Molar mass	B.P. (°C)
SbH_3	125	– 17·0	H_2Te	130	– 1·8	HI	127·9	– 3·5
AsH_3	78	– 55·1	H_2Se	81	– 42·0	HBr	80·9	– 67·1
PH_3	34	– 84·6	H_2S	33	– 59·6	HCl	36·5	– 85·0
NH_3	17	– 33·0	H_2O	18	+ 100	HF	20·0	+ 19·4

It is seen that although the boiling point in each group *decreases with decrease in molar mass*, there is a sudden *reversal* in the case of ammonia, water and hydrogen fluoride in Groups 15, 16 and 17, respectively. The unusually high boiling point of each compound, evidently, is a consequence of strong intermolecular forces due to hydrogen bonding.

Thus, while H_2S, in which there is no hydrogen bonding, is a *gas*, H_2O, in which there is considerable hydrogen bonding, is a *high boiling liquid*.

Some Unique Properties of Water. Water has some unique properties. Two of these are :

1. *Density in the solid state (ice) is less than that in the liquid state.* This is somewhat unusual because in most substances density in the solid state is more than that in the liquid state.

2. *Water contracts when heated between 0°C and 4°C.* This is again unusual because most substances expand when heated in all temperature ranges.

Both these peculiar features which are due to hydrogen bonding, are discussed below :

1. In ice, the hydrogen bonding between H_2O molecules is more extensive than in liquid water. A substance in solid state has a definite structure and the molecules are more rigidly fixed relative to one another than in liquid state. In ice, the H_2O molecules are *tetrahedrally oriented with respect to one another.* This has been shown in Fig. 44.

At the same time, each oxygen atom is surrounded tetrahedrally by four hydrogen atoms, two of these are bonded covalently and the other two by hydrogen bonds (Fig. 44).

The hydrogen bonds are *weaker* and, therefore, *longer* than the covalent bonds. This arrangement gives rise to an *open cage-like structure*, as shown in the figure. There are evidently a number of 'holes' or open spaces in this structure. These 'holes' are formed because the hydrogen bonds holding the H_2O molecules in ice *are directed at certain definite angles.* In liquid water such hydrogen bonds are fewer in number. Therefore, as ice melts, a large number of hydrogen bonds are broken. The molecules, therefore, move into the 'holes' or open spaces and come closer to one another than they were in the solid state. *This results in a sharp increase in the density.* The density of liquid water is, therefore, higher than that of ice.

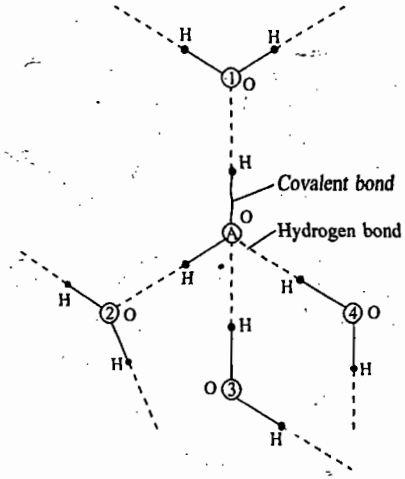


Fig. 44. The tetrahedral open cage-like crystal structure of ice. The central oxygen atom A is surrounded tetrahedrally by the oxygen atoms marked 1, 2, 3 and 4.

2. As liquid water is heated from 0° to 4°C, hydrogen bonds continue to be broken and the molecules come closer and closer together. This leads to *contraction*. However, there is also some expansion of water due to rise in temperature as in other liquids. It appears that upto 4°C, the former effect predominates and hence there is net *contraction in volume.* Above 4°C, however, the normal expansion effect, due to rise in temperature, predominates and hence *the volume increases as the temperature rises.*

Importance of Hydrogen Bonding in Sustaining Life. It can be easily realised that without hydrogen bonding, water would have existed as a gas like hydrogen sulphide. In that case, no life would have been possible on this globe.

Hydrogen bonding also exists in all living organisms whether of animal or of vegetable kingdom. Thus, it exists in various tissues, organs, blood, skin and bones in animal life. It plays an important role in determining structure of proteins which are so essential for life.

Hydrogen bonding plays an important role in making wood fibres more rigid and thus makes it an article of great utility to meet requirements of housing, furniture, etc. The cotton, silk or synthetic fibres owe their rigidity and tensile strength to hydrogen bonding. Thus, hydrogen bonding is of vital importance for our clothing as well. Most of our food materials also consist of hydrogen bonded molecules. Sugars and carbohydrates, for example, have many OH groups. The oxygen of one such group in one molecule is bonded with OH group of another molecule through hydrogen bonding. The stickiness of glue (a protein) or honey (which consists mainly of water and sugar) is also due to hydrogen bonding between the OH or other such groups of different molecules with one another. Hydrogen bonding is thus a phenomenon of great importance in everyday life.

INTERMOLECULAR FORCES

It is now fully established that forces of attraction exist between polar as well as non-polar molecules. These are known as **intermolecular forces** or **cohesive forces** or **van der Waals forces.** These forces originate from two types of interactions, *viz.*, 1. *Dipole-Dipole Interaction* and 2. *Induced dipole–Induced dipole Interaction.*

1. Dipole–Dipole Interaction. In the case of *polar molecules* which have permanent dipoles, the van der Waals' forces are mainly due to electrical interaction between the dipoles known as **dipole-dipole interaction.** For instance, gases such as ammonia, sulphur dioixde, hydrogen fluoride, hydrogen chloride, etc., have permanent dipoles as a result of which there is appreciable dipole–dipole interaction between the molecules of these gases. The magnitude of this type of interaction depends upon the dipole moments of the molecules concerned. The greater the dipole moments, the greater is the dipole–dipole interaction. Because of the attractive interaction, these gases can be easily liquified.

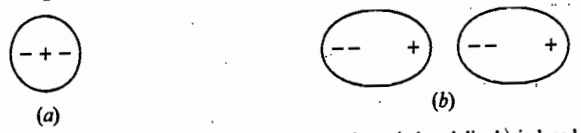
The average interaction energy of the two molecules with permanent dipole moments μ_1 and μ_2 is given by the expression :

$$\text{Interaction energy, } \phi(r) = -2\left(\frac{\mu_1\mu_2}{4\pi\varepsilon_0}\right)^2\left(\frac{1}{r^6}\right)\left(\frac{1}{3kT}\right) \quad ...(37)$$

where r is the distance between the molecules, k is the Boltzmann constant and $4\pi\varepsilon_0$ is the permittivity factor for the medium.

2. Induced dipole-Induced dipole Interaction. London Forces or **Dispersive Forces.** It is now well known that van der Waals forces exist even in non-polar diatomic molecules such as O_2 and N_2 and also in non-polar monoatomic molecules such as He, Ne, Ar, etc. This attraction is evident from the condensation of these gases into liquids at sufficiently high pressures and low temepratures. The existence of van der Waals forces in these molecules could not be understood for several years.

In 1930, F. London provided a satisfactory explanation for the existence of forces of attraction between non-polar molecules according to which electrons of a non-polar molecule keep on oscillating with respect to the nuclei of the atoms. As a result of this, at a given instant, positive charge may be concentrated in one region and negative charge in another region of the same molecule. Thus, a non-polar molecule may become momentarily self-polarised. This polarised molecule may induce a dipole moment in a neighbouring molecule, as shown in Fig. 45.



(*a*) shows average charge distribution in a non-polar molecule.

(*b*) shows induced dipole–induced dipole interaction.

Fig. 45. Origin of cohesive forces in non-polar molecules.

The electrostatic forces of attraction between induced dipoles and the original dipoles (due to oscillation of electrons) are known as **London forces.** These forces are also called **dispersive forces** because the well known phenomenon of dispersion of light is also connected with these dipoles. For a pair of adjacent molecules, London forces vary inversely as the *sixth power* of the distance between them, *i.e.*, $F \propto 1/r^6$.

The approximate interaction energy in this case is given by

$$\phi(r) = -\left(\frac{3E_1E_2}{2(E_1+E_2)}\right)\left(\frac{\alpha_1\alpha_2}{(4\pi\varepsilon_0)^2 r^6}\right) \quad ...(38)$$

where E_1 and E_2 are the ionization energies of the two molecules. Other parameters have the same significance as mentioned above.

The van der Waals' attraction in *non-polar molecules* is thus *exclusively* due to London forces. In the case of polar molecules showing permanent dipoles, however, other electrostatic forces due to dipole – dipole interaction also contribute towards the van der Waals attraction, as already discussed.

QUESTIONS

1. (*a*) What is an ionic bond ?
   (*b*) Discuss carefully the formation of an ionic bond in terms of decrease of energy. Derive from it the conditions for the formation of ionic bonds.
   (*c*) Explain giving suitable examples why ions with three positive or three negative charges are rare ?
2. (*a*) Discuss the formation of a covalent bond on the basis of the orbital overlap concept. What is meant by a sigma bond ?
   (*b*) Differentiate between a sigma bond and a pi bond. Explain why a sigma bond is stronger than a pi bond ?
   (*c*) Explain the term covalency. How would you account for variable covalency of an element ? What is the maximum covalency which an element can exhibit ?
   (*d*) Construct a plot of potential energy versus internuclear distance between two hydrogen atoms.
3. (*a*) What do you understand by polar and non-polar molecules ? Is it possible for the non-polar molecules to have polar bonds ? Justify you answer with examples.
   (*b*) Explain why CO_2 and CCl_4 molecules are non-polar while $CHCl_3$ molecule is polar ?
   (*c*) What is meant by dipole moment ? Can its magnitude give an idea about the structure of a molecule ? Explain giving examples.
   (*d*) Which is more polar, H_2S or H_2O and why ?
4. (*a*) What is the difference between coordinate bond and covalent bond ?
   (*b*) Under what circumstances can a fully filled orbital participate in bond formation? Discuss with an example.
   (*c*) PCl_5 exists while NCl_5 does not. Explain.
5. What is Valence Bond theory ? Explain.
   In the potential energy diagram for H_2 molecule, the combined wave function ψ for two hydrogen atoms $\psi = \psi_A(1)\psi_A(2)$ (where $\psi_A(1)$ and $\psi_B(2)$ represent wave functions for two hydrogen atoms H_A and H_B associated with electrons 1 and 2, respectively), results in decrease in energy of the system by 24 kJ mol^{-1}. But the experimental value is 458 kJ mol^{-1}. What improvements in the wave functions of the system are made to account for this difference?
6. (*a*) What is resonance ? Discuss by taking example of CO_3^{2-} ion.
   (*b*) What do you understand by the term resonance energy ? What are the essential rules for writing resonating structures?
7. (*a*) What is Molecular Orbital theory ?
   (*b*) Give the electron charge density diagrams for bonding and antibonding molecular orbitals.
   (*c*) Predict the bond order in C_2 molecule with the help of MO diagram.
8. (*a*) What do you understand by the terms bonding and antibonding molecular orbitals ? Why are they so called ? Illustrate your answer by taking into consideration the structure of hydrogen ion H_2^+.
   (*b*) Is B_2 molecule paramagnetic or diamagnetic ? Discuss.
9. Explain how the atomic orbitals combine to form bonding and antibonding molecular orbitals. What are the limitations to such combinations ? Explain why in a homonuclear molecule, an s orbital of one atom cannot combine with a p_x or a p_y orbital of another atom of the same element.
10. (*a*) Draw molecular orbital diagram for HF molecule.
11. Explain on the basis of MO theory as to why
    (*a*) Oxygen molecule is paramagnetic while nitrogen molecule is diamagnestic.
    (*b*) Hydrogen forms diatomic molecule while helium remains monoatomic.
    (*c*) The bond order in O_2^- is less than that in O_2 which, in turn, is less than that in O_2^+.
12. (*a*) The internuclear distances in some O – O bonds are as follows :

O_2^+	O_2	O_2^-	O_2^{2-}
1·12 Å	1·21 Å	1·30 Å	1·49 Å

    (*i*) Account for the gradation of the internuclear distances in the above series.
    (*ii*) Which of these species are paramagnetic ?
    (*b*) Is it correct to say that bond energy in a diatomic molecule always increases when an electron is lost ?
    (*c*) "While in the case of F_2 molecule, all the orbitals are molecular, in case of HF molecule there is only one orbital which is molecular." Comment on this statement.

(*ii*) Which of these species are paramagnetic ?

(*b*) Is it correct to say that bond energy in a diatomic molecule always increases when an electron is lost ?

(*c*) "While in the case of F_2 molecule, all the orbitals are molecular, in case of HF molecule there is only one orbital which is molecular." Comment on this statement.

13. (*a*) Discuss with the help of the MO theory the formaiton of N_2, O_2 and F_2 molecules. How does the theory explain the difference in the reactivity of N_2, O_2 and F_2 ?

(*b*) Discuss carefully the electronic configurations of NO, CO, HF and HCl molecules.

14. Draw the MO diagrams for the following species :

Be_2, HHe (hypothetical), O_2^-, CO, BN

Explain the magnetic character of these species.

15. Write the electronic configuration of NO molecule.

(*a*) What is the bond order ? (*b*) Will the bond length be shorter or larger than in NO^+ ?

(*c*) How many unpaired electrons will be present ? (*d*) What will be the bond order in NO^- ?

16. With the help of molecular orbital diagrams explain why

(*a*) the bond order in N_2^+ ion is less than that in N_2 molecule whereas the bond order in O_2^+ is greater than that in O_2 molecule.

(*b*) the bond energy of NO^+ is higher than that of NO. (*c*) the bond length of CO^+ is larger than that of CO.

17. (*a*) Write the electronic configuration of a diatomic molecule having bond order three.

(*b*) Compare briefly valence bond and molecular orbital theories.

18. What is meant by metallic bond ? Illustrate the nature of metallic bond on the basis of (*i*) Electron sea model. (*ii*) Valence bond model and (*iii*) The band model (MO approach).

19. Discuss in details the band model of metallic bond. What type of energy bands are obtained in, (*i*) sodium metal (*ii*) an insulator (*iii*) semi-conductor

20. What is meant by hydrogen bonding ? Discuss the nature and consequences of hydrogen bonding. Discuss the importance of hydrogen bonding in sustaining life. Why do H_2O and HF have abnormally high boiling points ?

21. (*a*) What are intermolecular forces ? How do these forces originate ?

(*b*) What are London forces ? What is their origin ?

22. Explain why in the valence bond treatment of H_2, $\psi_{+\ complete}$ is called a singlet state while $\psi_{-\ complete}$ is called a triplet state.

23. What are term symbols ? What is the advantage of using three term symbols ? Wrtie down the term symbols for the following :

H_2^+ molecular ion, O_2 molecule, F_2 molecule, N_2 molecule F_2^+ molecular ion, Be_2, Li_2

24. What are Walsh diagrams ? To what use these diagrams are put ? Explain with the help of a Walsh diagram that[1] the BeH_2 molecule would have a linear geometry and H_2O molecule would have an angular geometry.

25. Discuss the geometry of CO_2 molecule on the basis of Walsh diagram.

5 HYBRIDISATION AND SHAPES OF COVALENT MOLECULES

HYBRIDISATION

Beryllium, boron and carbon (atomic numbers 4, 5 and 6) furnish interesting cases of compound formation. The electronic configurations of these elements are :

Beryllium	(At. No. 4) :	$1s^2\,2s^2$
Boron	(At. No. 5) :	$1s^2 2s^2\,2p_z^1$
Carbon	(At. No. 6) :	$1s^2 2s^2\,2p_z^1 2p_x^1$

According to the atomic orbital overlap concept, beryllium should behave like a *noble gas* since it has no half-filled orbital. Boron, which has only one half-filled orbital, should behave as a *univalent* element and form compounds like BH and BF. Carbon, which has only two half-filled orbitals, should behave as a *bivalent* element and form compounds like CH_2 and CCl_2. But this is not actually the case. Beryllium, unlike noble gases, forms a number of compounds like BeF_2 and BeH_2 in which it is bivalent. Boron forms a number of compounds like BCl_3 and BH_3 in which it is trivalent. Carbon forms millions of compounds in which it is almost invariably tetravalent. The simple examples are CH_4, CCl_4, etc.

In order to explain these anomalies, we make use of a concept called **hybridisation.** This concept, though hypothetical, is extremely helpful.

***sp* Hybridisation of Orbitals of Beryllium.** As mentioned above, the electronic configuration of Be atom in its ground state is $1s^2\,2s^2$. As such, Be should be zero-valent, as already stated. However, the promotion of a $2s$ electron to a $2p$ orbital results in an excited state configuration of Be, *viz.*, $1s^2\,2s^1p^1$ which has *two half-filled orbitals.* Thus, Be atom in its excited state is capable of showing a covalency of 2. The energy required for the promotion of the $2s$ electron comes from the energy that is released when Be and, say, F atoms approach each other to form BeF_2 molecule. It may be pointed out pertinently that all feasible chemical combinations are invariably accompanied by decrease and hence release of energy. Since the energy required by Be atom for the promotion of the electron from $2s$ to $2p$ orbital is less than the energy released due to the formation of the two covalent bonds, the formation of beryllium fluoride is energetically feasible. This offers a plausible explanation for the existence of stable compounds of beryllium such as BeF_2, BeH_2, etc.

Here a difficulty arises. We know that $2s$ and $2p$ orbitals have different energies and hence the two bonds in BeF_2 should have different strengths. This is because one Be–F bond will be formed by the overlapping of $2s$ orbital of beryllium and $2p$ orbital of fluorine while the second Be–F bond will be formed by the overlapping of $2p$ orbital of beryllium and $2p$ orbital of fluorine. But, actually both the bonds are of equal strength. How are we then going to explain equal strengths of both the bonds in beryllium fluoride, F–Be–F ? This is done by *postulating* that *the s and p orbitals of beryllium mix, i.e., hybridise, to give two orbitals of equivalent energy.*

The concept of redistribution of energy in different orbitals of an atom associated with different energies to give new orbitals of equivalent energy (rarely of non-equivalent energy as well) oriented in

space in definite directions is called **hybridisation.** The new orbitals thus formed are called **hybrid orbitals.** The bonds formed by such orbitals are called **hybrid bonds.** The process of mixing of orbitals itself requires some energy. Thus, some additional energy, over and above the energy required for the promotion of the required number of electrons to the higher energy orbitals, is needed for the hybridisation (mixing) of atomic orbitals.

Since in the formation of bivalent compounds of beryllium, *one s* and *one p* orbital is involved in hybridisation, it is called *sp hybridisation* and the two identical orbitals which result from this process are known as *sp hybrid orbitals.*

The amount of energy released $(B.E.)_1$ due to the formation of sigma bonds between Be and X atoms involving *hybrid orbitals* is greater than the energy released $(B.E.)_2$ in case the sigma bonds had involved the *pure s* and *p orbitals.* This is illustrated in Fig. 1 where $(B.E.)_1$ and $(B.E.)_2$ are represented by *AC* and *DF*, respectively

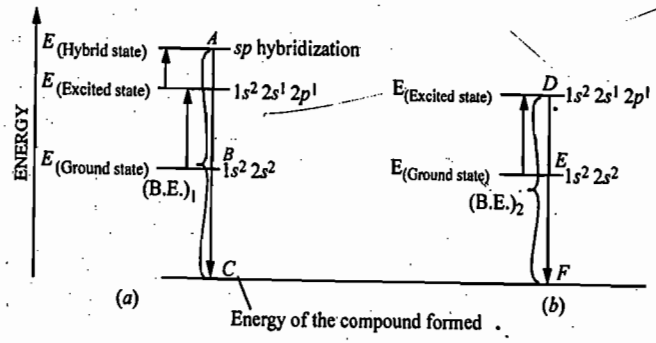


Fig. (1) (*a*) Energy *required* for the promotion of a 2*s* electron to a 2*p* orbital as also for the hybridisation of *s* and *p* orbitals to give *sp* hybrid orbitals in case of Be. $(B.E.)_1$ is the energy *released* when hybrid orbitals are involved in covalent bond formation. $(B.E.)_2$ is the energy *released* in the formation of covalent bonds involving pure *s* and *p* orbitals.

It is evident from the figure that some additional energy is released due to the involvement of the *sp hybrid orbitals* in bond formation. Because of this additional decrease of energy, the sigma bonds formed by *hybrid orbitals* of Be atom are stronger than the bonds formed by *pure s* and *p orbitals.*

The formation of *sp* hybrid orbitals is shown pictorially in Fig. 2.

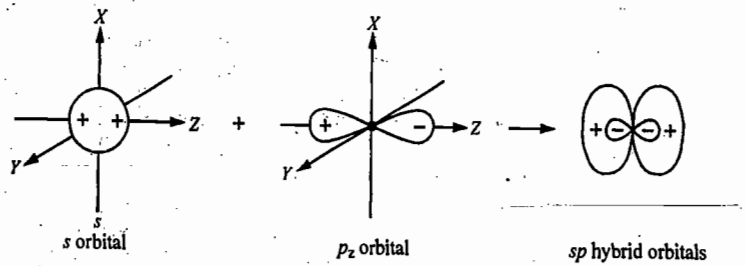

Fig. 2. Formation of two *sp* hybrid orbitals. + and – are geometric signs of the curves.

A pure *s* and a pure *p* orbital (oriented in the Z direction) are shown on the left of the arrow. The two *sp* hybrid orbitals which result from this combination are shown on the right. Each *sp* hybrid orbital consists of one large lobe and one small lobe. The large lobe, it may be noted, is much more spread than the original *p* orbital. This is due to the incorporation of the spherical character of the *s* orbital into

the resulting *sp* hybrid orbitals. The actual shape of an *sp* hybrid orbital is shown in Fig. 3. This clearly depicts the broader size of one of the lobes of the hybrid orbital. Wave mechanically, the shape of the *sp* hybrid orbital is obtained by plotting the hybrid orbital wave function in three-dimensional space. The wave function of the mixed (or hybrid) orbital is obtained by linearly combining the wave functions of pure atomic orbitals as illustrated in a subsequent section. The broader shape enables the hybrid orbital of one atom to bring about *a higher degree of overlapping* with the orbital of the other atom. The resulting bond is very strong since, the greater the degree of overlapping, the stronger is the bond.

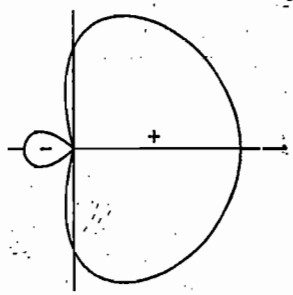

Fig. 3. The actual shape of an *sp* hybrid orbital.

In the formation of BeF_2 molecule, the half-filled p_z orbital of each fluorine atom overlaps with each of the two half-filled *sp* hybrid orbitals of the beryllium atom. In this electron-sharing process, each orbital contains two electrons and beryllium fluoride, BeF_2, results. This is represented in Fig. 4. As is clear from the figure, the overlap which leads to bonding has a + sign always.

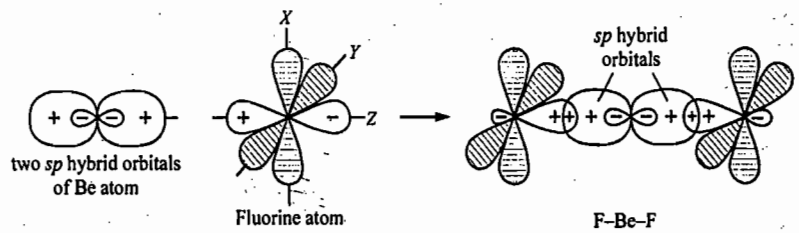

Fig. 4. Formation of beryllium fluoride molecule by overlapping of the half-filled $2p_z$ orbitals of flourine atoms with the two *sp* hybrid orbitals of beryllium atom. The shaded orbitals of fluorine are fully occupied.

sp^2 Hybridisation of Orbitals of Boron. As mentioned earlier, the outer electronic configuration of boron atom in its ground state is $2s^2\ 2p^1$. Promotion of one of the 2*s* electrons into one of the vacant 2*p* orbitals gives rise to an excited state configuration, *viz.*, $2s^1 p_z^1 p_x^1$. There are, thus, three half-filled orbitals which account for tri-covalency of boron. The three orbitals, *viz.*, *one* 2*s* and *two* 2*p* hybridise to give three hybrid orbitals of equivalent energy. The formation of sp^2 hybrid orbitals is shown in Fig. 5.

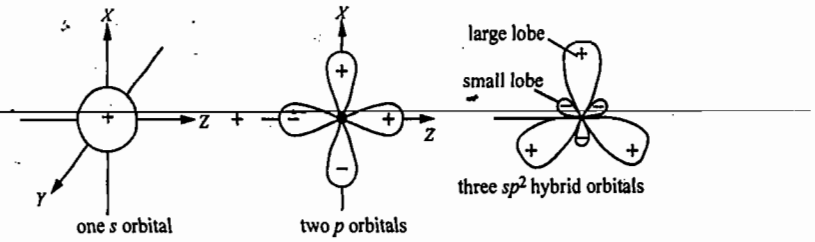

Fig. 5. Formation of three sp^2 hybrid orbitals by overlapping of one *s* and two *p* orbitals.

In the formation of **boron trifluoride molecule**, the half-filled p_z orbital of each fluorine atom

overlaps with each of the three half-filled sp^2 hybrid orbitals of the boron atom, as shown in Fig. 6.

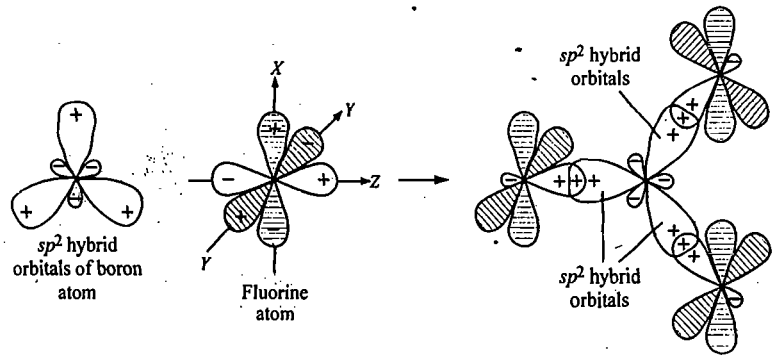

Fig. 6. Formation of boron trifluoride molecule by the overlapping of the half-filled p_z orbitals of three fluorine atoms with the three sp^2 hybrid orbitals of boron atom. The shaded orbitals of fluorine are fully occupied.

A large amount of energy is released during the formation of $sp^2 - p$ sigma bonds in BF_3 molecule. This is illustrated in Fig. 7. The amount of energy thus released is much more than the energy which might have been released if pure s and p orbitals of boron had overlapped with the half-filled p orbitals of fluorine atoms. This accounts for the greater stability of $sp^2 - p$ sigma bonds as compared to the stability of $s - p$ and $p - p$ sigma bonds.

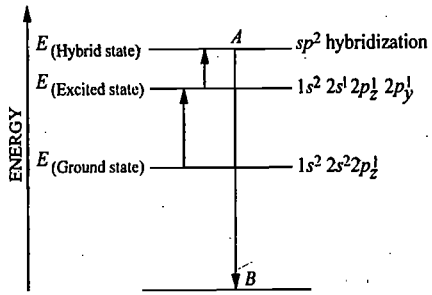

Fig. 7. Energy *required* (*i*) for the promotion of a $2s$ electron to a $2p$ orbital (*ii*) for the hybridisation of s and p orbitals to give sp^2 hybrid orbitals in case of boron atom and (*iii*) energy *released* (represented by *AB*) in the formation of covalent bonds involving sp^2 hybrid orbitals.

sp^3 Hybridisation of Orbitals of Carbon. As mentioned earlier, the outer electronic configuration of carbon atom in ground state is $2s^2 p_z^1 p_x^1$. Promotion of one of the $2s$ electrons into one of the vacant $2p$ orbitals due to the energy released in the formation of CH_4 molecule gives rise to excited state configuration, *viz.*, $2s^1 p_z^1 p_x^1 p_y^1$. There are now four half-filled orbitals which account for tetra-covalency of carbon. The four orbitals, *viz.*, *one s* and *three p*, hybridise to give four sp^3 hybrid orbitals of equivalent energy. The formation of sp^3 hybrid orbitals is shown in Fig. 8.

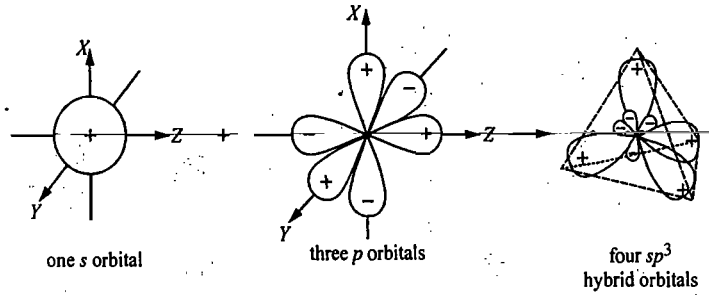

Fig. 8. Formation of four sp^3 hybrid orbitals by overlapping of one s and three p orbitals.

In the formation of **methane molecule,** the half-filled $1s$ orbital of each hydrogen atom overlaps with each of the four half-filled sp^3 hybrid orbitals of carbon atom, as shown in Fig. 9.

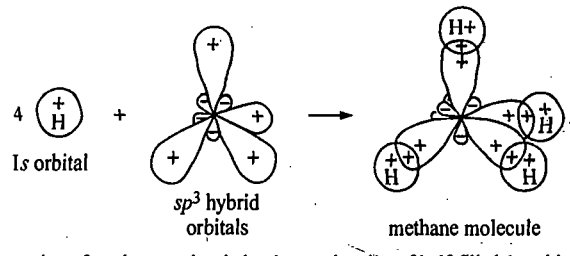

Fig. 9. Formation of methane molecule by the overlapping of half-filled $1s$ orbitals of four hydrogen atoms with the four sp^3 hybrid orbitals of carbon atom.

As before, a large amount of energy is released during the formation of $sp^3 - p$ sigma bonds. This is illustrated in Fig. 10.

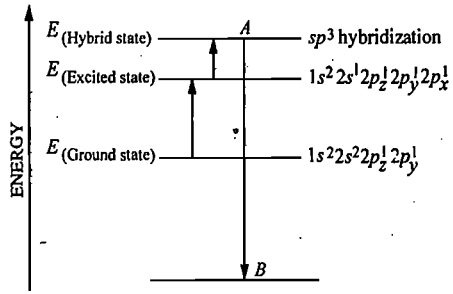

Fig. 10. Energy *required* (*i*) for the promotion of a $2s$ electron to a $2p$ orbital (*ii*) for the hybridisation of s and p orbitals to give sp^3 hybrid orbitals in case of carbon atom and (*iii*) energy *released* (*i.e.*, *AB*) in the formation of covalent bonds involving sp^3 hybrid orbitals.

The salient features of the concept of hybridisation may thus be summed up as follows.

1. One or more electrons from fully filled orbitals of the atom in the ground state, get promoted to the next available orbitals of higher energy (as, for example, from $2s$ to $2p$ orbitals in the case of second row elements and from ns to $(n-1)d$ orbitals in the case of transition elements), resulting in an excited state with appropriate number of half-filled orbitals. This process requires sufficient amount of energy. This energy becomes available as a result of the formation of the compounds from their respective elements. The orbitals in the excited state then undergo hybridisation giving hybrid orbitals of equivalent energy. The process of hybridisation, *i.e.*, mixing of orbitals, further requires some energy. The entire input of energy is, however, more than recovered when the hybrid orbitals combine with the orbitals of other atoms to form covalent bonds.

2. The number of hybrid orbitals formed is equal to the number of pure atomic orbitals which undergo hybridisation.

3. The energy released during covalent bond formation involving the hybrid orbitals is much more than the energy released if covalent bond formation involves the pure atomic orbitals. Therefore, the covalent bonds formed with hybrid orbitals are more stable than those formed with pure atomic orbitals.

4. Hybridisation necessarily involves atomic orbitals of the same atom.

5. Effective hybridisation occurs only when the orbitals undergoing hybridisation are of comparable energy.

6. Hybrid orbitals generally form either a sigma bond or contain a lone pair of electrons.

7. The hybrid orbitals are associated with higher energy than the pure atomic orbitals from which they are formed. The greater stability of bonds formed by the hybrid orbitals is due to *enhanced overlapping capacity* of such orbitals.

Shapes of Hybrid Orbitals. A reference to Figs. 2, 3, 5 and 8 indicates that the shapes of hybrid orbitals are different from those of the parent orbitals. For example, *s* orbital is spherical and *p* orbital is dumb-bell shaped and, thus, the shape of the bigger lobe of ***sp* hybrid orbital** which results from the mixing of one *s* and one *p* orbital, is different. It has the characteristics of both the mixing orbitals,and thus has an oval shape, as illustrated in Figs. 2 and 3. The bigger lobes of ***sp*^{2} hybrid orbitals** which result from the combination of one *s* and two *p* orbitals are pear-shaped because of the greater contribution of the two dumb-bell shaped *p* orbitals, as shown in Fig. 5. In the case of ***sp*^{3} hybrid orbitals** which result from the mixing of one *s* and three *p* orbitals, the contribution of the three *p*-orbitals predominates over the contribution of one *s* orbital. The resulting shape of their bigger lobes, therefore, is practically the same as that of the parent *p* orbitals except for the fact that the lobes in *sp*^{3} hybrid orbitals are somewhat more spread and are somewhat shorter in length than the pure *p* orbitals, as shown in Fig. 8. As can be seen, one lobe of the hybrid orbital in each type of hybridisation is considerably bigger in size than the other lobe. It is the bigger-sized lobe of the hybrid orbital of an atom which overlaps with the orbital of another atom to maximise the overlap to form a stable chemical bond.

Wave Functions for Hybrid Orbitals. We shall now illustrate the construction of wave functions for some common hybrid orbitals, namely, *sp*, *sp*^{2} and *sp*^{3} hybrid orbitals.

We shall first give **rules for constructing wave functions for hybrid orbitals.** These rules are :

1. The wave functions of hybrid orbitals are constructed by taking into consideration the linear combination of the wave functions of the appropriate AOs. Thus, the wave function of the *i*th hybrid orbital formed from *s* and *p* AOs is

$$\psi_i = a_i\phi_s + b_i\phi_{p_x} + c_i\phi_{p_y} + d_i\phi_{p_z}$$

where $\phi_s, \phi_{p_x}, \phi_{p_y}, \phi_{p_z}$ are the atomic orbital wave functions which constitute an *orthonormal* set. Two wave functions ϕ_m and ϕ_n are said to form an orthonormal set if

$$\int_{-\infty}^{+\infty} \phi_n\phi_n \, d\tau = 1, \quad \int_{-\infty}^{+\infty} \phi_m\phi_m \, d\tau = 1 \text{ and } \int_{-\infty}^{+\infty} \phi_m\phi_n \, d\tau = 0$$

The coefficients of wave functions a_i, b_i, c_i, d_i can be calculated by observing the following three conditions :

(*i*) Each wave function of a hybrid orbital is normalized, that is,

$\int_{-\infty}^{+\infty} \psi_i^2 \, d\tau = 1$. It can be shown that for such a normalised wave function ψ_i,

$$a_i^2 + b_i^2 + c_i^2 + d_i^2 = 1$$

(*ii*) Each hybrid orbital in the set of hybrid orbitals is orthogonal to the other hybrid orbitals, *i.e.*, $\int_{-\infty}^{+\infty} \psi_i \psi_j \, d\tau = 0$. From this relation, it can be shown that

$$a_i a_j + b_i b_j + c_i c_j + d_i d_j = 0$$

(*iii*) The squares of the coefficients of component wave functions which give contributions of the component wave functions to the hybrid orbital wave functions summed over all the hybrid orbitals wherein they participate, equal unity, *i.e.*,

$$\Sigma a_i^2 = 1$$

This is because the pure orbitals must be completely utilised in the formation of hybrid orbitals.

2. In order to obtain the equivalent hybrid orbitals, we specify a cartesian co-ordinate system and place one of the *i*th hybrid orbitals along one co-ordinate axis (usually +Z axis) and as many of other hybrid orbitals as possible in the plane containing this axis and the other co-ordinate axis (usually XZ plane). This simplifies the procedure for (*i*) constructing wave functions for hybrid orbitals (*ii*) for calculating angles between hybrid orbitals and (*iii*) for determining orientations of hybrid orbitals in space around the central atom.

3. Since the *s* orbital is spherically symmetric, each equivalent hybrid orbital of a set contains $1/\sqrt{n}$ of the *s* orbital distributed in *n* hybrid orbitals, that is, the coefficient of ϕ_s in each hybrid orbital is $1/\sqrt{n}$.

Problem 1. Construct the wave functions for the *sp* hybrid orbitals.

Procedure. Since one of the *sp* hybrid orbitals is to be placed along the +Z axis, we shall invoke the hybridisation of *s* and p_z orbitals. The wave functions for the two *sp* hybrid orbitals are :

$$\psi_1 = a_1\phi_s + b_1\phi_{p_z} \quad ...(i)$$

$$\psi_2 = a_2\phi_s + b_2\phi_{p_z} \quad ...(ii)$$

Since the *s* orbital is equally distributed between the two hybrid orbitals and since the square of the coefficient of a wave function gives its contribution to the hybrid orbital, we have

$$a_1^2 = a_2^2 = 1/2$$

$$\therefore \quad a_1 = a_2 = 1/\sqrt{2}$$

Since ψ_1 is normalized, we have

$$\int \psi_1^2 d\tau = \int (a_1\phi_s + b_1\phi_{p_z})^2 d\tau$$

$$= a_1^2 \int \phi_s^2 d\tau + b_1^2 \int \phi_{p_z}^2 d\tau + 2a_1b_1 \int \phi_s\phi_{p_z} d\tau = 1$$

Since the atomic orbital wave functions are orthogonal and individually normalized, we have

$$\int \psi_1^2 d\tau = a_1^2(1) + b_1^2(1) + 2a_1b_1(0) = a_1^2 + b_1^2 = 1$$

Since $a_1 = 1/\sqrt{2}$, hence $b_1 = 1/\sqrt{2}$.

Again, since ψ_1 and ψ_2 are orthogonal,

$$a_1a_2 + b_1b_2 = 0$$

Substituting for a_1, a_2 and b_1, we have

$$(1/\sqrt{2})\ (1/\sqrt{2}) + (1/\sqrt{2})b_2 = 0. \text{ Hence } b_2 = -1/\sqrt{2}$$

Thus, from Eqs. (*i*) and (*ii*), the two ***sp* hybrid orbital wave functions** are :

$$\psi_1 = (1/\sqrt{2})\ (\phi_s + \phi_{p_z})$$

$$\psi_2 = (1/\sqrt{2})\ (\phi_s - \phi_{p_z})$$

Problem 2. Derive the wave functions for the *sp*^{2} hybrid orbitals.

Procedure. Since one of the *sp*^{2} hybrid orbitals is to be placed along the +*Z* axis, we shall invoke the hybridisation of *s*, p_z and p_x orbitals so that the resulting hybrid orbitals are in the *XZ* plane. The

wave functions for the three sp^2 hybrid orbitals are :

$$\psi_1 = a_1\phi_s + b_1\phi_{p_z} + c_1\phi_{p_x} \quad ...(i)$$

$$\psi_2 = a_2\phi_s + b_2\phi_{p_z} + c_2\phi_{p_x} \quad ...(ii)$$

$$\psi_3 = a_3\phi_s + b_3\phi_{p_z} + c_3\phi_{p_x} \quad ...(iii)$$

Since the s orbital is equally distributed among the three hybrid orbitals, we have

$$a_1^2 = a_2^2 = a_3^2 = \frac{1}{3}$$

$$\therefore \quad a_1 = a_2 = a_3 = 1/\sqrt{3}$$

Assuming that ψ_1 is pointed towards the +Z-axis, this hybrid orbital will have contribution from s and p_z orbitals only. The contribution of p_x orbital in this case will, therefore, vanish, *i.e.*, $c_1 = 0$.

Now, since ψ_1 is normalized, we have

$$a_1^2 + b_1^2 + c_1^2 = 1 \text{ so that } a_1^2 + b_1^2 = 1 \quad (\because c_1 = 0)$$

Since $a_1 = 1/\sqrt{3}$, we find that $b_1 = (2/3)^{1/2}$

The requirement of orthogonality condition for ψ_1, ψ_2 and ψ_3 gives

$$a_1a_2 + b_1b_2 + c_1c_2 = 0$$

or $$a_1a_2 + b_1b_2 = 0$$

and $$a_1a_3 + b_1b_3 + c_1c_3 = 0$$

or $$a_1a_3 + b_1b_3 = 0$$

Hence, $b_2 = -a_1a_2/b_1 = -(1/\sqrt{3})\ (1/\sqrt{3})/\sqrt{2}/3 = -1/\sqrt{6}$

$$b_3 = -a_1a_3/b_1 = -(1/\sqrt{3})\ (1/\sqrt{3})/\sqrt{2}/3 = -1/\sqrt{6}$$

Again, since ψ_2 is normalized, we have

$$a_2^2 + b_2^2 + c_2^2 = 1$$

$$\therefore \quad c_2^2 = 1 - (a_2^2 + b_2^2) = 1 - (1/3 + 1/6) = 1/2$$

$$\therefore \quad c_2 = \pm 1/\sqrt{2}$$

The normalization requirement of ψ_3 gives

$$a_3^2 + b_3^2 + c_3^2 = 1$$

$$\therefore \quad c_3^2 = 1 - (a_3^2 + b_3^2) = 1 - (1/3 + 1/6) = 1/2$$

$$\therefore \quad c_3 = \pm 1/\sqrt{2}$$

If we choose positive root for c_2, we shall have to choose negative root for c_3 so that ψ_2 and ψ_3 fulfil the condition of orthogonality, *i.e.*, $a_2a_3 + b_2b_3 + c_2c_3 = 0$. Thus, if c_2 is $+\sqrt{1/2}$, c_3 is $-\sqrt{1/2}$.

Thus, the three sp^2 **hybrid orbital wave functions** are

$$\psi_1 = 1/\sqrt{3}\ \phi_s + \sqrt{2/3}\ \phi_{p_z}$$

$$\psi_2 = 1/\sqrt{3}\ \phi_s - 1/\sqrt{6}\ \phi_{p_z} + 1/\sqrt{2}\ \phi_{p_x}$$

$$\psi_3 = 1/\sqrt{3}\ \phi_z - 1/\sqrt{6}\ \phi_{p_z} - 1/\sqrt{2}\ \phi_{p_x}$$

Problem 3. Construct the wave functions for the sp^3 hybrid orbitals.

Procedure. The four sp^3 hybrid orbitals are :

$$\psi_1 = a_1\phi_s + b_1\phi_{p_z} + c_1\phi_{p_x} + d_1\phi_{p_y} \quad ...(i)$$

$$\psi_2 = a_2\phi_s + b_2\phi_{p_z} + c_2\phi_{p_x} + d_2\phi_{p_y} \quad ....(ii)$$

$$\psi_3 = a_3\phi_s + b_3\phi_{p_z} + c_3\phi_{p_x} + d_3\phi_{p_y} \quad ...(iii)$$

$$\psi_3 = a_4\phi_s + b_4\phi_{p_z} + c_4\phi_{p_x} + d_4\phi_{p_y} \quad ...(iv)$$

Since the s orbital is equally distributed among the four hybrid orbitals, we have

$$a_1^2 = a_2^2 = a_3^2 = a_4^2 = 1/4$$

$$a_1 = a_2 = a_3 = a_4 = 1/\sqrt{4} = 1/2$$

Assuming that ϕ_1 is developed along the +Z-axis, this hybrid orbital will have contribution from s and p_z orbitals only. The contributions of ϕ_{p_x} and ϕ_{p_y} orbitals in this case will, therefore, vanish so that we can write

$$c_1 = d_1 = 0$$

Since ψ_1 is normalized, we have

$$a_1^2 + b_1^2 + c_1^2 + d_1^2 = 1$$

or $$a_1^2 + b_1^2 = 1 \quad (\because c_1 = d_1 = 0)$$

$$\therefore \quad b_1 = \sqrt{1 - a_1^2} = \sqrt{1 - (1/4)} = \sqrt{3}/2$$

The requirement of orthogonality condition for ψ_1 and ψ_2 ; ψ_1 and ψ_3 and ψ_1 and ψ_4, gives

$$a_1a_2 + b_1b_2 + c_1c_2 + d_1d_2 = 0 \quad (\because c_1 = d_1 = 0)$$

or $$a_1a_2 + b_1b_2 = 0$$

$$a_1a_3 + b_1b_3 + c_1c_3 + d_1d_3 = 0$$

or $$a_1a_3 + b_1b_3 = 0$$

$$a_1a_4 + b_1b_4 + c_1c_4 + d_1d_4 = 0$$

or $$a_1a_4 + b_1b_4 = 0$$

Hence,

$$b_2 = b_3 = b_4 = -a_1a_2/b_1 = -a_1a_3/b_1 = -a_1a_4/b_1$$

$$= -(1/2)\ (1/2)/\sqrt{3}/2 = -1/2\sqrt{3}$$

Assuming that ψ_2 lies in the XZ plane, the hybrid orbital will have contribution from s, p_z and p_x orbitals only. The contribution of p_y to ϕ_2 would be zero so that $c_2 = 0$..

The normalization requirement for ϕ_2 gives

$$a_2^2 + b_2^2 + c_2^2 + d_2^2 = 1$$

or $$a_2^2 + b_2^2 + d_2^2 = 1 \quad (\because c_2 = 0)$$

or $$d_2^2 = 1 - (a_2^2 + b_2^2) = 1 - (1/4 + 1/12) = 2/3$$

$$\therefore \quad d_2 = \sqrt{2/3}$$

The requirement of orthogonality condition for ϕ_2 and ϕ_3 and for ϕ_2 and ϕ_4 gives

$$a_2a_3 + b_2b_3 + c_2c_3 + d_2d_3 = 0$$

or

$$a_2a_3 + b_2b_3 + d_2d_3 = 0$$

$$a_2a_4 + b_2b_4 + c_2c_4 + d_2d_4 = 0$$

or

$$a_2a_4 + b_2b_4 + d_2d_4 = 0$$

Hence,

$$d_3 = d_4 = -(a_2a_3 + b_2b_3)/d_2$$

or

$$-(a_2a_4 + b_2b_4)/d_2 = -(1/4+1/12)/\sqrt{2/3} = -1/\sqrt{6}$$

The normalization requirement for ϕ_3 gives

$$a_3^2 + b_3^2 + c_3^2 + d_3^2 = 1$$

$$c_3^2 = 1-(a_3^2 + b_3^2 + d_3^2)$$

$$= 1 - (1/4 + 1/12 + 1/6) = 1/2$$

$$\therefore \quad c_3 = +1/\sqrt{2}$$

Proceeding as above, the normalization requirement for ϕ_4 and orthogonality condition for ϕ_3 and ϕ_4 gives $c_4 = -1/\sqrt{2}$

Hence, the four sp^3 **hybrid orbital wave functions** are :

$$\psi_1 = 1/2\phi_s + \sqrt{3}/2\phi_{p_z}$$

$$\psi_2 = 1/2\phi_s - 1/2\sqrt{3}\phi_{p_z} + \sqrt{2/3}\phi_{p_x}$$

$$\psi_3 = 1/2\phi_s - 1/2\sqrt{3}\phi_{p_z} + 1/\sqrt{2}\phi_{p_y} - 1/\sqrt{6}\phi_{p_x}$$

$$\psi_4 = 1/2\phi_s - 1/2\sqrt{3}\phi_{p_z} - 1/\sqrt{2}\phi_{p_y} - 1/\sqrt{6}\phi_{p_x}$$

Orientation of Hybrid Orbitals in Space

The directional characteritsitcs of atomic orbitals of central atom A in the compound AX_n get uniformly distributed in the hybrid orbitals involved in the formation of the compound. Therefore, *the arrangement of hybrid orbitals around A is an automatic consequence of the hybridisation of its atomic orbitals.* This point will become clear from the following discussion.

It follows from the discussion on the topic Angular Wave Functions and Shapes of Orbitals, given in Chapter 1, that the *s* and *p* orbital wave functions of A are :

$$\phi_s = \frac{1}{2\sqrt{\pi}} R(r)_{n,0}$$

$$\phi_{p_x} = \frac{3}{2\sqrt{\pi}} \sin\theta \cos\phi \; R(r)_{n,1}$$

$$\phi_{p_y} = \frac{3}{2\sqrt{\pi}} \sin\theta \sin\phi \; R(r)_{n,1}$$

$$\phi_{p_z} = \frac{3}{2\sqrt{\pi}} \cos\theta \; R(r)_{n,1}$$

For most efficient hybridisation (*i.e.*, mixing) of atomic orbitals of the central atom A, the hybrid orbital wave functions should be maximised by putting their first differential $\partial\psi/\partial\theta$ equal to zero. Let us now consider the wave functions of the various types of hybrid orbitals.

1. Consider the wave function ψ_1 of one of the *sp* hybrid orbitals. As illustrated earlier in Problem 1,

$$\psi_1 = \frac{1}{\sqrt{2}}\phi_s + \frac{1}{\sqrt{2}}\phi_{p_z}$$

In terms of polar coordinates, the above function becomes

$$\psi_1 = \frac{1}{\sqrt{2}} \times \frac{1}{2\sqrt{\pi}} R(r)_{n,0} + \frac{1}{\sqrt{2}} \times \frac{3}{2\sqrt{\pi}} \cos\theta \, R(r)_{n,1}$$

Applying conditions for maximising ψ_1, we get

$$\frac{\partial\psi_1}{\partial\theta} = 0 = 0 + \frac{1}{\sqrt{2}} \times \frac{3}{2\sqrt{\pi}} (-\sin\theta) R(r)_{n,1}$$

or $\sin\theta = 0$ so that $\theta = \mathbf{0°}$ or $\mathbf{180°}$

We get exactly the same result when we consider the wave function ψ_2 of the second *sp* hybrid orbital.

Under the maximising condition, θ is the angle which the directions of the hybrid orbitals ψ_1 and ψ_2 make with +*Z* axis. This automatically means that one of the *sp* hybrid orbitals is aligned along the +*Z* axis (for $\theta = 0$) and the other orbital is aligned along the –*Z* axis (for $\theta = 180°$) so that the angle between the two *sp* hybrid orbitals is 180° (Fig. 2.)

2. Consider the wave functions for the sp^2 hybrid orbitals. If the atomic orbitals invovled in sp^2 hybridisation are *s*, p_z and p_x, then all the three resulting hybrid orbitals would be in the *XZ* plane. Suppose one of the hybrid orbitals with wave function ψ_1 lies along the +*Z* axis. Then, as illustrated above in Problem 2, the wave function ψ_2 of the second hybrid orbital lying in the plane *XZ* would be given by

$$\psi_2 = \frac{1}{\sqrt{3}}\phi_s - \frac{1}{\sqrt{6}}\phi_{p_z} + \frac{1}{\sqrt{2}}\phi_{p_x}$$

In terms of polar coordinates, ψ_2 takes the form,

$$\psi_2 = \frac{1}{\sqrt{3}} \times \frac{1}{2\sqrt{\pi}} R(r)_{n,0} - \frac{1}{\sqrt{6}} \times \frac{3}{2\sqrt{\pi}} \cos\theta \, R(r)_{n,1} + \frac{1}{\sqrt{2}} \times \frac{3}{2\sqrt{\pi}} \sin\theta \cos\phi \, R(r)_{n,1}$$

The angle ϕ for any orbital in *XZ* plane is 0° so that $\cos\phi = 1$. (ϕ is the angle which the direction of the hybrid orbital makes with +*Z* axis, as shown in Fig. 11)

$$\therefore \quad \psi_2 = \frac{1}{\sqrt{3}} \times \frac{1}{2\sqrt{\pi}} R(r)_{n,0} - \frac{1}{\sqrt{6}} \times \frac{3}{2\sqrt{\pi}} \cos\theta \, R(r)_{n,1} + \frac{1}{\sqrt{2}} \times \frac{3}{2\sqrt{\pi}} \sin\theta \, R(r)_{n,1}$$

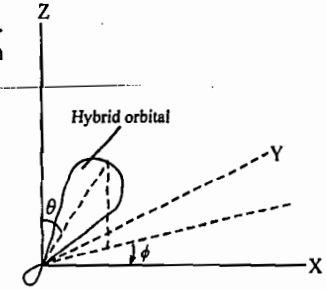

Fig. 11. Polar coordinates θ and ϕ of an sp^2 hybrid orbital.

Applying conditions for maximising ψ_1, we get

$$\frac{\partial\psi_2}{\partial\theta} = 0 = 0 + \frac{1}{\sqrt{6}} \times \frac{3}{2\sqrt{\pi}} \sin\theta\, R(r)_{n,1} + \frac{1}{\sqrt{2}} \times \frac{3}{2\sqrt{\pi}} \cos\theta\, R(r)_{n,1}$$

or $$\tan\theta = -\sqrt{3} \text{ so that } \theta = \mathbf{120°}$$

That is, the second sp^2 hybrid orbital in XZ plane is making an angle of 120° with the $+Z$ axis and hence with the first sp^2 hybrid orbital.

Similarly, $$\psi_3 = \frac{1}{\sqrt{3}}\phi_s - \frac{1}{\sqrt{6}}\phi_{p_z} - \frac{1}{\sqrt{2}}\phi_{p_x}$$

This function in polar coordinates becomes

$$\psi_3 = \frac{1}{\sqrt{3}} \times \frac{1}{2\sqrt{\pi}} R(r)_{n,0} - \frac{1}{\sqrt{6}} \times \frac{3}{2\sqrt{\pi}} \cos\theta\, R(r)_{n,1} - \frac{1}{\sqrt{2}} \times \frac{3}{2\sqrt{\pi}} \sin\theta \cos\phi\, R(r)_{n,1}$$

Applying the condition for maximising ψ_3 and simplifying the resulting equation, we get

$$\tan\theta = \sqrt{3} \text{ so that } \theta = \mathbf{240°}$$

Thus, the third sp^2 hybrid orbital in XZ plane makes an angle of 240° with the $+Z$ axis and hence with the first sp^2 hybrid orbital. Accordingly, the angle between the second and the third sp^2 hybrid orbitals is also 120° (Fig. 5)

3. Let us now consider the wave functions for the sp^3 hybrid orbitals. One of the hybrid orbitals is supposed to be lying along the +Z axis. Let us find out the angle which any other sp^3 hybrid orbital makes with the +Z axis and hence with the first sp^3 hybrid orbital. Let ψ_2 be the wave function for the second sp^3 hybrid orbital. Then, as illustrated above in Problem 3,

$$\psi_2 = \frac{1}{2}\phi_s - \frac{1}{2\sqrt{3}}\phi_{p_z} + \sqrt{\frac{2}{3}}\phi_{p_x}$$

Since this hybrid orbital utilises p_z and p_x atomic orbitals for hybridisation, it would lie in the XZ plane.

ψ_2, in terms of polar coordinate system, transforms as

$$\psi_2 = \frac{1}{2} \times \frac{1}{2\sqrt{\pi}} R(r)_{n,0} - \frac{1}{2\sqrt{3}} \times \frac{3}{2\sqrt{\pi}} \cos\theta\, R(r)_{n,1} + \sqrt{\frac{2}{3}} \times \frac{3}{2\sqrt{\pi}} \sin\theta \cos\phi\, R(r)_{n,1}$$

Since the hybrid orbital is in XZ plane, the angle ϕ is zero so that $\cos\phi = 1$.

Applying the condition for maximising ψ_2, we get

$$\frac{\partial\psi_2}{\partial\theta} = 0 = 0 + \frac{1}{2\sqrt{3}} \times \frac{3}{2\sqrt{\pi}} \sin\theta\, R(r)_{n,1} + \sqrt{\frac{2}{3}} \times \frac{3}{2\sqrt{\pi}} \cos\theta\, R(r)_{n,1}$$

or $$\frac{1}{2\sqrt{3}} \sin\theta = -\sqrt{\frac{2}{3}} \cos\theta$$

or $$\frac{\sin\theta}{\cos\theta} = \tan\theta = -\sqrt{\frac{2}{3}} \times 2\sqrt{3} = -2\sqrt{2}$$

$\therefore$ $$\theta = \mathbf{109° 28'}$$

Thus, the second sp^3 hybrid orbital makes an angle of 109° 28′ with the $+Z$ axis and hence with the first sp^3 hybrid orbital. We can similarly show that the angle between the first and the third hydrid orbital as also between the first and the fourth sp^3 hybrid orbital is 109°28′. Thus, the sp^3 hybrid orbitals are tetrahedrally spread around the central atom (Fig. 8).

Following the same procedure as discussed above, we can show that the arrangement of dsp^3 hybrid orbitals around the central atom is trigonal pyramidal while that of d^2sp^3 hybrid orbitals is octahedral and so on.

It is clear from the above discussion that the concept of hybridisation alone is sufficient to fix the arrangement of hybrid orbitals in space around the central atom.

VSEPR Theory

We have seen that in the formation of simple covalent molecules, there is one central atom which forms covalent bonds with other atoms. For example, in the formation of a molecule of water, the central atom is oxygen which forms *two* covalent bonds with two hydrogen atoms (*i.e.*, one bond with each hydrogen atom). Similarly, in the formation of a molecule of ammonia, the central atom is nitrogen which forms *three* covalent bonds with three hydrogen atoms and in the formation of a molecule of methane, the central atom is carbon which forms *four* covalent bonds with four hydrogen atoms and so on.

According to the **valence shell electron pair repulsion theory (VSEPR theory)**, the geometry of a covalent compound depends upon the number and arrangement in space of electron pairs present in the valency shell of the central atom. This number is *half* of the summation of electrons present in the valence shell of the central atom and the electrons contributed by the combining atoms. Thus, in the case of H_2O molecule, the number of electron pairs present around the oxygen atom would be $\frac{1}{2}(6+2)$ and in the case of PCl_5 molecule, this number would be $\frac{1}{2}(5+5)$ and so on. These electron pairs occupy the available orbitals around the central atom, each orbital accommodating only one electron pair. These electron pairs experience electrostatic repulsion from one another. Such electron pairs, therefore, tend to keep apart from one another as far as possible so that they may experience minimum electrostatic repulsion. This would result in minimum energy and maximum stability of the molecule.

The charge of a lone pair of electrons is more spread around the central atom than the charge of a bond pair of electrons with the result that the distance between charges of two lone pairs of electrons on the central atom is less than the distance between the charges of a lone pair and a bond pair of electrons which, in turn, is less than the distance between the charges of two bond pairs of electrons. Hence the electrostatic repulsion between lone pair–lone pair of electrons is greater than the repulsion between lone pair–bond pair of electrons which, in turn, is greater than the repulsion between bond pair–bond pair of electrons. Since the repulsion between electron pairs recedes very rapidly with distance between the centres of charges of electron pairs, therefore, in molecules which are capable of existing in more than one geometries, the most stable geometry is determined by assuming that the electrostatic repulsion between any two electron pairs is taken to be negligibly small if the angle between them is more than about 100°.

The VSEPR theory, however, has a weak theoretical basis and is associated with some snags. For instance, if in a compound AX_2, there are two electron pairs around the central atom, one pair would be in the *s* orbital and the other pair would be in the *p* orbital. In the compound AX_2, therefore, the two A–X bonds would be non-equivalent. This is evidently a wrong conclusion. For instance, both the Be – F bonds in BeF_2 molecule are equivalent.

However, we can explain the geometry of molecules more satisfactorily if we assume, before applying principles of VSEPR theory, that in the formation of covalent compounds, the orbitals (containing electron pairs) present around the central atom *undergo hybridisation* before entering into covalent bond

formation with other atoms. Thus, the VSEPR theory would lead to correct conclusions only in combination with the concept of hybridisation. The combination of the two concepts helps us to predict correctly the geometry of covalent molecules. This aspect has been discussed below in adequate details.

GEOMETRY OF COVALENT MOLECULES

We shall first discuss the geometry of molecules in which the central atom has no lone pair of electrons in any of its hybrid orbitals. In such cases if only two electron pairs are present around the central atom, they would be accommodated in the two *sp* hybrid orbitals of equal energy obtained by the hybridisation of *s* and p_z orbitals of the central atom. For minimum energy and maximum stability, these hybrid orbitals arrange themselves at an angle of 180° to each other. The molecule (AB_2) in such a case is thus **linear** and the bond angle is 180°.

If there are three electron pairs around the central atom, they would be accommodated in the three sp^2 hybrid orbitals obtained by the hybridisation of one *s* and two *p* orbitals of the central atom. According to the VSEPR theory, these orbitals are arranged at an angle of 120° to one another. The molecule (AB_3) in such a case is **planar trigonal** and the bond angle is 120°.

If there are four electron pairs around the central atom, they would occupy the four sp^3 hybrid orbitals of the central atom which according to the VSEPR theory are directed towards the four corners of a regular tetrahedron. The molecule (AB_4) in such a case is, therefore, **tetrahedral** and the bond angle is 109·5°.

It can thus be argued that if there are five electron pairs around the central atom, the hybrid orbitals around the central atom containing the electron pairs would be sp^3d hybridised and the molecule (AB_5) adopts **trigonal bipyramidal** geometry. In this geometry, all the bond angles are not equal. Three of the hybrid orbitals are in the same plane at an angle of 120° to one another and form, what are known as, **equatorial bonds.** Of the remaining two hybrid orbitals, one lies above and the other lies below the plane of the equatorial bonds. These orbitals form, what are known as, **axial bonds.** Thus, in this arrangement, the bond angles between equatorial bonds are of 120° each and the bond angles between axial bonds are of 90° each.

If there are six electron pairs around the central atom, the molecule (AB_6) utilises sp^3d^2 hybrid orbitals of the central atom and has **octahedral** geometry. The angles between any two of the six hybrid orbitals are 90° each. Similarly, if there are seven electron pairs around the central atom, the molecule (AB_7) utilises sp^3d^3 hybrid orbitals of the central atom and has **pentagonal bipyramidal** geometry. Like trigonal bipyramidal geometry, all the bond angles in this case also are not equal. Five of the hybrid orbitals are in the same plane at an angle of 72° to one another while the remaining two (one above and one below the plane) are at 90° to the plane.

From the above discussion it is evident that *the geometry of a covalent molecule depends upon the type of hybridisation which the orbitals around the central atom undergo.* If the valency shell orbitals of the central atom containing only shared pairs of electrons undergo *sp* hybridisation, the molecule is *linear*, if they undergo sp^2 hybridisation, the molecule is plane triangular and if they undergo sp^3 hybridisation, the molecule has a *tetrahedral* geometry and so on.

Regular and Irregular Geometry. It may be noted that if the central atom A of a molecule AB_x is surrounded by hybrid orbitals containing only shared pairs of electrons, *i.e., bond pairs* and there are no hybrid orbitals containing lone pairs in the valency shell, the molecule has a **regular geometry.** There is no distortion of the shape. If, however, the central atom is surrounded also by one or more hybrid orbitals containing lone pairs of electrons in the valency shell, the geometry of the molecule is **distorted** to some extent. This is because the repulsive interactions between lone pair–lone pair, lone pair–bond pair and bond pair–bond pair are different. We know that the bond pair between two atoms is under the influence of two nuclei and most of the electron charge cloud is oriented between them. On

the other hand, the lone pair of electrons is under the influence of only one nucleus and, therefore, its electron charge cloud is spread out and tends to occupy more space. For example, in the case of **ammonia**, there are three bond pairs and one lone pair (Fig. 12). Since the lone pair occupies more space around the central atom, it can interact more and, therefore, it will repel the electron pairs in the neighbouring orbitals more strongly whereas the repulsive interactions between the two bond pairs will be less. Thus, it may be concluded that the lone pair–lone pair repulsion is greater than the lone pair–bond pair repulsion which, in turn, is greater than the bond pair–bond pair repulsion, *i.e.,*

Lone pair–Lone pair Repulsion > Lone pair–Bond pair Repulsion > Bond pair–Bond pair Repulsion

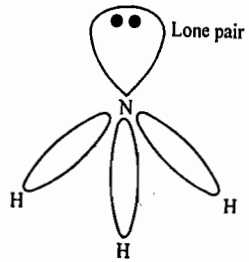

Fig. 12. Lone pair and bond pairs in ammonia molecule.

Accordingly, the presence of one or more hybrid orbitals with lone pairs of electrons has the effect of altering the bond angles to some extent. The molecules now do not retain any regular geometry (such as triangular, tetrahedral, etc.) This type of behaviour is met with, for example, in ammonia and water molecules (Figs. 22 and 23).

We shall now discuss the geometry of some typical covalent molecules resulting from different types of hybridisation of their valence shell orbitals.

Geometry of Molecules Containing only Bond Pairs of Electrons

1. Geometry of beryllium fluoride molecule involving *sp* hybrid orbitals of Be. Beryllium atom, in ground state, has electronic configuration $1s^2\,2s^2$, as shown in Fig. 13(*a*). It has no unpaired electron and, therefore, should be chemically inert. However, in the excited state, it has two unpaired electrons, as represented in Fig. 13(*b*). Beryllium atom can, therefore, form two covalent bonds as, for example, with fluorine atoms to give a molecule of beryllium fluoride, F–Be–F. Since both the bonds are of equal strength, it follows that *s* and *p* orbitals hybridise to give two *sp* hybrid orbitals of equivalent energy. These hybrid orbitals must lie as far apart from each other as possible in order to minimise the force of repulsion between them and thus to have a stable structure. Hence, the two hybrid orbitals point in opposite directions, as shown in Fig. 13. The molecule is, therefore, linear and the F–Be–F bond angle is equal to 180°.

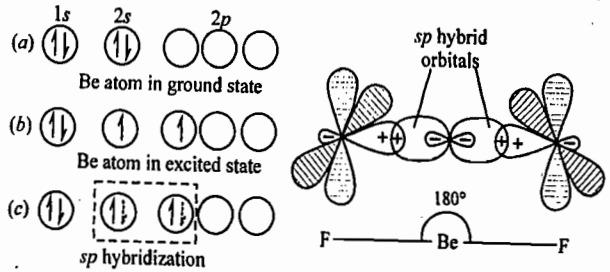

Fig. 13. Linear beryllium fluoride molecule resulting from *sp* hybridisation of valence shell orbitals of the central Be atom. Dotted arrows represent electrons supplied by fluorine atoms.

The molecules such as BeH_2, $BeCl_2$, $ZnCl_2$, $HgCl_2$, etc., have similar geometry.

2. Geometry of boron trifluoride molecule involving sp^2 hybrid orbitals of B atom. The electronic configuration of the central atom, boron, in ground state is $1s^2\,2s^2\,2p^1$. This is shown in Fig. 14(*a*). It has only one unpaired electron and, therefore, it can form only one covalent bond. In the excited state, however, it has three unpaired electrons, as represented in Fig. 14(*b*).

Evidently, now three covalent bonds can be formed, as, for example, with fluorine atoms, giving a molecule of boron trifluoride, BF_3. Since all the three B – F bonds are known to be equivalent, it follows

that the s and p orbitals of boron hybridise to give three sp^2 hybrid orbitals of equivalent energy. According to the VSEPR theory, the three sp^2 hybrid orbitals should be held at an angle of 120° to one another. This arrangement would lower the force of repulsion between electron pairs to the minimum. Since these three hybrid orbitals overlap with orbitals of three fluorine atoms, each F–B–F bond angle would be equal to 120° and the molecule would, therefore, be **trigonal planar**, as shown in Fig. 14.

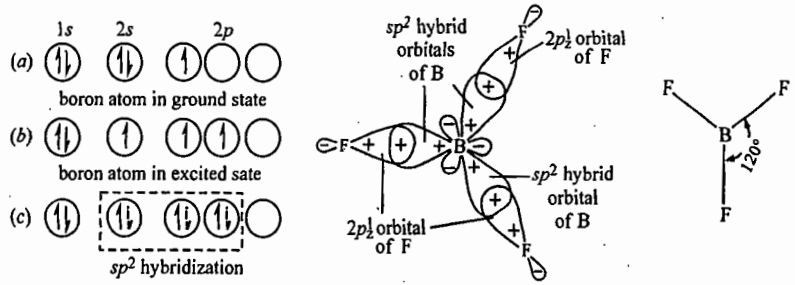

Fig. 14. Trigonal planar molecule of boron trifluoride resulting from sp^2 hybridisation of valence shell orbitals of the central boron atom. Dotted arrows represent electrons supplied by fluorine atoms.

Molecules such as BH_3, BCl_3, etc., have similar geometry.

3. Geometry of methane molecule involving sp^3 hybrid orbitals of C atom. The electronic configuration of carbon atom (the central atom in this case) is $1s^2 2s^2 2p_x^1 2p_y^1$, as shown in Fig. 15(*a*). It has only two unpaired electrons and hence it can form only two covalent bonds. In the excited state, however, it has four unpaired electrons, as represented in Fig. 15(*b*) and, therefore, it can form four covalent bonds with hydrogen atoms to give a molecule of methane. Since all the four C–H bonds are known to be exactly equivalent, it is evident that the s and p orbitals hybridise to give four sp^3 hybrid orbitals of equivalent energy. The orientation of these orbitals should be such as to have minimum repulsion between them. This is possible if the orbitals are directed towards the four corners of a regular tetrahedron. Thus, methane molecule has **tetrahedral geometry**, as shown in Fig. 15. The carbon atom is at the centre of the tetrahedron and four hydrogens are at the four corners. The H–C–H bond angle is 109·5°.

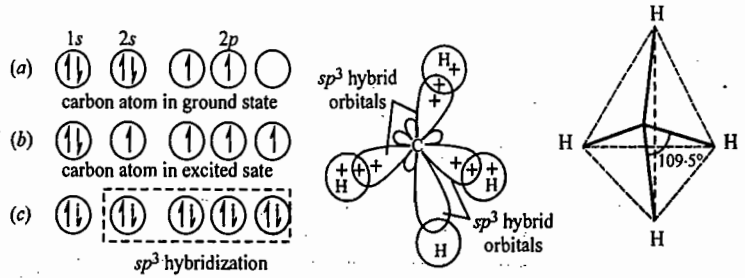

Fig. 15. Tetrahedral molecule of methane resulting from sp^3 hybridisation of valence shell orbitals of the central carbon atom. Dotted arrows represent electrons supplied by hydrogen atoms.

Molecules such as CCl_4, SiF_4 etc., have similar geometry.

4. Geometry of phosphorus pentafluoride molecule involving sp^3d hybrid orbitals of P atom. The outer electronic configuration of phosphorus, the central atom in this case, is $3s^2\ 3p^3$ which may be represented as in Fig. 16(*a*), in accordance with the Hund's rule.

As can be seen from Fig. 16(*a*), phosphorus in its ground state has only three unpaired electrons in the valency shell. Two more unpaired electrons should be made available in order to explain the formation of PF_5. This happens by the unpairing of electrons in the 3s orbitals by the excitation of the atom, as shown in Fig. 16(*b*).

Now five orbitals are available for chemical combination which permit the formation of five covalent bonds with five fluorine atoms to give PF_5 molecule, as shown in Fig. 16 (*d*). These orbitals hybridise to form five sp^3d hybrid orbitals. The d orbital used in sp^3d hybridisation is $3d_{z^2}$. It may be noted that all the five hybridised orbitals are not equivalent. Three of these are oriented towards the three corners of an equilateral triangle making an angle of 120° between them. The bonds formed by these orbitals are called *equatorial bonds*. These three orbitals are planar, as shown. The remaining two orbitals are oriented at right angles to the plane of the first set of three orbitals, as shown in the figure. The bonds formed by these orbitals are called *axial bonds*. Phosphorus pentafluoride thus, has a **trigonal bipyramidal** geometry (Table 1), as shown in Fig. 16. In this molecule, therefore, while the bond angles between equatorial bonds are of 120° each, the bond angles between axial and equatorial bonds are of 90° each. Such unsymmetrical structures are not stable. Consequently, PF_5 is a very reactive molecule.

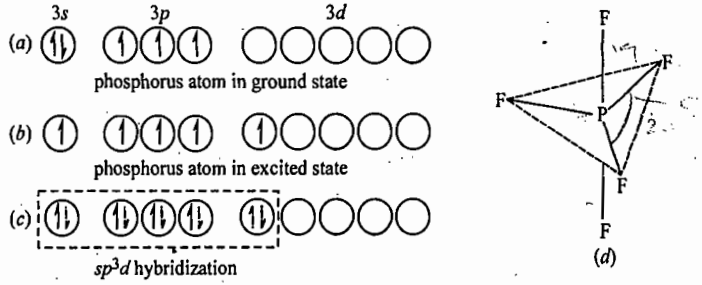

Fig. 16. Trigonal bipyramidal geometry of PF_5 molecule resulting from sp^3d hybridisation of valence shell orbitals of the central P atom. Dotted arrows represent electrons supplied by fluorine atoms.

It has been observed that in trigonal bipyramidal geometry, the axial bonds are slightly longer than the equatorial bonds. This is because of the fact that axial bonds experience greater repulsion from other bonds than the equatorial bonds. The electron pair repulsions decrease very sharply with increase in the bond angle so that the repulsions between bond pairs of electrons where the bond angle is greater than 100° are generally neglected. For the bond pair of electrons of the axial P–F bond, there are *three* bond pair–bond pair repulsions whereas for the bond pair of electrons of the equatorial P–F bond, there are only *two* bond pair–bond pair repulsions. Thus, in the case of PF_5 molecule, the length of each P–F axial bond is 2·19 Å while the length of each P–F equatorial bond is 2·04 Å.

Molecules such as PCl_5 and $SbCl_5$ have similar geometry.

It may be noted that if the d orbital involved in sp^3d hybridisation is the $d_{x^2-y^2}$ orbital, the molecule (AB_5) formed would have a **square pyramidal geometry,** as shown in Fig. 17.

This geometry, however, is less stable than the trigonal bipyramidal geometry unless stabilised by some other factors such as greater probability of pi bonding in the plane containing one A and four B atoms.

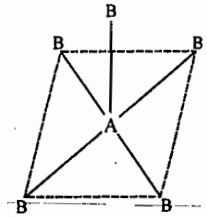

Fig. 17. Square pyramidal geometry of AB_5 molecule resulting from $sp^3d_{x^2-y^2}$ hybridisation of valence shell orbitals of the central atom A.

5. Geometry of sulphur hexafluoride molecule involving sp^3d^2 hybrid orbitals of S atom. Here the central atom is sulphur. Its outer electronic configuration is $3s^2 p_x^2 p_y^1 p_z^1$, as represented in Fig. 18(*a*).

There are only two unpaired electrons. Four more unpaired electrons have to be there in order to explain the formation of SF_6. This happens by the unpairing of 3*s* and 3*p* electrons which move into the 3*d* orbitals, by the excitation of the atom. This is shown in Fig. 18(*b*). Now, six unpaired electrons are available in six orbitals (one *s*, three *p* and two *d* orbitals) for bond formation to give SF_6 molecule, as shown in Fig. 18(*c*). These six orbitals hybridise to form six sp^3d^2 hybrid orbitals. The *d* orbitals used are $d_{x^2-y^2}$ and d_{z^2}. The six hybrid orbitals are now directed towards the six corners of a regular octahedron. Each of these six sp^3d^2 hybrid orbitals overlaps with the half-filled *p* orbital of each fluorine atom to form SF_6 molecule. The sulphur hexafluoride molecule thus has an octahedral geometry, as shown in Fig. 18(*d*).

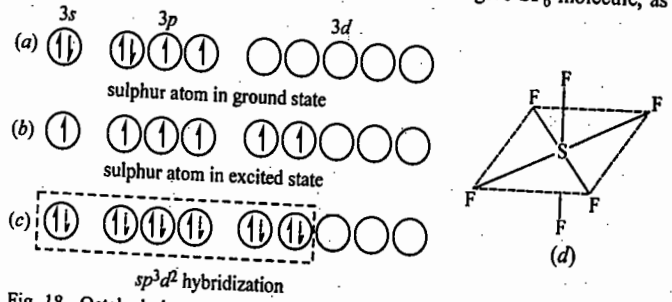

Fig. 18. Octahedral geometry of SF_6 molecule resulting from sp^3d^2 hybridisation of valency shell orbitals of the central S atom. Dotted arrows represent electrons supplied by fluorine atoms.

TeF_6 molecule has also octahedral geometry.

6. Geometry of iodine heptafluoride molecule involving sp^3d^3 hybrid orbitals of I atom. The outer electronic configuration of the central atom, iodine, in the ground state is $5s^2p_x^2p_y^2p_z^1$, as represented in Fig. 19(*a*). On excitation, unpairing of 5*s* as well as of $5p_x$ and $5p_y$ electrons takes place, as shown in Fig. 19(*b*). Now the seven orbitals ($5s$, $5p_x$, $5p_y$, $5p_z$, $5d_{xy}$, $5d_{yz}$ and $5d_{zx}$) hybridise to give seven sp^3d^3 hybrid orbitals. Each of these hybrid orbitals overlaps with the half-filled 2*p* orbitals of each fluorine atom to form IF_7 molecule, as shown in Fig. 19(*d*).

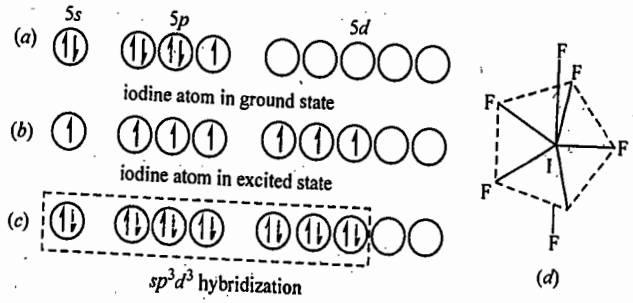

Fig. 19. Pentagonal bipyramidal geometry of IF_7 molecule resulting from sp^3d^3 hybridisation of valence shell orbitals of the central iodine atom. Dotted arrows represent electrons supplied by fluorine atoms.

The resulting molecule acquires **pentagonal bipyramidal** geometry, as shown in Fig. 19. In this molecule, again, all the seven bonds are not equivalent. Five of these are directed towards the vertices of a regular pentagon making an angle of 72° with one another. The remaining two are oriented at right angles to the plane of the first set of five orbitals. Thus, the bond angles in this molecule are of 72° and 90°.

The various kinds of hybridisation of valence shell orbitals discussed above together with the name of one compound formed in each case and the geometry acquired by the molecule, are summed

up in Table 1.

TABLE 1

Geometry of Covalent Molecules involving Different Types of Hybrid Orbitals of the Central Atom

Type of Hybridisation Involved	Name of the Compound	Geometry of the Molecule	Bond Angles ∠ABA
sp	BeF_2	Linear	180°
sp^2	BF_3	Trigonal plannar	120°
sp^3	CH_4	Tetrahedral	109·5°
sp^3d^2	PF_5	Trigonal bipyramidal	120° and 90°
sp^3d^2	SF_6	Octahedral	90°
sp^3d^3	IF_7	Pentagonal bipyramidal	72° and 90°

It may be noted that in the above compounds, all the electron pairs are *bonded* and the geometry and bond angles are exactly the same as expected according to VSEPR theory.

GEOMETRY OF MOLECULES CONTAINING BOND PAIRS AS WELL AS LONE PAIRS OF ELECTRONS

So far we have seen that in a molecule in which central atom has no lone pairs of electrons in any of its hybrid orbitals, the arrangement of hybrid orbitals around the central atom and the geometry of the molecule are the same. But, as already mentioned, the presence of one or more orbitals containing lone pairs in the valency shell cause some distortion in the geometry of the molecule. A few examples of molecules containing bond pairs as well as lone pairs of electrons and involving different types of hybridisation may now be considered. The + and – signs in the overlapping orbitals are not shown in the figures that follow for the sake of simplification.

1. Geometry of $SnCl_2$ Molecule. The outer electronic configuration of the central atom, tin, in this case, is $5s^2p_x^1p_y^1$. There are two unpaired electrons in 5*p* orbitals of tin and these are sufficient to form two bonds with chlorine atoms and, therefore, there is no need of promotion of electrons. The bond formation can take place by the overlapping of the two mutually perpendicular half-filled p_x and p_y orbitals of tin atom with the half-filled *p* orbitals of the two chlorine atoms. The molecule should thus be angular with Cl–Sn–Cl bond angle equal to 90°. However, as revealed by X-ray analysis and other properties, the Cl–Sn–Cl bond angle is quite close to 120°. Hence, it has been postulated that one *s* and two *p* orbitals of tin hybridise to give three sp^2 *hybrid orbitals of equivalent* energy, as shown in Fig. 20.

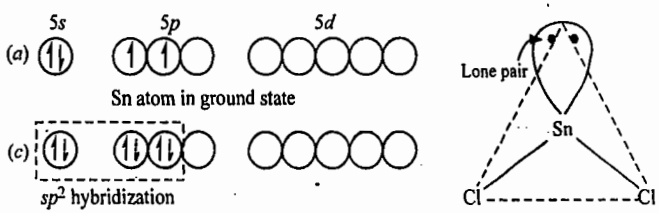

Fig. 20. V-shaped geometry of $SnCl_2$ molecule resulting from sp^2 hybridisation of the valence shell orbitals of Sn atom.

These sp^2 hybrid orbitals are arranged around the central atom in a *trigonal planar* geometry. One of these hybrid orbitals contains a lone pair of electrons while the remaining two contain one unpaired electron each. These two sp^2 hybrid orbitals containing unpaired electrons overlap with the half-filled

$2p$ orbitals of two chlorine atoms to form two Sn–Cl bonds. Thus, the central atom Sn in $SnCl_2$ is surrounded by three orbitals, each containing a pair of electrons. Two of these orbitals contain *shared* pairs while the third contains a *lone pair* of electrons (Fig. 21). The geometry of the molecule should have been V-shaped with bond angle of exactly 120°. However, on account of the fact that lone pair–bond pair repulsion is greater than bond pair–bond pair repulsion, the bond angle is slightly less than 120° although the molecule is still V-shaped.

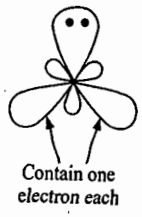

Fig. 21. Three sp^2 hybrid orbitals around tin.

2. Geometry of Ammonia Molecule. In this case, nitrogen is the central atom. Its outer electronic configuration is $2s^2p_x^1p_y^1p_z^1$. All the three p orbitals contain one electron each, in accordance with Hund's rule, as shown in Fig. 22(*a*). There are three unpaired electrons in the $2p$ orbitals and these are sufficient to form three bonds with hydrogen atoms giving ammonia molecule without involving any excitation of the atom. In that case, however, the molecule, utilising only three p orbitals of N atom, would have three mutually perpendicular N–H bonds. But actually it is not so. NH_3 molecule is *pyramidal* in structure with H–N–H bond angle of 107°. This is explained by postulating that one $2s$ and three $2p$ orbitals hybridise to form four sp^3 hybrid orbitals. One of these hybrid orbitals contains a lone pair of electrons while the remaining three contain one unpaired electron each. These three hybrid orbitals of N atom overlap with $1s$ orbitals of hydrogen atoms to form three N–H sigma bonds.

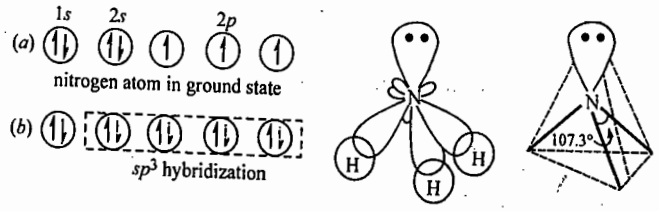

Fig. 22. Pyramidal geometry of ammonia molecule resulting from sp^3 hybridisation of valence shell orbitals of the central N atom. Dotted arrows represent electrons supplied by hydrogen atoms.

According to VSEPR theory, the force of repulsion between a lone pair and a bond pair is greater than the force of repulsion between the bond pairs of electrons. The molecule, therefore, gets a little distorted and the bond angle H–N–H decreases from the tetrahedral angle of 109·5° to 107°. The shape of the molecule is thus **pyramidal** in which the nitrogen atom lies at the centre, three hydrogens form the base and the lone pair of electrons lies at the apex of the pyramid, as shown in the figure.

3. Geometry of Hydronium Ion, H_3O^+. The formation of hydronium ion involving a coordinate covalent bond has been discussed in the last chapter. Since a coordinate covalent bond once formed is indistinguishable from a covalent bond, all the O–H bonds in hydronium ion are equivalent. The number of valence electrons to be accommodated in the orbitals of the central oxygen atom are 6 + 2 = 8. Therefore, four hybrid orbitals are required to accommodate these 8 valence electrons. The orbitals of the central oxygen atom would thus undergo sp^3 hybridisation. Of the four pairs of electrons accommodated in the four sp^3 hybrid orbitals, the three are bond pairs between O and H atoms and the fourth one is a lone pair. Because of the presence of this lone pair, the shape of H_3O^+ molecule becomes **pyramidal.** The positive charge is not confined to a single H atom but is delocalised over the entire hydronium ion so that the ion is better written as $(H_3O)^+$.

4. Geometry of Water Molecule. In water the central atom is oxygen. Its outer electronic configuration is $2s^22p_x^2p_y^1p_z^1$, as represented in Fig. 23 (*a*).

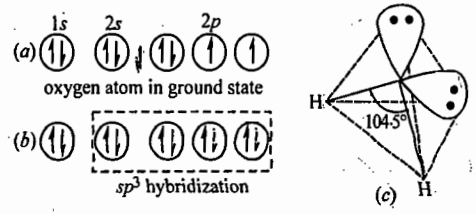

Fig. 23. V-shaped geometry of water molecule resulting from sp^3 hybridisation of valence shell orbitals of the central O atom. Dotted arrows represent electrons supplied by hydrogen atom.

Thus, there are two unpaired electrons which can form two bonds with hydrogen atoms without involving any excitation of the oxygen atom. But, in that case, the H_2O molecule, utilising only two p orbitals should have had H–O–H bond angle of 90°. This is not so actually. Water molecule is known to have a *bent structure* with H–O–H angle of 104·5°. This is explained by postulating that one $2s$ and three $2p$ orbitals of oxygen undergo hybridisation to give four sp^3 hybrid orbitals of equivalent energy. According to VSEPR theory, these hybrid orbitals are arranged *tetrahedrally* around the oxygen atom. Two of these orbitals contain bond pairs and the other two contain lone pairs of electrons. Since, as stated before, the force of repulsion between the two lone pairs of electrons amongst themselves is more than the force of repulsion between a lone pair and a bond pair which, in turn, is more than the force of repulsion between two bond pairs of electrons, there is greater distortion in this molecule than in ammonia. Consequently, the bond angle H–O–H in water is even smaller than the bond angle H–N–H in ammonia. This angle has been found to be 104·5°. The water molecule is thus said to have a **V-shaped geometry** as shown in Fig. 23(*c*).

It is evident from the above discussion that although ammonia and water molecules have essentially tetrahedral arrangement of hybrid orbitals around their central atoms as in methane, yet the four pairs of electrons are not equivalent in each of ammonia and water molecules. The result is that while methane molecule has a symmetrical tetrahedral geometry, ammonia molecule has pyramidal and water molecule has V-shaped geometry.

5. Geometry of Sulphur Tetrafluoride Molecule. In SF_4 molecule, the central atom, sulphur (Z = 16) has the outer electronic configuration $3s^23p_x^2p_y^1p_z^1$, as shown in Fig. 24. In the formation of SF_4 molecule, sulphur needs four half-filled orbitals to overlap with $2p$ orbitals of four fluorine atoms. This happens by the unpairing of the two p_x electrons and movement of one of them into one of the $3d$ orbitals on the excitation of atom [Fig. 24(*b*)]. These five orbitals ($3s$, $3p_x$, $3p_y$, $3p_z$ and $3d$) hybridise to give five sp^3d hybrid orbitals of equivalent energy. The central atom is, therefore, surrounded by five hybrid orbitals. One of these contains a lone pair of electrons while the other four contain one unpaired electron each which overlap with p orbitals of fluorine atoms to form four S – F bonds. According to VSEPR theory, such a molecule should have bond angles of 90°, 120° and 180°. However, due to the presence of a lone pair of electrons, there is distortion in the molecule and the bond angles are 89°, 118° and 177° instead of normal bond angles of 90°, 120° and 180°, respectively. The molecule thus has an irregular tetrahedral geometry.

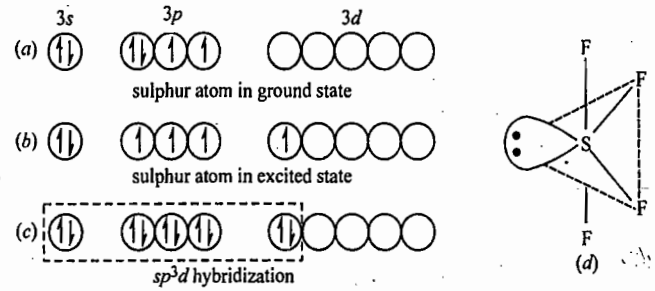

Fig. 24. Irregular tetrahedral geometry of SF_4 molecule resulting from sp^3d hybridisation of valence shell orbitals of the central S atom.

It may be noted that the lone pair in SF_4 structure is present in equatorial position and not in axial position. This may be understood in terms of stability of structure. We have seen that in the case of trigonal bipyramidal geometry (Fig. 16*d*), the electron pair present in axial position experiences more repulsion than the electron pair present in equatorial position. Therefore, in SF_4 molecule, if the lone pair is present in axial position, it would experience greater repulsion and the structure would be unstable. On the other hand, if the lone pair is present in equatorial position, it would experience comparatively less repulsion and the molecular structure would be stable.

6. Geometry of Chlorine Trifluoride Molecule. In ClF_3 molecule, chlorine is the central atom. Its outer electronic configuration is $3s^2 3p_x^2 p_y^2 p_z^1$. In the formation of ClF_3 molecule, chlorine requires three half-filled orbitals to form three Cl – F bonds. This becomes possible by the promotion of one of the electrons of $3p_y$ orbital to one of the vacant $3d$ orbitals as a result of the excitation of the atom. The five orbitals (one $3s$, three $3p$ and one $3d$) hybridise to form five sp^3d hybrid orbitals (Fig. 25 *c*). Two of these hybrid orbitals are occupied by lone pairs of electrons. The remaining three hybrid orbitals contain single electron each and form three sigma bonds with three fluorine atoms. Thus, in ClF_3, the central chlorine atom is surrounded by three bond pairs and two lone pairs of electrons. On the basis of VSEPR theory, the molecule is expected to be T-shaped with *cis* ∠ FClF of 90°. However, due to the presence of lone pairs, there is distortion in the structure and bond angle is 87·6° instead of 90°. Such a structure is also described as **distorted T-shaped** taking into consideration the positions occupied by atoms only.

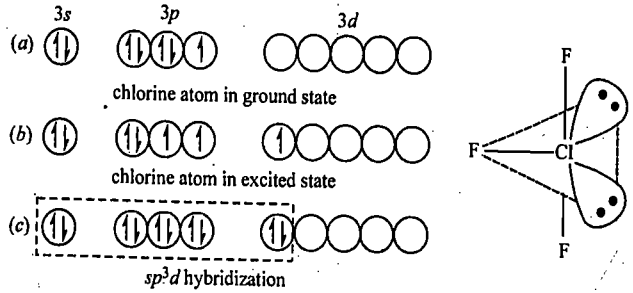

Fig. 25. Distorted T-shaped geometry of ClF_3 molecule resulting from sp^3d hybridisation of valence shell orbitals of the central Cl atom.

7. Geometry of Xenon Difluoride Molecule. The outer electronic configuration of the central atom, xenon, is $5s^2 5p_x^2 p_y^2 p_z^2$, as shown in Fig. 26(*a*). In the formation of XeF_2 molecule, one of the $5p$ electrons of xenon atom gets unpaired and shifts to one of the $5d$ orbitals (Fig. 26 *b*) as a result of the excitation of the xenon atom. One $5s$, three $5p$ and one $5d$ orbitals of Xe hybridise to yield five sp^3d hybrid orbitals of equivalent energy, as shown in Fig. 26 (*c*). Three of these hybrid orbitals contain lone pairs and the remaining two are half-filled. The two half-filled hybrid orbitals overlap with the *p* orbitals of the two fluorine atoms to form two Xe–F bonds. Thus, in XeF_2 molecule, the central atom, Xe, is surrounded by the five completely filled orbitals, two of which contain shared pairs of electrons and the remaining three contain lone pairs of electrons. The molecule is **linear**, as shown in Fig. 26(*d*). This is due to the fact that the three lone pairs are present on equatorial positions to

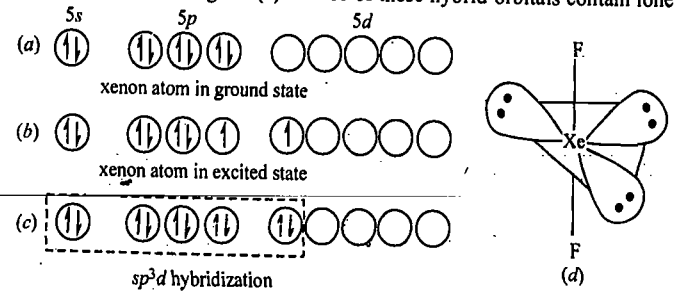

Fig. 26. Linear geometry of XeF_2 molecule resulting from sp^3d hybridisation of valence shell orbitals of the central Xe atom.

minimise electron pair repulsions. Due to symmetrical arrangement of lone pairs around the central xenon atom, the molecule has linear structure.

8. Geometry of Xenon Tetrafluoride Molecule. The outer electronic configuration of the central atom, xenon, in the ground state (*viz.*, $5s^2 5p_x^2 p_y^2 p_z^2$) is represented in Fig. 27 (*a*). In the excited state, two of the $5p$ electrons go to the $5d$ orbitals so that there are now four unpaired electrons (two in $5p$ and two in $5d$ orbitals), as shown in Fig. 27 (*b*). The six orbitals (one $5s$, three $5p$ and two $5d$) hybridise to form six sp^3d^2 hybrid orbitals. Two of these contain lone pairs of electrons. The remaining four contain unpaired electrons which are involved in bonding with four atoms of fluorine, as shown in Fig. 27 (*c*). The central atom, Xe, is thus surrounded by 6 fully filled hybrid orbitals. Four of these orbitals contain shared pairs while the remaining two contain lone pairs of electrons, as shown in Fig. 27 (*d*). The two orbitals containing lone pairs are present in axial position, one above and the other below the plane of the four fluorine atoms. Lone pair orbitals in these positions cause minimum repulsion. The geometry of XeF_4 molecule is **square planar**, as shown in the figure.

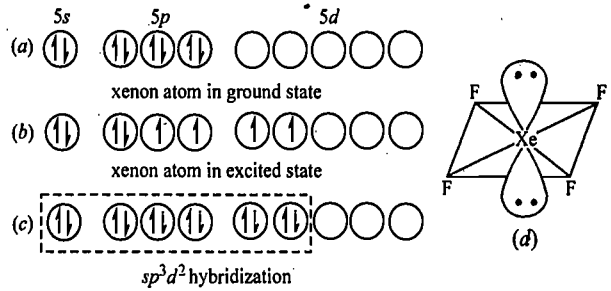

Fig. 27. Square planar geometry of XeF_4 molecule resulting from sp^3d^2 hybridisation of valence shell orbitals of the central Xe atom.

9. Geometry of Iodine Pentafluoride Molecule. The formation of IF_5 molecule involves sp^3d^2 hybridisation, as will be clear on reference to Fig. 28. In the excited state, the central atom, iodine, after combining with five fluorine atoms, is surrounded by six completely filled hybrid orbitals, five of which contain bond pairs and one contains a lone pair of electrons. Its geometry is **square pyramidal**, as shown in Fig. 28(*d*).

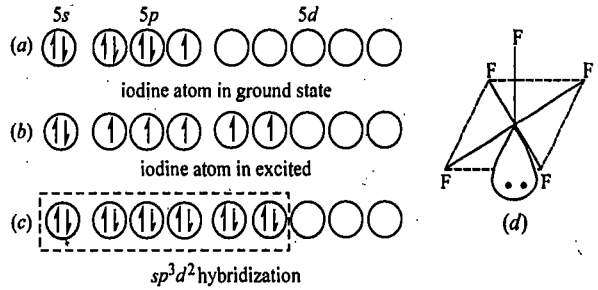

Fig. 28. Square pyramidal geometry of IF_5 molecule resulting from sp^3d^2 hybridisation of valence shell orbitals of the central iodine atom.

General Treatment. If A, B and L represent, respectively, the central atom, the bond pairs of electrons and the lone pairs of electrons, then the stability of a particular geometry would, evidently, depend upon the magnitude and the number of repulsive interactions between the various types of electron pairs. Since the electrostatic repulsion between two like charges decreases sharply with the distance between them, the electron pair repulsion is taken to be negligible and stands rejected if the angle between the electron pairs is more than 100°. The lone pair (L) is shown by an orbital having two electrons which are represented by two dots. Based on the above discussion, the geometry of the various molecules would be as follows.

Molecules of AB_3L Type. This type of molecules in which the sp^3 hybrid orbitals of the central atom are occupied by three bond pairs and one lone pair of electrons would have **pyramidal geometry**, as shown in Fig. 29. Examples are NH_3 and PCl_3. The bond angle BAB in such cases is less than 109·5°.

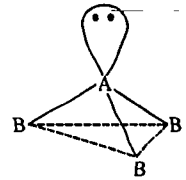

Fig. 29. Geometry of AB_3L type of molecules

Molecules of AB_2L_2 Type. This type of molecules in which the sp^3 hybrid orbitals of the central atom are occupied by two bond pairs and two lone pairs of electrons would have **V-shaped geometry**, as shown in Fig. 30. Examples are H_2O, $SeCl_2$ and NH_2^- ion. The bond angle BAB in this case is less than that in molecules of AB_3L type.

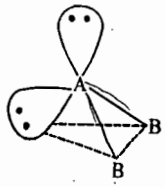

Fig. 30. Geometry of AB_2L_2 type of molecules

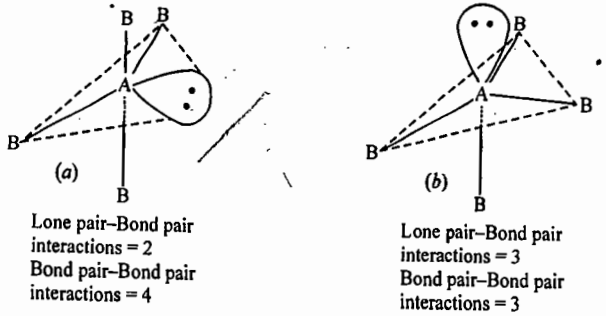
Molecules of AB_4L Type. *Molecules having four bond pairs and one lone pair of electrons accommodated in sp^3d hybrid orbitals, of the central atom can have two types of geometry, as shown in Fig. 32.*



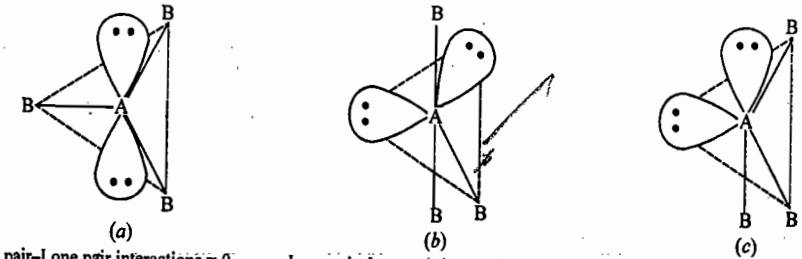
Lone pair–Bond pair interactions = 2
Bond pair–Bond pair interactions = 4

Lone pair–Bond pair interactions = 3
Bond pair–Bond pair interactions = 3

Fig. 31. Geometry of AB_4L type of molecules

The repulsive interactions involved in the above geometries are as indicated above. Since geometry (*a*) involves lesser electronic repulsion, it is more stable than geometry (*b*). Thus, molecules of the type AB_4L would have geometry (*a*).

Molecules of AB_3L_2 Type. Molecules having three bond pairs and two lone pairs accommodated in sp^3d hybrid orbitals of the central atom can have three types of **trigonal bipyramidal** arrangements of orbitals around the central atom, as shown in Fig. 32.

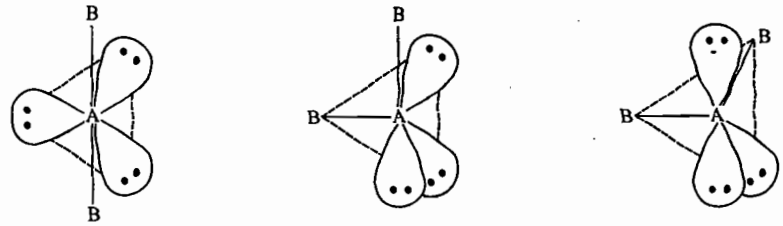


(*a*)	(*b*)	(*c*)
Lone pair–Lone pair interactions = 0	Lone pair–Lone pair interactions = 0	Lone pair–Lone pair interactions = 1
Lone pair–Bond pair interactions = 3 + 3 = 6	Lone pair–Bond pair interactions = 4	Lone pair–Bond pair interactions = 3
Bond pair–Bond pair interactions = 0	Bond pair–Bond pair interactions = 2	Bond pair–Bond pair interactions = 2

Fig. 32. Geometry of AB_3L_2 type of molecules

Neglecting the electron pair repulsions where the angle is greater than 100°, the various repulsive interactions involved in the three types of arrangements are as indicated above. Of the three resulting geometries, geometry (*b*) involves the minimum electronic repulsion. It is, therefore, most stable. The actual geometry of molecules of the type AB_3L_2 is thus geometry (*b*).

Molecules of AB_2L_3 Type. Molecules having two bond pairs and three lone pairs of electrons accommodated in sp^3d^2 hybrid orbitals of the atom can have the following three types of arrangements of orbitals around the central atom, as shown in Fig. 33.

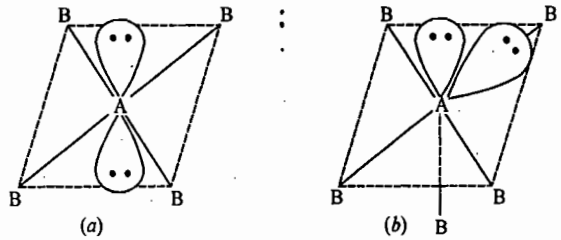


(*a*)	(*b*)	(*c*)
Lone pair–Lone pair interactions = 0	Lone pair–Lone pair interactions = 2	Lone pair–Lone pair interactions = 2
Lone pair–Bond pair interactions = 6	Lone pair–Bond pair interactions = 3	Lone pair–Bond pair interactions = 4
	Bond pair–Bond pair interactions = 1	Bond pair–Bond pair interactions = 0

Fig. 33. Geometry of AB_2L_3 type of molecules

It readily follows from the above that the resulting geometry (*a*), involving minimum electronic repulsion, would be the most stable and most probable geometry of compounds of AB_2L_3 type. It is evidently a linear geometry. Examples are XeF_2 and ICl_2^-.

Compounds of AB_4L_2 Type. Compounds having four bond pairs and two lone pairs of electrons accommodated in sp^3d^2 hybrid orbitals of the central atom can have either of the following two types of arrangements of orbitals around the central atom shown in Fig. 34.



(*a*)	(*b*)
Lone pair–Lone pair interactions = 0	Lone pair–Lone pair interactions = 1
Lone pair–Lone pair interactions = 8	Lone pair–Lone Bond interactions = 6
Bond pair–Lone pair interactions = 4	Bond pair–Lone pair interactions = 5

Fig. 34. Geometry of AB_4L_2 type of molecules

A perusal of various interactions suggests that the resulting geometry (*a*) is more stable than geometry (*b*). Thus, molecules of the type AB_4L_2 would have **a square planar geometry** depicted by (*a*). Examples are XeF_4 and ICl_4.

Molecules of AB_5L Type. Molecules having five bond pairs and one lone pair of electrons accommodated in sp^3d^2 hybrid orbitals of the central atom would have a square pyramidal geometry, as shown in Fig. 35.

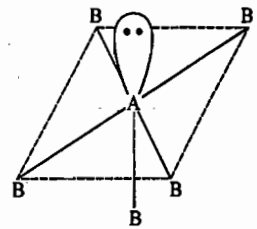


Fig. 35. Geometry of AB_5L type of molecules

Molecules of AB_7 Type. Molecules of the type AB_7 would have **pentagonal bipyramidal** geometry, as already illustrated in Fig. 19.

The geometries of various types of molecules are summed up in Table 3.

TABLE 3

Geometries of Various Types of Molecules

Type of molecules	No. of bond pairs of electrons	No. of lone pairs of electrons	Total number of electron pairs	Type of hybridisation involved	Geometry of molecules	Examples
AB_2	2	0	2	sp	Linear	$BeF_2[Ag(NH_3)_2]^+$
AB_3	3	0	3	sp^2	Trigonal planar	BCl_3, BH_3
AB_2L	2	1	3	sp^2	V-shaped	$SnCl_2$, $PbCl_2$
AB_4	4	0	4	sp^3	Tetrahedral	CH_4, NH_4^+
AB_3L	3	1	4	sp^3	Trigonal pyramidal	NH_3, PX_3
AB_2L_2	2	2	4	sp^3	V-shaped	H_2O, $SeCl_2$, NH_2
AB_5	5	0	5	sp^3d	Trigonal bipyramidal	PF_5, $Fe(CO)_5$
AB_4L	4	1	5	sp^3d	Irregular tetrahedral	SF_4, $TeBr_4$
AB_3L_2	3	2	5	sp^3d	T-shaped	ClF_3
AB_2L_3	2	3	4	sp^3d	Linear	XeF_2, ICl_2^-
AB_6	6	0	6	sp^3d^2	Octahedral	SF_6, $[SbF_6]^-$
AB_5L	5	1	6	sp^3d^2	Square pyramidal	IF_5, ClF_5, $[SbF_5]^{2-}$
AB_4L_2	4	2	6	sp^3d^2	Square planar	XeF_4, ICl_4
AB_7	7	0	7	sp^3d^3	Pentagonal bipyramidal	IF_7

Structure of Carbon Dioxide Molecule. The outer electronic configuration of carbon in ground state is $2s^2 2p_x^1 p_y^1$ and in excited state is $2s^1 2p_x^1 p_y^1 p_z^1$. The outer electronic configuration of oxygen atom in ground state is $2s^2 2p_x^2 p_y^1 p_z^1$. In the formation of CO_2 molecule, hybridisation of orbitals of carbon occurs only to a limited extent involving only one s and one p orbital, as shown in Fig. 36. There is thus sp hybridisation of valence shell orbitals of the carbon atom resulting in the formation of two *sp hybrid orbitals*. The remaining two p orbitals of carbon are excluded from hybridisation.

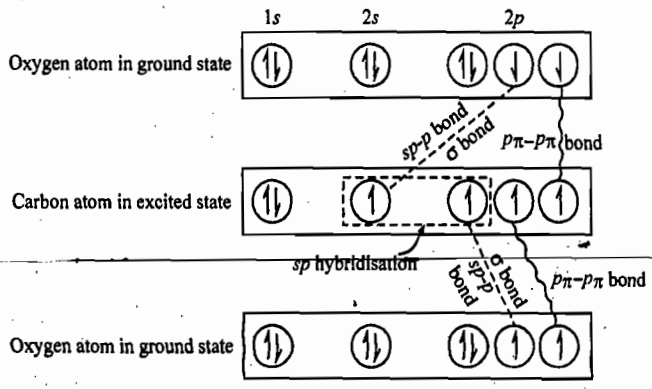

Fig. 36. Linear geometry of CO_2 molecule resulting from sp hybridisation of orbitals of valence shell of the carbon atom.

The two sp hybrid orbitals of carbon atom form sigma bonds with one p orbital of each of the two oxygen atoms, as shown by means of dotted lines. These are, evidently, $sp - p$ bonds. This leaves *two unhybridised* half-filled p orbitals in the carbon atom and one half-filled p orbital in each oxygen atom. This permits *pi bond formation* between the two half-filled p orbitals of carbon atom with the half-filled p orbitals of the two oxygen atoms. This is shown by dotted lines (Fig. 36). These bonds are called $p\pi - p\pi$ bonds.

The formation of CO_2 molecule is shown pictorially in Fig. 37.

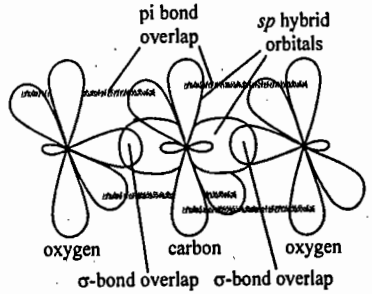

Fig. 37. Pictorial representation of the formation of linear carbon dioxide molecule.

As already mentioned, in CO_2 molecule, the two p orbitals of carbon atom are excluded from hybridisation. This is a case of only sp hybridisation of carbon orbitals and hence the molecule of carbon dioxide is ***linear***.

GEOMETRY OF SOME IONS

The **geometry of an ion** is determined to a large extent by the following two factors :

1. *The number of sigma bonds* involved in the bonding of atoms.
2. The *number of lone pairs of electrons* present around the central atom.

It is to be noted that double bonds, if any, involved in the formation of an ion do not influence the geometry of the ion.

In cases where the central atom forms multiple bonds, the number of orbitals involved in hydridisation is equal to $\frac{1}{2}$ (Number of valence shell electrons of the central atom + Number of electrons gained by the central atom through σ covalent bonding). The π bonds are invariably *excluded* from hybridisation.

We shall now consider geometry of a few common ions.

1. Geometry of Carbonate Ion. The outer electronic configuration of carbon atom in ground state is $2s^2 p_x^1 p_y^1$ and in excited state is $2s^1 2p_x^1 p_y^1 p_z^1$, as shown in Fig. 38.

Since carbonate ion is doubly charged, two of the oxygen atoms carry one additional electron each, so that they contain only one half-filled p orbital each, as shown. The third oxygen atom, however, has the normal outer electronic configuration, *i.e.*, it has two half-filled p orbitals.

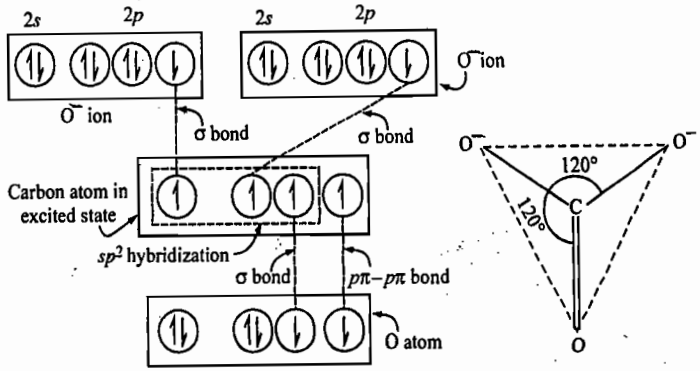

Fig. 38. Geometry of carbonate ion. A trigonal planar geometry results from sp^2 hybridisation of valence shell orbitals of the central atom.

The three orbitals (one $2s$ and two $2p$) of the carbon atom hybridise to form three sp^2 hybrid orbitals. The covalent sigma bonds are formed by overlapping of two of the three sp^2 hybrid orbitals of the carbon atom with the p orbitals of the two oxygen anions each of which contains only one unpaired electron. One more covalent sigma bond is formed by overlapping of the third sp^2 hybrid

orbital of the carbon atom with one of the two half-filled p orbitals of the *third* oxygen atom. Now only one of the p orbitals of the carbon atom and one of the p orbitals of the *third* oxygen atom remain half-filled. These two p orbitals *overlap laterally* forming a *pi bond*. The various types of overlappings are shown in Fig. 38.

Since, as mentioned above, there are three sp^2 hybrid orbitals around the central carbon atom which are involved in the formation of three sigma bonds with the three oxygen atoms, the CO_3^- ion has a **trigonal planar geometry**, as shown in the figure. It is evident that all the three sigma bonds in the carbonate ion are $sp^2 - p$ bonds.

Since all the C – C bonds in CO_3^- ion are equivalent, the actual structure of CO_2 molecule is a resonance hybrid of three resonating structures, as discussed in the previous chapter.

2. Geometry of Nitrate Ion. The outer electronic configuration of nitrogen atom is $2s^2 2p_x^1 p_y^1 p_z^1$ while that of oxygen atom is $2s^2 2p_x^2 p_y^1 p_z^1$. The nitrate ion carries a unit negative charge. This means that one of the oxygen atoms carries an extra electron. The outer electronic configurations of the three oxygen atoms are represented in Fig. 39.

The three orbitals (one $2s$ and two $2p$) of the N atom hybridise to give three sp^2 hybrid orbitals. One of the three sp^2 hybrid orbitals of the N atom contains a lone pair of electrons while the other two contain unpaired electrons. The orbital with lone pair of electrons overlaps with p orbital of oxygen atom which is vacated by rearranging the electrons of this atom. This results in the formation of a sigma dative bond, N→O. A sigma covalent bond is formed between nitrogen and oxygen atoms by the overlapping of one of the sp^2 hybrid orbitals of nitrogen with the *only* half-filled p orbital of the second oxygen atom (which already contains one additional electron). Another covalent bond (σ bond) is formed by the overlapping of another sp^2 hybrid orbital of nitrogen with one of the half-filled p orbitals of the *third* oxygen atom. We still have one unhybridised p orbital of nitrogen atom containing one electron and one half-filled p orbital of the third oxygen atom. These two half-filled p orbitals overlap laterally forming a pi bond.

The various types of overlappings are shown in Fig. 39.

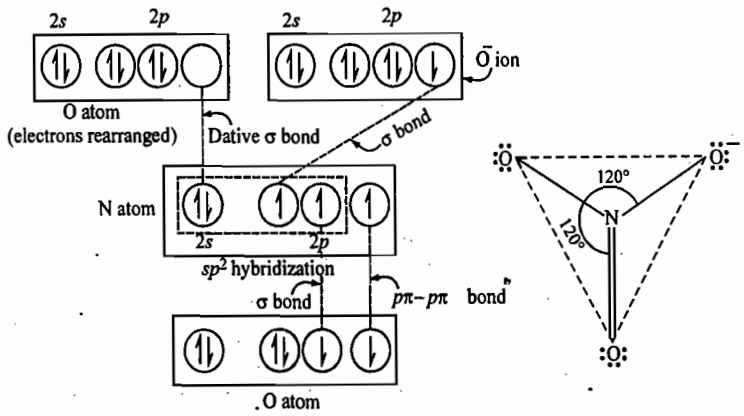

Fig. 39. Geometry of nitrate ion. A trigonal planar geometry results from sp^2 hybridisation of the valence shell orbitals of the central N atom.

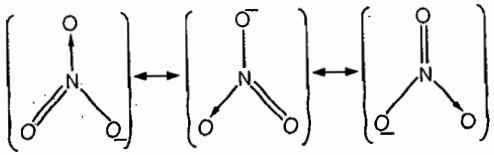
Since there are three sp^2 hybrid orbitals around the central N atom which are involved in forming two sigma covalent and one sigma dative covalent bond with the three oxygen atoms, the NO_3^- ion has **trigonal planar geometry**, as shown in Fig. 39. As is evident, all the three covalent bonds in nitrate ion are sp^2–p bonds.

Actually the nitrate ion is a *resonance hybrid* of the three resonating structures given below :



3. Geometry of Sulphate Ion. The outer electronic configuration of sulphur is $3s^2 3p_x^2 p_y^1 p_z^1$, in the normal state and $3s^1 3p_x^1 p_y^1 p_z^1 d_{xy}^1 d_{yz}^1$, in the excited state, as shown in Fig. 40. One $3s$ and three $3p$ orbitals hydridise to produce four sp^3 hybrid orbitals, as shown. The d orbitals are excluded from hybridisation. The sulphate ion carries two units of negative charge. Therefore, two of the oxygen atoms may be considered to have one additional electron each forming O^- ions. These two ions of oxygen marked (a), therefore, have only one half-filled p orbital each. Thus, two of the four sp^3 hybrid orbitals of the sulphur atom overlap with the half-filled orbitals of the two oxygen ions giving rise to two sigma covalent bonds.

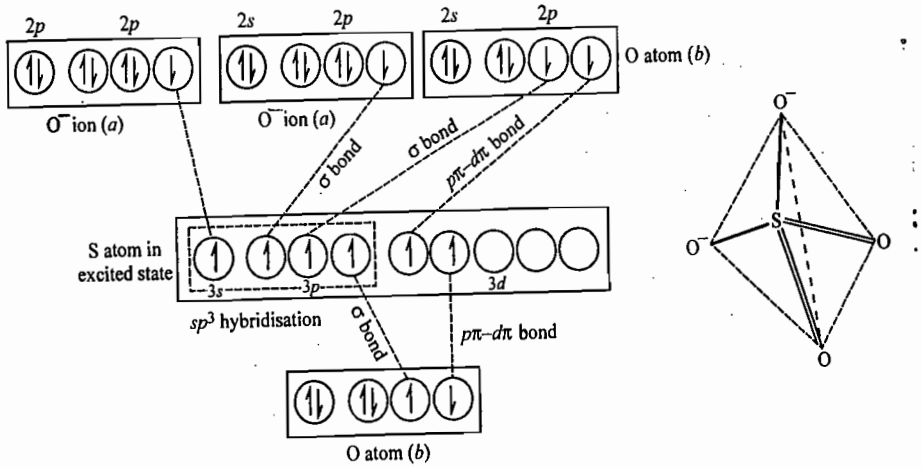


Fig. 40. Geometry of sulphate ion. A tetrahedral geometry results from sp^3 hybridisation of the orbitals of the central S atom.

We are left with two sp^3 hybrid orbitals of sulphur atom. Also we have two oxygen atoms more (marked b), the outer electronic configuration of each of which is $2s^2 2p_x^2 p_y^1 p_z^1$. The two sp^3 hybrid orbitals of sulphur atom form two more *sigma covalent bonds* by overlapping with one half-filled p orbital of each of the two oxygen atoms. Now we are left with two half-filled $3d$ orbitals of sulphur and also with one half-filled p orbital of each of the two oxygen atoms (marked b). The $3d$ orbitals of sulphur, therefore, form π bonds with the two oxygen atoms.

It is evident that all the four sigma bonds in the sulphate ion are $sp^3 - p$ bonds. The SO_4^{2-} ion is actually a resonance hybrid of several structures so that all the S–O bonds are exactly equivalent.

4. Geometry of Perchlorate Ion. The outer electronic configuration of chlorine atom in ground state is $3s^2 3p_x^2 p_y^2 p_z^1$ while in excited state is $3s^1 3p_x^1 p_y^1 p_z^1 d_{xy}^1 d_{yz}^1 d_{xz}^1$. One $3s$ and three $3p$ orbitals hybridise

to give four sp^3 hybrid orbitals. The d orbitals are excluded from hybridisation. This is illustrated in Fig. 41.

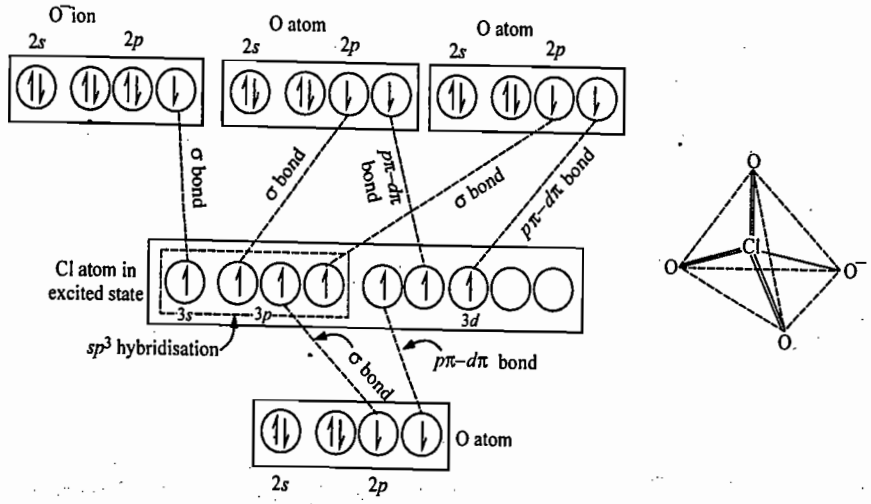

Fig. 41. Geometry of perchlorate ion. A tetrahedral geometry results from sp^3 hybridisation of valence shell orbitals of the central atom.

The outer electronic configuration of oxygen is $2s^2 2p_x^2 p_y^1 p_z^1$. There are four oxygen atoms in ClO_4^- ion. One of these carries an extra electron due to the negative charge on the ClO_4^- ion forming O^- ion. Chlorine forms a sigma covalent bond with this oxygen ion through the overlapping of one of its sp^3 hybrid orbitals with the only half-filled p orbital of the oxygen ion. Chlorine also forms three more sigma covalent bonds with three other oxygen atoms. For this purpose, three half-filled sp^3 hybrid orbitals of chlorine atom overlap with one of the half-filled p orbitals of each of the three oxygen atoms.

Now we have three half-filled $3d$ orbitals of the chlorine atom and one half-filled $2p$ orbital in each of the the three oxygen atoms. The $3d$ orbitals of chlorine atom overlap with the half-filled p orbitals of the three oxygen atoms *laterally*, thus, forming three π bonds, one with each of the three oxygen atoms.

Since there are four sp^3 hybrid orbitals around the central Cl atom which are involved in the formation of four sigma covalent bonds with the oxygen atoms, the ClO_4^- ion has a **tetrahedral geometry,** as shown in the figure.

As can be seen, all the four sigma bonds in perchlorate ion are $sp^3 - p$ bond. The ClO_4^- ion is actually a resonance hybrid of several structures so that all the Cl – O bonds are exactly equivalent.

5. Geometry of Chlorate Ion. The chlorate ion differs from the perchlorate ion in having one oxygen atom less. In this case, the central atom, chlorine, is attached to three oxygen atoms instead of four. One of the oxygen atoms carries an extra electron thus forming O^- ion due to the negative charge on the chlorate ion.

One $3s$ and three $3p$ orbitals of the chlorine atom hybridise to give four sp^3 hybrid orbitals. Chlorine forms three sigma covalent bonds by overlapping of three of the four sp^3 hybrid orbitals with three oxygen atoms and also two π bonds by lateral overlapping of $3d$ orbitals of chlorine with the half-filled p orbitals of two of the oxygen atoms, as shown.

Since the central Cl atom forms three sigma bonds with oxygen atoms, the ClO_3^- ion should have a planar trigonal geometry. But the geometry of chlorate ion is actually **pyramidal.** This is due to the fact that one of the sp^3 hybrid orbitals is occupied by a lone pair of electrons, as is evident from Fig. 42.

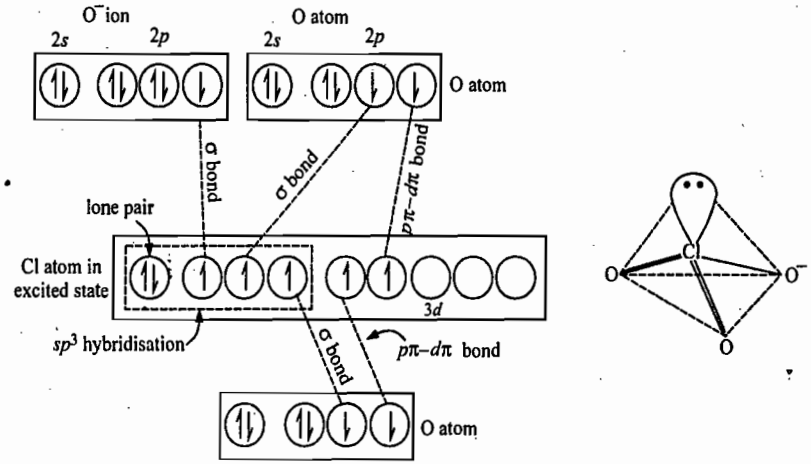

Fig. 42. Geometry of chlorate ion. The molecule is pyramidal because of the presence of a lone pair of electrons on Cl atom.

The ClO_3^- ion is a resonance hybrid of several structures so that all the Cl – O bonds are exactly equivalent.

Problem. (*a*) In the hydrides of Group 16 elements, *viz.*, H_2O, H_2S, H_2Se and H_2Te, the central atom in each case involves sp^3 hybridisation but the bond angles decrease as shown below :

H_2O	H_2S	H_2Se	H_2Te
104·5°	92·5°	91·0°	89·5°

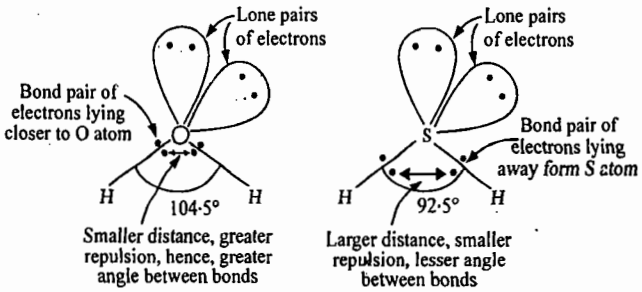
How would you account for this ?

(*b*) Why is the bond angle in F_2O smaller than that in H_2O ?

Answer. (*a*) In the hydrides of Group 16 elements, the orbitals around the central atom in each case undergo sp^3 hybridisation and the atom is surrounded by two lone pairs and two bond pairs of electrons (*cf.* geometry of H_2O molecule, Fig. 23). Since lone pair–lone pair repulsion is greater than the lone pair–bond pair repulsion, the bonded electron pairs are forced closer to each other and, therefore, the bond angle decreases from the normal tetrahedral angle of 109·5°. It is a general observation that the bond angles in the hydrides of the elements belonging to third or higher periods of a group are smaller than the bond angles in the hydrides of the elements of the second period of the same group. For instance, the bond angle in H_2O is 104·5° whereas it is close to 90° in H_2S, H_2Se and H_2Te. Thus it appears that the repulsions between bond pairs around the smaller atoms of an element of a group are stronger than between the bigger atoms of the same group. This may be explained in the following manner :

An orbital containing a lone pair when present in a bigger-sized atom occupies much more space than the lone pair orbital on a smaller-sized atom of an element of the same group. Therefore, the lone pair–bond pair distances are smaller and hence the lone pair–bond pair repulsions are stronger in the hydrides of bigger- sized S, Se and Te atoms compared to the hydride of O atom, *i.e.*, H_2O. Apart from this, the electronegativity goes on decreasing from O to Te. Consequently, the position of the bond pairs

of electrons shifts more and more away from the central atom in moving from H_2O to H_2Te. For example, as shown below, the bond pair is closer to oxygen in O–H bond than it is to sulphur atom in S – H bond. As a result, the force of repulsion between the bonded pairs of electrons in H_2O is more than that in H_2S. The force of repulsion between the bonded pairs of electrons decreases as we move from H_2O to H_2Te. Therefore, the bond angle also decreases in the same order. Since the increase in size and decrease in electronegativity is more significant in going from O to S than from S to Se to Te, the decrease in bond angle is also more significant in going from O to S than from H_2S to H_2Se to H_2Te.



(*b*) In F_2O, the bond pairs of electrons would lie *closer to fluorine atom* because fluorine is more electronegative than oxygen.

In H_2O, the bond pairs of electrons would lie *closer to oxygen atom* because oxygen is more electronegative than hydrogen.

Following the same arguments as advanced for (*a*), it can be easily realised that the bond angle in F_2O would be smaller than that in H_2O.

QUESTIONS

1. (*a*) What do you understand by hybridisation ? Explain giving examples.
   (*b*) What type of geometry is possible for molecules undergoing the following types of hybridisation :
   (*i*) sp (*ii*) sp^2 (*iii*) sp^3 (*iv*) sp^3d (*v*) sp^3d^2 (*vi*) sp^3d^3
2. (*a*) Why do molecules have definite geometry ? In which of the following types of geometry, all the bond angles are not the same :
   (*i*) Octahedral (*ii*) trigonal planar (*iii*) trigonal bipyramidal
   (*iv*) tetrahedral (*v*) pentagonal bipyramidal. [Ans. (*iii*), (*v*)]
   (*b*) Beryllium (Z = 4) has no unpaired electron in its ground state. However, in all its compounds beryllium shows divalency. Explain.
3. (*a*) What is hybridisation ? What are the important characteristics of hybridisation ?
   (*b*) The central atom in the molecules of CH_4, NH_3 and H_2O involves sp^3 hybridisation of its valence shell orbitals. But the bond angles in these molecules are 109·5, 107° and 104·5°, respectively. Account for this.
   (*c*) What shapes are associated with the molecules involving sp^3d^2 and sp^3d^3 hybridisation ?
4. Discuss the stereochemistry of the following molecules on the basis of hybridisation : PF_5, $SnCl_2$, NH_3, ClF_3
5. The ground state electronic configuration of chlorine is $1s^22s^2p^63s^2p^5$. Account for the geometry of the following molecules/ions of chlorine :
   (*a*) ClF_3 (*b*) ClO_4^- (*c*) ClO_3^-
6. On the basis of hybridisation, discuss the geometry of the following molecules :
   SF_6, IF_7, $SnCl_2$, XeF_4, SF_4, H_2O, PCl_5 and NH_3.
7. (*a*) According to electronic configuration, water should have bond angle H – O – H of 90° and ammonia should have three mutually perpendicular N – H bonds but actually both the molecules have unsymmetrical tetrahedral structure. How would you explain this ?
   (*b*) Account for the following decreasing trend of repulsive interactions : lone pair–lone pair > lone pair–bond pair > bond pair–bond pair.

   (*c*) Discuss the geometry of molecules having
   (*i*) two lone pairs and two bond pairs (*ii*) one lone pair and three bond pairs
   (*iii*) one lone pair and four bond pairs (*iv*) one lone pair and five bond pairs
8. Discuss the geometry of the following ions :
   (*a*) NO_3^- (*b*) CO_3^{2-} (*c*) SO_4^{2-} (*d*) ClO_3^- (*e*) ClO_4^-
9. (*a*) Why is it necessary to involve hybrid orbitals while trying to account for the geometry of methane molecule ?
   (*b*) Which of PF_5 or SF_6 does not have symmetrical geometry and why ?
   (*c*) Account for the geometry of PH_3, OF_2 and IF_5 on the basis of concept of hybridisation.
   (*d*) Discuss sp^3d^3 hybridisation with one example.
10. Construct wave functions for sp, sp^2 and sp^3 hybrid orbitals.
11. Involving the wave mechanical treatment, discuss the orientation of hybrid orbitals in space.
12. Discuss the VSEPR theory. Illustrate carefully that VSEPR theory has to be combined with the concept of hybridisation to account for the geometry of covalent molecules.

6 THE STRUCTURE OF SOLIDS

Solids, as is well known, are characterised by *incompressibility, rigidity* and *mechanical strength.* This indicates that the molecules, atoms or ions that make up a solid are *closely packed, i.e.,* they are held together by strong forces and cannot move at random. Thus, *in solids there is well-ordered arrangement of molecules, atoms or ions.* The properties of solids not only depend upon the number and kind of constituents but also on their arrangements.

Solids can be classified into the following two categories.

1. Crystalline Solids. *A substance whose constituents are arranged in an orderly manner in a definite geometric form is called a* **crystalline solid.** X–ray diffraction studies of these solids reveal that the regular arrangement of the constituents (molecules, atoms or ions) *extends over large distances* in three-dimensional network of crystals. In other words, the crystalline solids are said to exhibit *long range order.* Some common examples of crystalline solids are sodium chloride, sulphur, diamond, sugar, etc.

2. Amorphous Solids. *A substance whose constituents are not arranged in an orderly manner is called an* **amorphous solid.** These substances do possess properties such as incompressibility and rigidity to a certain extent but they do not have definite geometric forms. Some amorphous solids may have some orderly arrangement but *it does not extend to more than a few Angstrom units.* Thus, amorphous solids have only *short range order.* Some common examples of amorphous solids are glass, rubber, plastics, etc.

Difference between Crystalline and Amorphous Solids. Crystalline and amorphous solids differ from one another in the following respects.

1. Characteristic Geometry. A crystalline solid has a definite and regular geometry due to definite and orderly arrangement of molecules, atoms or ions in three-dimensional space. An amorphous solid, on the other hand, does not have any pattern or arrangement of its constituents and, therefore, does not have any definite geometric shape.

2. Melting Points. A crystalline substance has a *sharp melting point, i.e.,* it changes abruptly into liquid state at a fixed temperature. An amorphous substance, on the contrary, does not have a sharp melting point. For example, if glass is heated gradually, it softens and starts to flow without undergoing a definite and abrupt change into liquid state. Strictly speaking, *solid state refers only to crystalline state, i.e., only a crystalline material can be considered to be a* **true solid.**

3. Isotropy and Anistropy. Amorphous solids differ from crystalline solids in another important respect. *The properties such as electrical conductivity, thermal conductivity, mechanical strength and refractive index of an amorphous solid are the same in all directions.* Amorphous substances are, therefore, said to be **isotropic.** Liquids and gases are also isotropic.

Crystalline solids, on the other hand, are **anisotropic,** *i.e., their physical properties are different in different directions.* For example, the velocity of light passing through a crystal varies with the direction

in which it is measured. Thus, a ray of light entering such a crystal may split up into two components each following a different path and travelling with a different velocity. This phenomenon is known as **double refraction.** Thus, anisotropy in itself is a strong evidence for the existence of ordered molecular arrangement in such materials. This can be shown on reference to Fig. 1 in which a simple two-dimensional arrangement of only two different kinds of atoms is depicted. If the properties are measured along the direction indicated by the slanting line *CD,* they will be different from those measured in the direction indicated by the vertical line *AB.* The reason is that while in the first case, each row is made up of alternate types of atoms, in the second case, each row is made up of one type of atoms only. In amorphous solids, atoms or molecules are arranged at random and in a disorderly manner and, therefore, all directions are identical and all properties are alike in all directions.

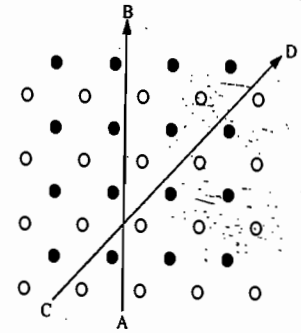


Fig. 1. Anisotropic behaviour of a crystal.

Size and Shape of Crystals. Several naturally occurring solids have definite crystalline shapes which can be recognised easily. There are many other solid materials which occur as powders or agglomerates of fine particles and appear to be amorphous. But when an individual particle is examined under a microscope, it is also seen to have a definite crystalline shape. *Such solids in which the crystals are so small that they can be recognised only under a powerful microscope, are said to be* **microcrystalline.** The size of a crystal depends on the rate at which it is formed ; the slower the rate, the bigger the crystal. This is because time is needed by the ions or atoms or molecules to get into their proper positions in the crystal structure. Thus, large transparent crystals of sodium chloride, silver chloride, lithium chloride, etc., can be prepared by melting these salts and allowing them to cool very slowly at a uniform rate. It is for this reason that crystals of most of the minerals formed by geological processes are often very large.

Interfacial Angles. Crystals are bound by plane faces. *The angle between any two faces is called an* **interfacial angle.** It is measured by an instrument called *goniometer.* It may be noted that the size of the faces or even shapes of the crystals of *one and the same substance* may vary widely with conditions of their formation. Although a crystal may have different shapes yet the interfacial angles between any two corresponding faces of the crystal remain invariably the same throughout. This is also known as law of constancy of interfacial angles or law of crystallography. This is illustrated in Fig. 2. Although the external shapes are different yet the interfacial angle is the same.

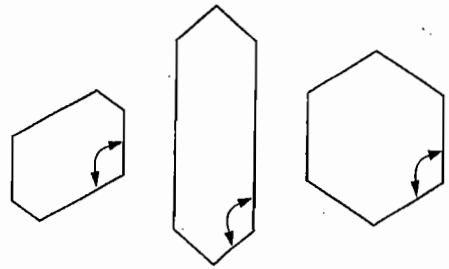

Fig. 2. Interfacial angles in a crystal.

SYMMETRY IN CRYSTALS

Besides the interfacial angles, another characteristic property of crystals is their symmetry. The symmetry of a crystal may be understood in terms of symmetry operation and symmetry elements.

The ***symmetry operation*** *is an operation performed around a line, plane or point on a body so that it yields the same or similar appearance of the body after the operation.* To illustrate this, let us consider a symmetry operation such as rotation around an axis. Suppose we are looking at a cube. If we rotate the cube through 90° about an imaginary axis passing through the centres of the top and bottom faces (Fig. 3), the appearance after rotation is exactly similar to the appearance before rotation. The cube on further rotation presents similar appearance three times more in one complete rotation. Thus, a cube gives similar

appearance by rotation through 90° about an axis passing perpendicularly through the centre. In this example, the *rotation about an axis* is called *symmetry operation* and the *axis of rotation* about which the cube is rotated is called a *symmetry element.*

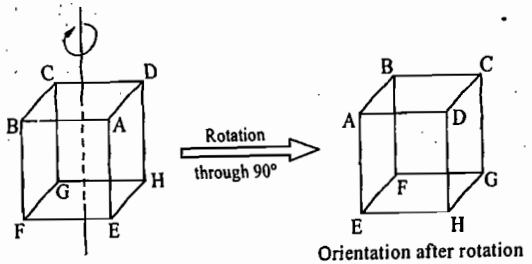

Fig. 3. Illustration of rotation of a cube around an axis. Rotation of a cube through 90° about an axis passing through the centres of the top and bottom faces yields exactly similar appearance.

There are various types of symmetry elements, only three of which will be described here. These are : (1) *Plane of symmetry* (2) *Axis of symmetry* and (3) *Centre of symmetry.*

1. Plane of symmetry. *When an imaginary plane can divide a crystal into two parts such that one is the exact mirror-image of the other, the crystal is said to have a plane of symmetry.*

2. Axis of Symmetry. *An axis of symmetry is an imaginary line about which the crystal may be rotated such that it presents the same or similar appearance more than once during the complete rotation.* For example, in the case of a *cube* (as discussed above), an axis passing *perpendicularly* through the centres is such that when the cube is rotated, it presents similar appearance in four rotations of 90° each and the same appearance after the fourth rotation. Such an axis is called **a four-fold** or **a tetrad axis** of symmetry (Fig. 3). In a cube, there are 3 four-fold axes of symmetry, as shown in Fig. 4.

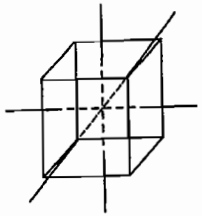

Fig. 4. Three four-fold axes in a cube.

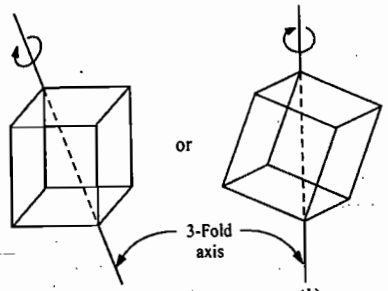
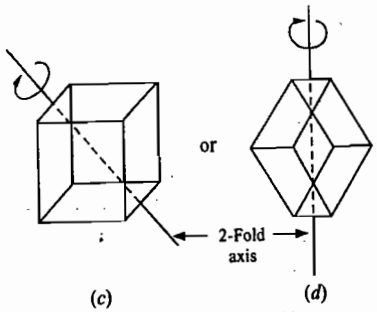
If the same or similar appearance is repeated after an angle of 120°, the axis is called a **three-fold** or **triad axis of symmetry**. One of the three-fold axes in a cube is shown in Fig. 5(*a*). To illustrate the rotation more clearly, it is held as shown in Fig. 5(*b*) and rotated around the body diagonal. Since there are four body diagonals in a cube, it has 4 three-fold axes of symmetry.



Rotation through 120°

Fig. 5. A three-fold axis in a cube.

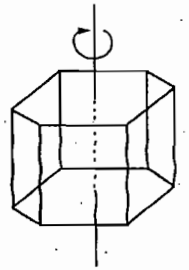


Rotation through 180°

Fig. 6. A two-fold axis in a cube.

Similarly, if the same or similar geometry appears after an angle of 180°, the axis is called a **two-fold** or a **diad axis**. One of the two-fold axes in a cube is shown in Fig. 6(*a*). The rotation can be understood by holding the cube as shown in Fig. 6(*b*). There are, evidently, 2 two-fold axes in a cube.

Likewise, if the same or similar geometry appears after rotation through an angle of 60°, the axis is called a **six-fold** or **hexad axis**. A hexagonal crystal has one six-fold axis (Fig. 7). It is clear from the figure that similar appearance is repeated after rotating the crystal through an angle of 60°.



6-Fold axis

Rotation through 60°

Fig. 7. A six-fold axis in a hexagonal crystal.

In general, if the same or similar appearance of a crystal is repeated on rotating it through an angle of 360°/n around an imaginary axis, the axis is called an **n-fold axis**. A crystal can have only the 2-fold, 3-fold 4-fold and 6-fold axes of rotation. The angle through which the crystal will have to be rotated to get the same or similar appearance, evidently, will be 180°, 120°, 90° and 60°, respectively.

3. Centre of Symmetry. *Centre of symmetry of a crystal is such a point that any line drawn through it intersects the surface of the crystal at equal distances in both directions.*

It may be pointed out that a crystal may have any number of planes or axes of symmetry but *it has only* **one** *centre of symmetry.*

Elements of Symmetry of a Crystal. As mentioned above, there are three different types of symmetry elements which are possible in a crystal. A crystal may have different numbers of each type of symmetry element. *The total number of* **planes, axes** *and* **centres of symmetries** *possessed by a crystal is termed as the* **elements of symmetry** of the crystal. To explain this term further, we may consider the elements of symmetry possessed by a **cubic crystal,** such as NaCl crystal. A cubic crystal possesses **a total of 23 elements of symmetry,** as will be clear from the discussion that follows. These elements of symmetry are :

a. Rectangular planes of symmetry. One rectangular plane of symmetry is shown in Fig. 8(*a*). There will be two more such planes, each of which will be at right angles to the plane shown in the figure. Thus, *there are 3 rectangular planes of symmetry in all.*

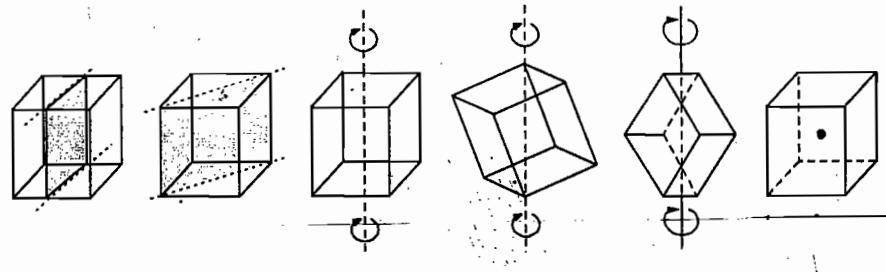
b. Diagonal planes of symmetry. One plane passing *diagonally* through the cube is shown in Fig. 8(*b*). *There can be a total of 6 such planes passing diagonally through the cube.*

c. Axes of four-fold symmetry. One of the four-fold axes is shown in Fig. 8(*c*). Evidently, *there can be a total of 3 such four-fold axes at right angles to one another.*

d. Axes of three-fold symmetry. One such axis passing through opposite corners is shown in Fig. 8(*d*). *There can be a total of 4 such three-fold axes.*

e. Axes of two-fold symmetry. One such axis emerging from opposite edges is shown in Fig. 8(*e*). There are, evidently, *6 such axes of two-fold symmetry.*

f. Centre of symmetry. There is *only one centre of symmetry* lying at the centre of the cube (Fig. 8*f*).



(*a*) A rectangular plane of symmetry
(*b*) A diagonal plane of symmetry
(*c*) An axis of four-fold symmetry
(*d*) An axis of three-fold symmetry
(*e*) An axis of two-fold symmetry
(*f*) Centre of symmetry

Fig. 8. Various elements of symmetry in a cubic crystal.

Thus, the numbers of symmetry elements of various types in a cubic crystal are :

Planes of symmetry $= 3 + 6 = 9$

Axes of symmetry $= 3 + 4 + 6 = 13$

Center of symmetry $= 1$

Total number of symmetry elements $= 23$

Basic Crystal Systems. It can be shown from geometrical considerations that, theoretically, there can be 32 different combinations of elements of symmetry of a crystal. These are called **32 systems.** Some of the systems, however, have been grouped together so that we have only seven differents categories, known as the **seven basic crystal systems.** These are *cubic, orthorhombic, tetragonal, monoclinic, triclinic, hexagonal* and *rhombohedral.*

These systems together with the maximum number of planes of symmetry and axes of symmetry and their examples are given in Table 1.

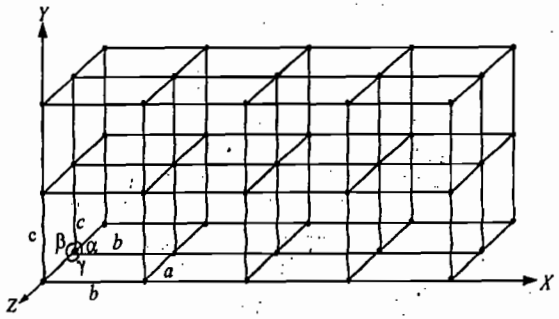
TABLE 1

The Basic Crystal Systems and Their Maximum Symmetry Elements

System	Number of Maximum Axes and Planes of Symmetry	Examples
1. Cubic	Nine planes of symmetry Thirteen axes of symmetry	NaCl, KCl, CaF_2, ZnS, Cu_2O, Diamond, Alums, Pb, Ag, Au
2. Orthorhombic	Three planes of symmetry Three axes of symmetry	KNO_3, K_2SO_4, $BaSO_4$, $PbCO_3$, Mg_2SiO_4, Rhombic sulphur
3. Tetragonal	Five planes of symmetry Five axes of symmetry	SnO_2, TiO_2, $ZrSiO_4$, KH_2PO_4, $PbWO_4$, Sn
4. Monoclinic	One plane of symmetry One axis of symmetry	$Na_2SO_4.10H_2O$, $Na_2B_4O_7.10H_2O$, $CaSO_4.2H_2O$, Monoclinic sulphur
5. Triclinic	No plane of symmetry No axis of symmetry	$CuSO_4.5H_2O$, $K_2Cr_2O_7$, H_3BO_3
6. Hexagonal	Seven planes of symmetry Seven axes of symmetry	ZnO, CdS, HgS, Graphite, Ice, PbI_2, Beryl, Mg, Zn, Cd
7. Rhombohedral	Seven planes of symmetry Seven axes of symmetry	$NaNO_3$, ICl, Calcite, Magnesite, Quartz, As, Sb, Bi

Space Lattice and Unit Cell

Crystals have definite orderly arrangements of their constituents (atoms, molecules or ions) in three dimensions. The positions of atoms, molecules or ions in a crystal, relative to one another in space, are designated usually by points. Such a representation is called *space lattice.* A **space lattice** *is an array of points showing how atoms, molecules or ions are arranged at different sites in a three-dimensional space.* An example of an array of points in a three-dimensional space lattice is shown in Fig. 9. Each point represents an identical atom or group of atoms.



If we carefully look at a space lattice, it is observed that the entire lattice can be considered as a *repetition of a small pattern* (or *motif*). This smallest repeating pattern is called a *unit cell.* Thus, a **unit cell** *is the smallest repeating unit in space lattice which when repeated over and over again results in a crystal of the given substance.* The crystal may be considered to consist of infinite number of unit cells. Each unit cell in a three-dimensional space has, evidently, three vectors, *a, b* and *c*, as shown in Fig. 9.

Note that these are the *points* and not the lines which constitute the space lattice. The lines joining the points are drawn simply for representing the three axes by means of which the relative positions of the points can be described. For example, in Fig. 9, three imaginary axes, *OX, OY* and *OZ*, which are used to represent the unit cell, have been shown. In order to describe a unit cell, we should know : (*i*) the distances *a, b* and *c* which give the lengths of the edges of the unit cell and (*ii*) the angles α, β and γ which give the angles between the three imaginary axes *OX, OY* and *OZ.*

Knowing the unit cell dimensions, the **theoretical density** of a crystal can be calculated from the relation

$$\rho = n M_m / (N_A V) \qquad ...(1)$$

where n is the number of atoms in the unit cell, M_m is the molar mass, N_A is Avogadro's number and V is the volume of the unit cell.

Bravais Lattices

Bravais (1848) showed from geometrical considerations that there can be only 14 different ways in which similar points can be arranged in a three-dimensional space. Thus, the total number of space lattices belonging to all the seven basic crystal systems put together is only 14, as given in Table 2 (column 2). These are known as **Bravais lattices.**

The crystals have four kinds of Bravais lattices depending upon the shapes of the unit cells. These are :

1. Simple or **primitive lattice** *in which there are points at all the corners of the unit cell.* It is labelled as **P.** A primitive cubic unit cell is shown in Fig. 10 (*a*). This unit cell consists of one atom at each of the eight corners. Since each atom at the corner is shared by 8 unit cells, therefore, only 1/8 th of the atom is within the unit cell. Thus, the number of atoms per unit cell in primitive lattice is $8 \times (1/8) = 1$.

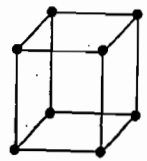


Fig. 10 (*a*). Primitive (*P*) cubic unit cell.

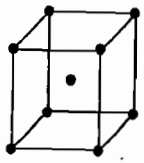

Fig. 10 (*b*). Body centred (*I*) cubic unit cell.

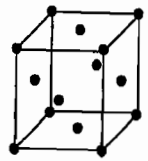

Fig. 10 (*c*). Face centred (*F*) cubic unit cell.

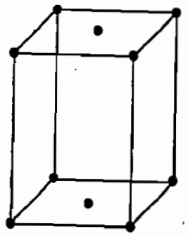

Fig. 10 (*d*). End centred (*C*) orthorhombic unit cell.

2. Body centred lattice *in which there are points at all the corners as well as in the centre of the unit cell.* It is labelled as **I.** For example, in body centred cubic unit cell (Fig. 10 *b*), there are eight atoms at the corners (each shared by 8 unit cells) and one at the centre (belonging to only one unit cell). Therefore, the number of atoms per unit cell is $8 \times (1/8) + 1 = 2$.

3. Face centred lattice *in which there are points at the corners as well as at the centre of each face.* It is labelled as **F.** In a face centred cubic unit cell (Fig. 10 *c*), there are eight atoms at the corners (each shared by 8 unit cells) and six at the faces (each shared by two unit cells). Therefore, the number of atoms per unit cell is $8 \times (1/8) + 6 \times (1/2) = 4$.

4. End centered lattice *in which there are points at the corners and at the centres of two end faces.* It is labelled as **C**. For example, in an end centred orthorhombic unit cell* (Fig. 10 *d*), there are eight atoms at the corners and two at the end faces so that the number of atoms per unit cell is $8\times(1/8)+2\times(1/2)=2$.

The Bravais space lattices associated with various crystal systems are shown in Figs. 11 (*a*), (*b*), (*c*) and (*d*). The unit cell is described by the lengths *a*, *b* and *c* of the three intersecting edges and the angles α, β and γ between the pairs of edges *b*, *c* ; *a*, *c* and *a*, *b*, respectively.

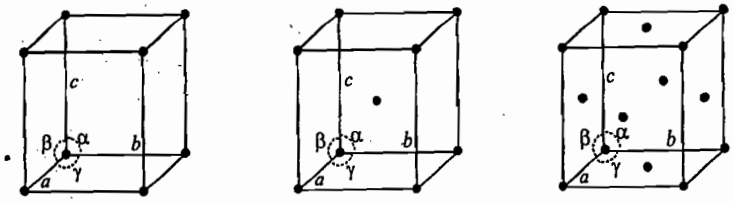

Fig. 11 (*a*). Cubic Space Lattices

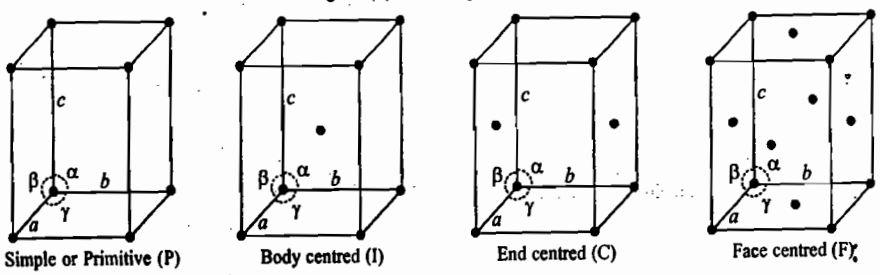

Fig. 11 (*b*). Orthorhombic Space Lattices.

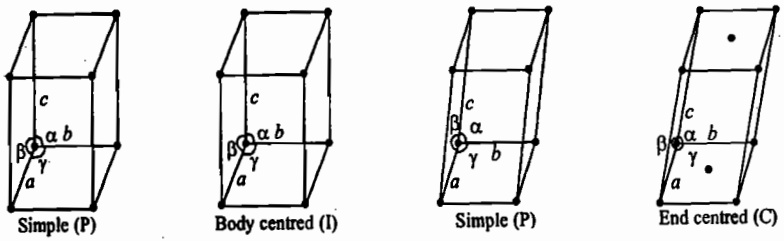

Fig. 11 (c). Tetragonal and Monoclinic Space Lattices

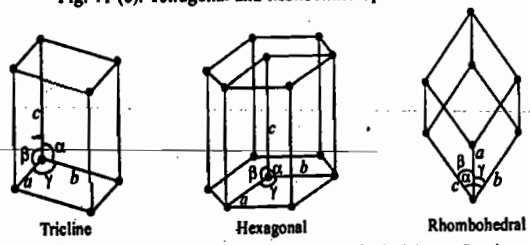

Fig. 11(*d*). Triclinic, Hexagonal and Rhombohedral Space Lattices.

* There is no end centred cubic unit cell.

The actual lattice in a crystal of a given kind consists of a repetition of a unit cell of that kind all over in three-dimensional space. As already mentioned, there can only be a maximum of 32 combinations of elements of symmetry (point groups).

Some detailed descriptions of the seven basic crystal systems and their Bravais lattices are given in Table 2.

TABLE 2

Important Characteristics of the Seven Basic Crystal Systems

Crystal System	Bravais Lattices	Minimum Symmetry Elements	Parameters of Unit Cell	
			Intercepts	Crystal Angles
1. Cubic	Primitive, Face centred, Body centred = 3	Four 3-fold axes Three 4-fold axes	$a=b=c$	$\alpha=\beta=\gamma=90°$
2. Orthorhombic	Primitive, Face centred, Body centred, End centred = 4	Three mutually perpendicular 2-fold axes	$a\neq b\neq c$	$\alpha=\beta=\gamma=90°$
3. Tetragonal	Primitive, Body centred = 2	One 4-fold axis	$a=b\neq c$	$\alpha=\beta=\gamma=90°$
4. Monoclinic	Primitive, End centred = 2	One 2-fold axis	$a\neq b\neq c$	$\alpha=\gamma=90°$ $\beta\neq 90°$
5. Triclinic	Primitive = 1	One 1-fold axis	$a\neq b\neq c$	$\alpha\neq\beta\neq\gamma\neq 90°$
6. Hexagonal	Primitive = 1	One 6-fold axis	$a=b\neq c$	$\alpha=\beta=90°$ $\gamma=120°$
7. Rhombohedral	Primitive = 1	One 3-fold axis	$a=b=c$	$\alpha=\beta=\gamma\neq 90°$
	Total = 14			

The first column gives the name of the crystal system. The second column gives the number and types of space lattices present in the given crystal system. The third column contains information with regard to *minimum symmetry elements* of each system. These are the absolutely essential symmetry requirements of a given crystal system. A crystal belonging to that system may have more symmetry elements but it cannot have less. The unit cell parameters, *viz.*, the intercepts *a*, *b* and *c* and the interfacial angles α, β and γ between the three imaginary axes are given in the last column.

Example 1. A metallic element has a cubic lattice. Each edge of the unit cell is 2·88 Å. The density of the metal is 7·20 g cm^{-3}. How many unit cells will there be in 100 g of the metal ?

Solution : Volume of unit cell $= (2{\cdot}88\ \text{Å})^3 = (2{\cdot}88\times10^{-8}\ \text{cm})^3 = 23{\cdot}9\times10^{-24}\ \text{cm}^3$

$$\text{Volume of 100 g of the metal} = \frac{100\ \text{g}}{7{\cdot}20\ \text{g cm}^{-3}} = 13{\cdot}9\ \text{cm}^3$$

$$\left.\begin{array}{l}\text{Number of the unit cells}\\ \text{in this volume}\end{array}\right\} = \frac{13{\cdot}9\ \text{cm}^3}{23{\cdot}9\times10^{-24}\ \text{cm}^3} = 5{\cdot}82\times10^{23}$$

Example 2. Ferrous oxide (FeO) crystal has a cubic structure and each edge of the unit cell is 5·0 Å. Taking density of the oxide as 4·0 g cm^{-3}, calculate the number of Fe^{2+} and O^{2-} ions present in each unit cell.

Solution : Volume of the unit cell, $V = (5\ \text{Å})^3 = (5\times10^{-8}\ \text{cm})^3 = 1{\cdot}25\times10^{-22}\ \text{cm}^3$

Density of FeO, $\rho = 4{\cdot}0\ \text{g cm}^{-3}$

$\therefore$ Mass of unit cell $= V\times\rho = 1{\cdot}25\times10^{-22}\ \text{cm}^3 \times 4{\cdot}0\ \text{g cm}^{-3} = 5{\cdot}0\times10^{-22}\ \text{g}$

$$\text{Mass of one molecule of FeO} = \frac{\text{Molar mass in grams}}{\text{Avogadro's number}} = \frac{72\ \text{g mol}^{-1}}{6{\cdot}022\times10^{23}\ \text{mol}^{-1}} = 1{\cdot}195\times10^{-22}\ \text{g}$$

$$\therefore\ \text{Number of FeO molecules per unit cell} = \frac{5{\cdot}0\times10^{-22}\ \text{g}}{1{\cdot}195\times10^{-22}\ \text{g}} = 4{\cdot}19 = 4$$

Thus, there are **four Fe^{2+} ions and four O^{2-} ions** in each unit cell.

Example 3. At room temperature, pollonium crystallises in a primitive cubic unit cell. If $a = 3{\cdot}36$ Å, calculate the density of pollonium. Its atomic mass is 209 g mol^{-1}.

Solution : A primitive cubic unit cell contains atoms only at the 8 corners with each corner contributing 1/8th of an atom. Hence, total number of atoms per unit cell $= 8\times(1/8) = 1$.

Volume, $V = a^3 = (3{\cdot}36\ \text{Å})^3 = (3{\cdot}36\times10^{-8}\ \text{cm})^3$

$$\text{From Eq. 1, } \rho = \frac{nM_m}{N_A V} = \frac{(1)(209\ \text{g mol}^{-1})}{(6{\cdot}022\times10^{23}\ \text{mol}^{-1})(3{\cdot}36\times10^{-8}\ \text{cm})^3} = 9{\cdot}15\ \text{g cm}^{-3}$$

Example 4. Lithium borohydride, $LiBH_4$, crystallises in an orthorhombic system with 4 molecules per unit cell. The unit cell dimensions are : $a = 6{\cdot}81$ Å, $b = 4{\cdot}43$ Å and $c = 7{\cdot}17$ Å . If the molar mass of $LiBH_4$ is 21·76 g mol^{-1}, calculate the density of the crystal.

Solution : Density of the crystal, $\rho = nM_m/(N_A V)$ (Eq 1)

$$= \frac{4\times(21{\cdot}76\ \text{g mol}^{-1})}{(6{\cdot}022\times10^{23}\text{mol}^{-1})(6{\cdot}81\times4{\cdot}43\times7{\cdot}17\times10^{-24}\text{cm})^3} = 0{\cdot}668\ \text{g cm}^{-3}$$

Example 5. An organic compound crystallises in an orthorhombic system with two molecules per unit cell. The unit cell dimensions are 12·05, 15·05 and 2·69 Å. If the density of the crystal is 1·419 g cm^{-3}, calculate the molar mass of the organic compound.

Solution : Molar mass, $M_m = \rho N_A V/n$ (Eq. 1)

$$= \frac{(1{\cdot}419\text{g cm}^{-3})(6{\cdot}022\times10^{23}\ \text{mol}^{-1})(12{\cdot}05\times15{\cdot}05\times2{\cdot}69\times10^{-24}\ \text{cm}^3)}{2}$$

$$= 208{\cdot}4\ \text{g mol}^{-1}$$

Designation of Planes in Crystals : Miller Indices

A number of methods have been suggested to represent the various planes in crystals. The method proposed by W.H. Miller is commonly used. In this method, the planes are described by a set of integers (h, k and l) known as **Miller indices.** *The Miller indices of a plane of a crystal are the reciprocals of the fractional intercepts of that plane on the various axes.*

The procedure for determining Miller indices for a plane is as follows :

1. Prepare a three-column table with the unit cell axes at the tops of the columns.
2. Enter in each column the intercept (expressed as a multiple of a, b or c) of the plane with these axes.

Devide these intercepts by the corresponding lengths a, b, c of axis of unit cell to obtain fractional intercepts on the axis.

3. Invert all numbers.
4. Clear fractions to obtain h, k and l.

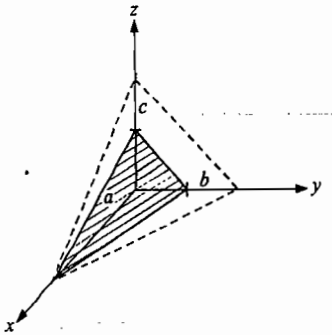

Fig. 12. A plane having Miller indices 122.

The concept of Miller indices may be illustrated as follows :

Consider the shaded plane in Fig. 12. It is clear from the figure that the intercepts of the shaded plane along X, Y and Z axes are :

a $b/2$ $c/2$ and the fractional intercepts are a/a $b/2b$ $c/2c$ or 1 1/2 1/2

$\therefore$ Miller indices (reciprocals of the intercepts) are :

1/1 2/1 2/1 or **1 2 2**

Let us now describe the planes in a cube. It should be remembered that if a plane is parallel to an axis, its intercept with that axis would be infinity. Thus, the Miller index for that plane will be zero ($1/\infty = 0$). For example, consider the shaded plane in Fig. 13. It is clear from the figure that the fractional intercepts of the shaded plane are :

∞ 1 ∞

$\therefore$ Miller indices are

$1/\infty$ 1/1 $1/\infty$ or 0 1 0

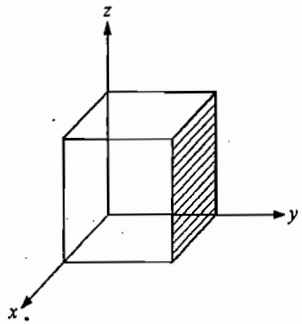

Fig. 13. A plane in a cube having Miller indices 010.

Similarly, the Miller indices of some planes in cubic crystals, shown shaded in Fig. 14 are as given below.

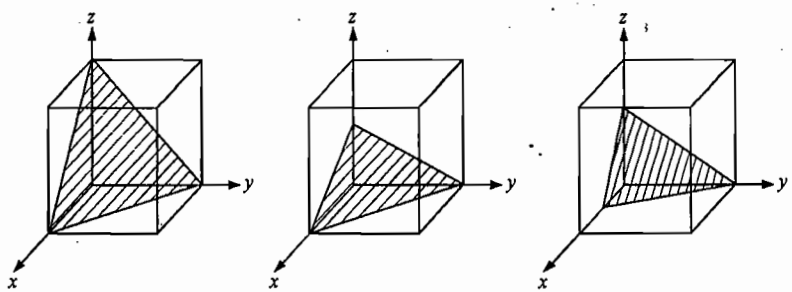

Fig. 14. Miller indices for some planes in cubic crystals.

Fractional intercepts	1	1	1	Fractional intercepts	1	1	1/2	Fractional intercepts	1/3	1	2/3
Miller indices	1/1	1/1	1/1	Miller indices	1/1	1/1	2/1	Miller Indices	3/1	1/1	3/2
	1	**1**	**1**		**1**	**1**	**2**		**6**	**2**	**3**

Example 6. Calculate the Miller indices of crystal planes which cut through the crystal axes at (*i*) (2*a*, 3*b*, *c*) (*ii*) (*a*, *b*, *c*) (*iii*) (6*a*, 3*b*, 3*c*)

Solution : Following the procedure given above, we prepare the table as follows :

(*i*)	*a*	*b*	*c*	
	2	3	1	Fractional Intercepts
	1/2	1/3	1	Reciprocals
	3	2	6	Clear fractions

Hence, the Miller Indices are (326).

(*ii*)	*a*	*b*	*c*	
	1	1	1	Fractional Intercepts
	1	1	1	Reciprocals
	1	1	1	Clear fractions

Hence, the Miller indices are (111).

(iii)

	a	b	c	
	6	3	3	Fractional Intercepts
	1/6	1/3	1/3	Reciprocals
	1	2	2	Clear fractions

Hence, the Miller indices are (122).

Types of Crystals

It is convenient to classify crystals into the following four types depending upon the nature of the units which occupy the lattice points.

1. **Ionic crystals** in which the units are positively and negatively charged ions.
2. **Covalent crystals** in which the units are atoms.
3. **Metallic crystals** in which the units are metal atoms bonded by metallic bonds.
4. **Molecular crystals** in which the units occupying the lattice points are molecules.

1. Ionic Crystals. In ionic crystals, the units occupying lattice points are positive and negative ions. In sodium chloride, for example, the units are Na^+ ions and Cl^- ions. These ions are held together by coulombic forces of attraction. X-ray studies have shown that in ionic crystals, each ion is surrounded by a number of ions of opposite charge. For example, in NaCl, each Na^+ ion is surrounded by six Cl^- ions and each Cl^- ion is surrounded by six Na^+ ions. Some other common ionic crystals are KNO_3, Na_2SO_4, etc. The coulombic forces of attraction between the oppositely charged ions are very strong and, therefore, the amount of energy required to separate ions from one another is very high. Accordingly, the **ionic crystals** have the following **characteristics :**

1. The heats of vaporisation of ionic crystals are high.
2. The vapour pressures of ionic crystals at ordinary temperatures are very low.
3. The melting and boiling points of ionic crystals are very high.
4. Ionic crystals are hard and brittle.
5. Ionic crystals are insulators in the solid state. The reason is that ions are entrapped in fixed places in the crystal lattice and cannot move when electric field is applied. However, when melted they become good conductors of electricity. This is due to the fact that in the molten state, the well-ordered arrangement of ions in the crystal is destroyed and the ions are in a position to move about freely in the liquid medium when an electric field is applied.
6. Ionic crystals are soluble in water and also in other polar solvents. They are insoluble or very slightly soluble in non-polar solvents such as benzene and carbon tetrachloride.
7. Ionic crystals are good conductors of electricity when dissolved in water. The ions held by coulombic forces fall away from one another when dissolved in water or in any other solvent having high dielectric constant. This is in accordance with the Coulomb's law that forces of attraction between oppositely charged particles vary inversely as the dielectric constant.

2. Covalent Crystals. The lattice in covalent crystals consists of atoms linked together by a continuous system of covalent bonds. The covalent bonds extend in two or three dimensions forming a giant interlocking structure called *network*. **Diamond** furnishes a good example of a covalent crystal. Its structure is represented in Fig. 15.

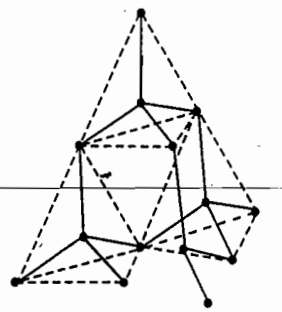

Fig. 15. Structure of diamond.

Each carbon atom in this structure is bonded to *four* other carbon atoms through sp^3 hybrid bonds. Thus, each carbon atom (with complete outer electron octet) is surrounded by four others which lie at the four corners of a regular tetrahedron. This gives rise to a *rigid three-dimensional network*. This is also the reason why diamond is the hardest substance known, with a high density and melting point. The entire crystal is regarded as one large carbon molecule and is called a **macromolecule**. The other examples of covalent crystals are silicon carbide (SiC), quartz (SiO_2) and boron nitride (BN).

The important **characteristics of covalent crystals** are given below.

1. There is a continuous network of covalent bonds forming a giant three-dimensional structure as in diamond and quartz.
2. Due to multi-dimensional network, covalent crystals have generally high melting points.
3. Covalent crystals are generally poor conductors of electricity.
4. They are generally hard. In fact, diamond is the hardest substance known.
5. Covalent crystals are insoluble in polar solvents.
6. Covalent crystals have generally high heats of fusion and low coefficients of expansion.

3. Metallic Crystals. As discussed earlier (Chapter 4), a metallic crystal consists of an assemblage of atoms held together by metallic bonds. The force of attraction between the atoms due to the metallic bond is sufficiently strong and is thus responsible for a compact solid structure of metals.

The important **characteristics of metallic crystals** are given below.

1. Metallic crystals are good conductors of heat and electricity.
2. Most of the metals are quite hard and tough.
3. Metals are malleable and ductile. Due to malleable nature of metals, they can be beaten into sheets and drawn into wires.
4. They exhibit lustre, especially when freshly cut.
5. Except alkali metals, they have very high melting and boiling points.
6. Metals also possess elasticity.
7. Metals have high tensile strength, *i.e.*, they can resist stretching without breaking.

4. Molecular Crystals. In molecular crystals, the lattice positions are occupied by molecules which do not carry any charge. The forces binding the molecules together are of two types : (*i*) *Dipole-dipole forces* (*ii*) *van der Waals forces*. Dipole-dipole forces occur in crystals which consist of polar molecules. Thus, in the case of water molecules (in ice or even in liquid state), the negative end of one molecule attracts the positive end of a neighbouring molecule, as shown in Fig. 16.

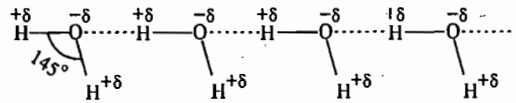

Fig. 16. Dipole-dipole forces of attraction between water molecules.

The van der Waals forces are more general and occur in all kinds of molecular crystals. Both types of molecular forces mentioned above are much weaker than the coulombic forces of attraction between oppositely charged ions existing in ionic crystals. The binding energy in molecular crystals, therefore, is considerably less than in ionic crystals. Accordingly, the **heat of vaporisation**, *i.e., the energy required to separate molecules from one another* in a molecular crystal is very low in comparison to the value for ionic or covalent crystals.

The important **characteristics of molecular crystals** are given below.

1. Molecular crystals are generally soft.
2. They have low melting and boiling points.
3. They are bad conductors of electricity because they consist of neutral molecules in solid as well as in dissolved state.
4. They are volatile and have low heats of vaporisation.

Close Packing of Identical Solid Spheres

In order to understand the packing of atoms, molecules or ions in crystals, let us consider the packing of hard spheres of equal size in two dimensions, *i.e.*, in a layer and extend the arrangement to three dimensions by putting such layers above one another. There can be a number of possible arrangements but the one in *which maximum available space is occupied will be economical*. Such an arrangement is called *close packing*. Hence, the closer the packing, the greater is the stability of the packed system.

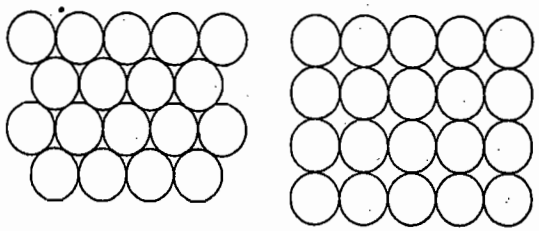

Fig. 17. Two common ways of packing of spheres of equal size. In arrangement I, 60·4% of the volume is occupied and in arrangement II, 52·4% of the volume is occupied.

There are two common ways of packing spheres of equal size in a layer. These are shown in Fig. 17.

A comparison of the two ways of packing of spheres shows that in arrangement I, the spheres are more closely packed than in arrangement II. It has been calculated that in the first arrangement, 60·4% of the available space is occupied by the spheres. The remaining 39·6% of the space is empty and is called **void volume**. In the second arrangement, only 52·4% of the space is filled and 47·6% of the space is empty. Thus, the arrangement I is more economical and it represents a *close packing of spheres*.

It can be seen that in the close packing arrangement, the spheres arrange themselves in such a way that their centres are at the corners of an equilateral triangle. Each sphere is in contact with six other similar spheres shown shaded in Fig. 18. *The number of nearest neighbours with which a given sphere is in contact is called the* **coordination number**. Thus, the coordination number of each sphere packed in the above manner in a layer is 6.

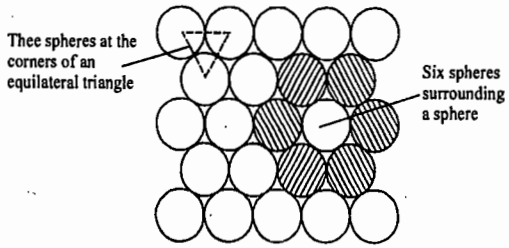

Fig. 18. Close packing of spheres.

The above arrangement can be extended in three dimensions by placing other closest packed layers on the top of hollows (or voids) of the first layer. Let us label the first layer as *A* layer.

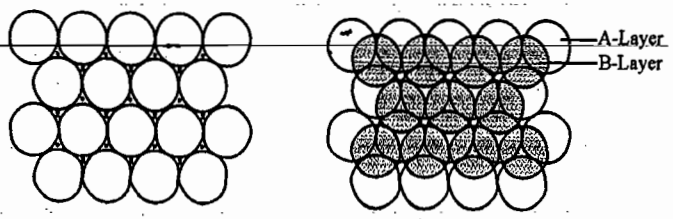

Fig. 19. Building of second layer (*B*, shown shaded) covering hollows marked by dots (·). The hollows marked by crosses (×) remain unoccupied.

There are two types of hollows in the first layer

which are marked by dots (·) and crosses (x). All the hollows are equivalent but the spheres of second layer may be placed either on hollows which are marked by dots or on other set of hollows marked by crosses. It may be noted that it is not possible to place spheres on both types of hollows simultaneously. Let us place spheres on hollows marked by dots to make the second layer which may be labelled as *B* layer (Fig. 19)

When we come to packing of third layer, there are two alternative ways. One way is to put the spheres of third layer on the hollows of the second layer. In that case it is observed that each sphere of third layer (shown as dark spheres in Fig. 20) lies directly above those in the first layer. In other words, the third layer becomes identical to the first layer. This arrangement if continued indefinitely in the same sequence, is represented as *ABABABA*.....

This arrangement of layers, *viz.*, *ABABABA*.... is shown more clearly in Fig. 20(*b*). On examination, this arrangement is found to represent **hexagonal close packing** symmetry. This is abbreviated as ***hcp***. This means that the structure has one 6-fold axis of symmetry. This is illustrated in Fig. 20(*c*). The same or similar appearance is repeated on rotating the crystal through an angle of 60°. It may be noted that the symmetry axis is perpendicular to the layers of close packed spheres.

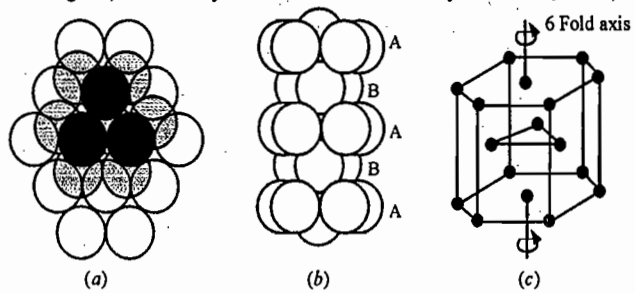

Fig. 20. *ABABABA*..... system of close packing or hexagonal close packing (*hcp*) of spheres.

The second way to pack spheres in third layer is to place them over the unoccupied hollows of the first layer marked by crosses. This will give a different type of close-packed arrangement (Fig. 21*a*). However, it can be shown that now the spheres in the fourth layer will correspond with those in the first layer. This arrangement of stacking, if continued indefinitely, is represented as *ABCABCABCA*... (Fig. 21 *b*). The resulting arrangement has cubic symmetry and, consequently, it is referred to as **cubic close packing** of spheres and is abbreviated as ***ccp***. According to Table 2, this structure has four **3-fold axes** of symmetry which pass through the diagonals of the cube. A closer study of *ABCABC*... system of close packing also shows that there is a sphere at the centre of each face of the unit cube and hence this structure is also known as **face centred cubic structure**. The face-centred cubic arrangement has been shown more clearly in Fig. 21(*c*).

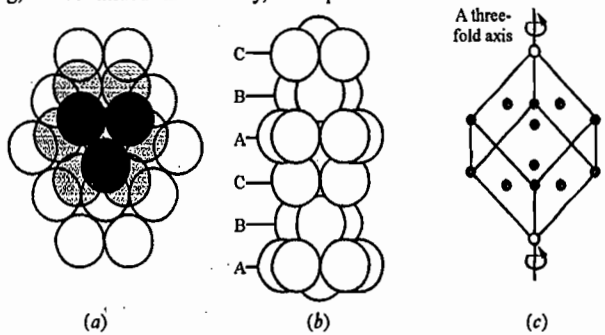

Fig. 21. *ABCABCA*.... system of close packing or cubic close packing (*ccp*) of spheres.

It may be noted that in both the types of structures discussed above, each sphere is surrounded by twelve other spheres. For example, a sphere marked x is in contact with six nearest spheres (marked 1, 2, 3, 4, 5 and 6) in the same layer, as shown in Fig. 22. In addition to this, the sphere marked x is also in contact with three spheres (marked 7, 8, 9) in the layer above and three spheres (marked 10, 11, 12) in the layer

below (shown at some distance for the sake of clarity). Thus, the coordination number in the *hcp* as well as in the *ccp* structure is 12.

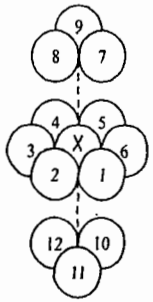

Fig. 22. Coordination number in *hcp* and *ccp* structures.

In addition to the above two close packed arrangements, another arrangement of packing of spheres is the **body centred cubic arrangement**. In this arrangement, the spheres in the first layer of close packing are slightly opened up. As a result, the spheres are not in contact with each other. This is shown in Fig. 23. To build the second layer (shown by dotted spheres in Fig. 23*a*), the spheres are placed at the top of hollows in the first layer. Each sphere in the second layer is in contact with four spheres of the first layer. In the third layer, spheres are placed exactly above the first layer. Thus, each sphere in this system of close packing is in contact with eight spheres, four in the layer below it and four in the layer above it. In other words, coordination number of each sphere is 8. In this arrangement, as can be easily visualised, there are eight spheres at the corners of a cube and one sphere is in the centre (or body) of the cube. Therefore, the structure is known as **body centred cubic** and is abbreviated as ***bcc***.

It can be shown by simple geometry that while the volume occupied in *ccp* arrangement is 74%, that in *bcc* arrangement is 68% of the total volume (see below).

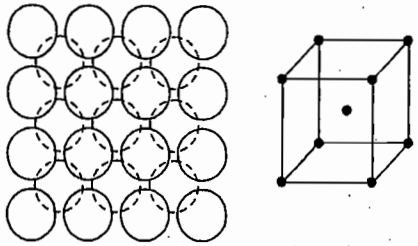

Fig. 23. Body centred cubic packing of spheres.

Volume occupied in *ccp* arrangement. Consider the cubic close packed arrangement, as shown in Fig. 24*. Let the length of each side be a so that the volume of the cube is a^3. Let us now calculate the volume occupied by spheres.

As shown in the figure, there are eight spheres at the corners and six spheres at the faces. But, each sphere at the corner is shared by eight unit cells and its contribution per unit cell is 1/8. Similarly, each sphere in the face is shared by two unit cells and its contribution per unit cell is 1/2 . Thus, the number of spheres per unit cell $= 8\times(1/8) + 6\times(1/2) = 4$.

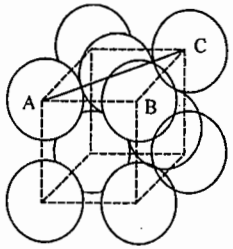

Fig.24. Volume occupied in *ccp* arrangement. Only one face centred sphere is shown here.

Consider Δ ABC. Since it is a right angled triangle, hence

$$AC^2 = AB^2 + BC^2 = a^2 + a^2 = 2a^2$$

$\therefore$ Face diagonal, $AC = \sqrt{2}a$

But, as is evident from the figure, $AC = 4r$ where r is the radius of the sphere.

$$\therefore \quad 4r = \sqrt{2}a \quad \text{or} \quad r = \sqrt{2}\,a/4$$

Since, as mentioned above, there are 4 spheres per unit cell, hence the volume occupied by 4 spheres

$$= 4\times 4/3\,\pi r^3 = 4\times 4/3\,\pi(\sqrt{2}a/4)^3$$

$$\text{Ratio of the volume occupied to total volume} = \frac{\text{Volume occupied by spheres}}{\text{Volume of the cube}}$$

$$= \frac{4\times 4/3\times 22/7\times(\sqrt{2}a/4)^3}{a^3} = 0{\cdot}7406$$

Thus, the volume occupied in *ccp* arrangement = 74·06%

*This is the simplified representation of the arrangement. Actually all the spheres in a face are touching one another. Each face has four spheres at its edges and one sphere in the middle.

Volume occupied in *bcc* arrangement. Consider the body-centred cubic arrangement, as shown in Fig. 25**. As before, let the length of each side be a so that the volume of the cube is a^3.

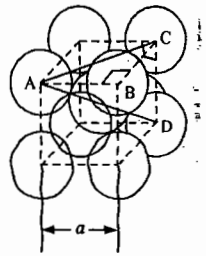

Fig. 25. Volume occupied in *bcc* arrangement.

It is clear from the figure that there are eight spheres at the corners and one in the body of the unit cell. But, each sphere at the corner is shared by eight unit cells and its contribution per unit cell is 1/8. However, the sphere at the body centre of the cube contributes fully to the cube. Thus,

The number of spheres per unit cell $= 8\times(1/8) + 1 = 2$ ...(*i*)

In right angled triangle ABC, $AC^2 = AB^2 + BC^2 = a^2 + a^2$

or $AC^2 = 2a^2$ or $AC = \sqrt{2}a$ ...(*ii*)

Similarly, in right angled triangle ACD, $AD^2 = AC^2 + CD^2 = (\sqrt{2}a)^2 + a^2 = 3a^2$

or $AD = \sqrt{3}a$ ...(*iii*)

But, as is evident from the figure,

the body diagonal $AD = 4r$

where r is the radius of the sphere. ...(*iv*)

From Eqs. (*iii*) and (*iv*), $4r = \sqrt{3}a$ or $r = \sqrt{3}a/4$

Since there are 2 spheres per unit cell (Eq. (*i*), hence,

Volume occupied by 2 spheres $= 2\times 4/3\pi r^3 = 2\times 4/3\times 22/7\times(\sqrt{3}a/4)^3$

Ratio of volume occupied to total volum $= 2\times 4/3\times 22/7\times(\sqrt{3}a/4)^3/a^3 = 0{\cdot}6805$

Thus, the volume occupied in *bcc* arrangement = 68·05%

Interstitial Sites in Close Packing of Spheres

We have seen before that even in the closest packing of spheres, there is some empty space left in between the spheres. This is known as an interstitial site. For example, when the spheres are closely packed in a single plane, the centres of three adjacent spheres lie at the vertices of an equilateral triangle. In between these three spheres, there is some empty space. This empty space (hole or void) is called **triangular** or **trigonal site**. In addition to this, we come across two more common interstitial sites, *viz.*, *tetrahedral* and *octahedral sites*, in closely packed lattices. These are discussed below.

Tetrahedral Sites. If one sphere is placed upon three other spheres which are touching one another, *tetrahedral structure* results. This is shown in Fig. 26. Since the four spheres touch one another at one point only, they leave a small space in between which is called a **tetrahedral site.** The size of the site is much smaller than that of the spheres. However, the bigger the spheres, the larger is the size of the tetrahedral site formed by them. We have seen already that in *hexagonal close packing* (*hcp*) as well as *in cubic close packing* (*ccp*) arrangement, *each sphere* is in contact with *three spheres* in the layer *above* and *three spheres* in the layer *below*. Thus, there would be *two tetrahedral sites associated with each sphere*. One of these sites will be immediately above and the other immediately below the sphere. It may be noted that tetrahedral site does not mean that the shape of

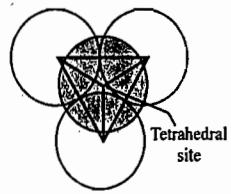

Fig. 26. A tetrahedral site.

**This is the simplified representation of the arrangement. All the spheres in a face are not only touching one another but are also touching the sphere at the centre of the cube.

the site is tetrahedral but it indicates that this site is surrounded by four spheres and the centres of these four spheres lie at the apices of a regular tetrahedron. It is this tetrahedral arrangement of the spheres which gives tetrahedral name to this site.

Octahedral Sites. Another type of interstitial site formed by close packing of spheres in *hcp* as well as in *ccp* systems is called an **octahedral site.** This interstitial site is formed at the *centre of six spheres,* the centres of which lie at the apices of a regular octahedron, as illustrated in Fig. 27.

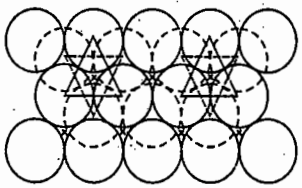

Fig.27. Octahedral interstitial sites formed by close packing of spheres in *hcp* as well as in *ccp* arrangement.

The figure shows two layers of close-packed spheres. The full circles represent the spheres in one plane while the dotted circles represent those in second plane. Two triangles have been drawn. One of these joins the centres of three spheres in one plane while the second (dotted lines) joins the centres of three spheres in the second plane. The octahedral sites, marked by x, are formed where two triangles of different layers are superimposed one above the other. In this position, the apices of these triangles point in opposite direction, as shown. Thus, each octahedral site is created, by two equilateral triangles with apices in opposite direction.

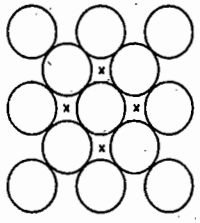

Fig. 28. Cross-section of octahedral interstitial sites in a face centred cubic lattice.

One of the faces of a cubic close packed (*ccp*) lattice is shown in Fig. 28. The cross sections of octahedral sites formed in this lattice are marked by x in the figure.

Sizes of Interstitial Sites in Ionic Crystals. Limiting Radius Ratios

In general, the size of a trigonal site is smaller than the size of a tetrahedral site which, in turn, is smaller than the size of an octahedral site. Further, the size of a site varies with the size of the spheres surrounding it. In the case of ionic crystals, the radius of a cation which may occupy a given site created by anionic spheres can be calculated by simple geometry. This has been done in terms of the ratio of the radius of cation to that of anion (r_+/r_-), also known as **radius ratio.**

In order to acquire minimum energy, the ions are close-packed in such a way that each ion is surrounded by as many ions of opposite charge as possible. The number of ions surrounding an oppositely charged ion is known as the *coordination number*, as already mentioned. The higher the coordination number, the greater would be the stability of the ionic compound, in general.

Only that particular structure will be adopted by the ionic compound which gives it the lowest energy or maximum stability. The energy of an ionic crystal is mainly determined by the resultant of the *energy of attraction* between the cations and anions and *energy of repulsion* between the anions surrounding the cation. Energy of attraction would, evidently, increase with the coordination number of the cation. The energy of repulsion would increase when anions of the same size and charge are squeezed together because the electron charge clouds of the squeezed ions would repel one another.

As already mentioned, the internuclear distance r is taken as the sum of the radii of cations and anions. If cations and anions do not touch each other (*i.e.*, the interstitial site formed by anions is too big for cations, then the internuclear distance would increase and the energy of attraction would decrease.

Thus, the optimum arrangement of cations and anions would be the one in which the required number of anions touch a cation without being squeezed. Such an arrangement would be of minimum energy and maximum stability. The limiting radius ratios for various types of ionic arrangements in crystals are determined by keeping the above principle in view.

a. Limiting radius ratio for trigonal site. A trigonal site is formed when the three anions represented by spheres lie at the vertices of an equilateral triangle and a cation, represented by a small sphere, occupies the trigonal site (Fig. 29). Let r_+ and r_- be the radii of the cation and the anion, respectively. As is evident from the figure, in equilateral triangle EBC,

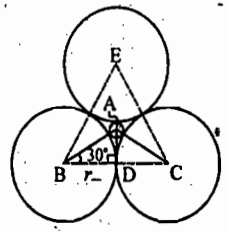

Fig. 29. Size of a trigonal site.

$$BC = CE = BE = 2r_-$$

If A is the centre of the triangle (and hence of the cation), then

$$BD = r_- \text{ and } AB = r_+ + r_-$$

In right angled triangle BDA, cos ∠ABD

$$= BD/AB, \text{ i.e., } \cos 30° = r_-/(r_- + r_+)$$

$$\text{Since } \cos 30° = \sqrt{3}/2, \text{ hence } \sqrt{3}/2 = r_-/(r_- + r_+)$$

On inverting both sides, $2/\sqrt{3} = (r_- + r_+)/r_- = 1 + (r_+/r_-)$

$$\therefore \quad r_+/r_- = 2/\sqrt{3} - 1 = 0{\cdot}155$$

Thus, the **limiting r_+/r_- ratio** for trigonal site is **0·155**.

b. Limiting radius ratio for tetrahedral site. A tetrahedral site is formed by placing one sphere over three spheres which are touching one another. In an ionic crystal such a site can be created by placing the anions at the alternate corners of a cube. Let the cation occupy the tetrahedral site. Suppose a is the length of each side of the cube and r_- and r_+ are the radii of anion and cation, respectively. For simplicity, the cations and anions are shown by separated spheres (Fig. 30). Actually the cations and anions are touching one another so that

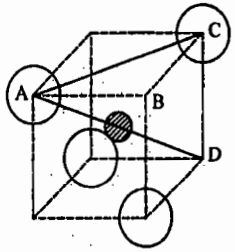

Fig. 30. A tetrahedral site. The spheres actually touch one another though not shown so in the figure for the sake of simplicity.

$$AC = 2r_- \text{ and } AD = 2AO = 2(r_+ + r_-)$$

As can be seen from the figure, the face diagonal,

$$AC = \sqrt{AB^2 + BC^2} = \sqrt{a^2 + a^2} = \sqrt{2}\,a$$

$$\therefore \quad 2r_- = \sqrt{2}\,a$$

or $$r_- = \sqrt{2}\,a/2 = a/\sqrt{2} \qquad ...(i)$$

As is also evident from the figure, the body diagonal

$$AD = \sqrt{AC^2 + CD^2} = \sqrt{2a^2 + a^2} = \sqrt{3}\,a \qquad ...(ii)$$

The cation is present at the centre of the body diagonal AD so that half the length of this diagonal is equal to the sum of the radii of the anion and the cation. Thus,

$$r_- + r_+ = AD/2 = \frac{\sqrt{3}\,a}{2} \qquad ...(iii)$$

Dividing Eq. (*iii*) by (*i*), we get

$$(r_- + r_+)/r_- = (\sqrt{3}\,a/2) \times (\sqrt{2}/a) = \sqrt{3}/\sqrt{2}$$

or $$r_+/r_- = (\sqrt{3}/\sqrt{2}) - 1 = (\sqrt{3} - \sqrt{2})/\sqrt{2}$$

$$= (1{\cdot}732 - 1{\cdot}414)/1{\cdot}414 = 0{\cdot}225$$

Thus, the **limiting r_+/r_- ratio** for tetrahedral site is **0·225**

If the radius ratio is less than 0·225, then either the anion is too big or the cation is too small in size. In either case, the anions will have to be squeezed so that the anions and the cation just touch one

another. The squeezing of anions would increase the repulsion between them and, as a result, *the tetrahedral arrangement would become less stable.* The squeezing of anions can be avoided by decreasing the number of anions surrounding the cation, *i.e.*, by decreasing the coordination number of the cation. This would change the structure of the crystal from tetrahedral to planar trigonal. Thus, *the crystal would have a trigonal structure if the radius ratio is less than* 0·225.

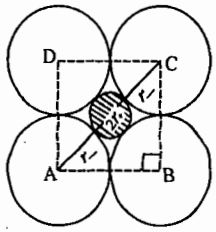

Fig. 31. An octahedral site. Only a cross-section through octahedral site is shown.

c. Limiting radius ratio for octahedral site. An octahedral site is shown in Fig. 31. A cross-section through an octahedral site shows that the four anions are at the corners of a square and the cation is at the centre. One anion at the top and one anion at the bottom of the plane formed by the four anions also touch the cation (the two anions at the top and at the bottom of the plane are not shown in the figure). Suppose each side of the square is a and r_- and r_+ are the radii of the anion and cation, respectively. In right angled triangle ABC,

$$AC = \sqrt{AB^2+BC^2} = \sqrt{a^2+a^2} = \sqrt{2}a$$

But, $$AC = r_- + 2r_+ + r_- = 2r_- + 2r_+$$

$$\therefore \quad 2r_- + 2r_+ = \sqrt{2}a$$

or $$r_- + r_+ = \sqrt{2}\, a/2 \qquad ...(i)$$

As is evident from the figure, $AB = a = 2r_-$

or $$r_- = a/2 \qquad ...(ii)$$

Dividing Eq. (*i*) by (*ii*), we get

$$(r_- + r_+)/r_- = \sqrt{2}a/2\times 2/a = \sqrt{2}$$

or $$r_+/r_- = 1{\cdot}414 - 1 = 0{\cdot}414$$

Thus, the **limiting** r_+/r_- **ratio** for octahedral site is **0·414.**

If the radius ratio is less than 0·414, then either the anion is too big or the cation is too small in size. In either case, the anions shall have to be squeezed so that the cation and the anions just touch one another. This would increase the repulsion between the anions and destabilise the octahedral arrangement of anions. The squeezing of anions can be avoided by decreasing the coordination number of the cation. In other words, the system would prefer to change from octahedral to tetrahedral arrangement of anions. Thus, *ionic crystals with radius ratio less than 0·414 would tend to have a tetrahedral structure.*

d. Limiting radius ratio for cubic site. Consider a cubic site, as shown in Fig. 32. The spheres are not shown touching one another for the sake of clarity. Suppose the length of each side of the cube is a and r_- and r_+ are the radii of the anion and the cation, respectively.

As is evident from the figure, $AB = 2r_- = a$

or $$r_- = a/2 \qquad ...(i)$$

Length of the face diagonal $AC = \sqrt{AB^2+BC^2} = \sqrt{a^2+a^2} = \sqrt{2}\, a$

Length of body diagonal $AD = \sqrt{AC^2+CD^2}$

$$= \sqrt{(\sqrt{2}\,a)^2+a^2} = \sqrt{3}\, a$$

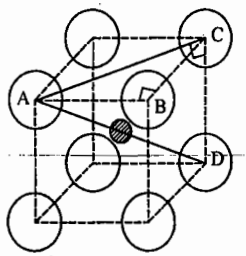

Fig. 32. A cubic site. The spheres are not shown touching for simplicity.

But, the length of the body diagonal $AD = r_- + 2r_+ + r_- = 2r_- + 2r_+$

or $$r_- + r_+ = \sqrt{3}a/2 \qquad ...(ii)$$

Dividing Eq. (*ii*) by (*i*), we get,

$$(r_- + r_+)/r_- = \sqrt{3}\, a/2\times 2/a = \sqrt{3}$$

or $$r_+/r_- = \sqrt{3} - 1 = 1{\cdot}732 - 1 = 0{\cdot}732$$

Thus, the **limiting** r_+/r_- **ratio** for cubic site is **0·732.**

If the radius ratio is less than 0·732, then, as discussed in earlier cases, the arrangement would become unstable. The coordination number of the cation would, therefore, tend to decrease to stabilise the system. In other words, the system would prefer to change from cubic to octahedral arrangement of anions. Thus, *ionic crystals with radius ratios less than* 0·732 *would tend to adopt an octahedral geometry.*

Determination of Ionic Radii. In the ordinary sense, **ionic radius** may be defined as *the distance from the nucleus of an ion up to which the nucleus has influence on the electron charge cloud.* The electron charge cloud, no doubt, may extend theoretically up to a very large distance. Nevertheless, it is essential to characterise the radius of each ion by some specific value. For this purpose, the internuclear distance in an ionic compound is determined from X-ray measurements. *This distance is then taken as the sum of the radii of the two ions involved.* For example, the distance between the nuclei of Na^+ and F^- ions is found from X-ray studies of NaF crystals to be 2·31 Å. Thus, $r_{Na^+} + n_{F^-} = 2{\cdot}31$ Å. The problem remains unsolved unless the radius of one of the ions is known. Several solutions have been suggested in this context. One proposed by Pauling has been most widely followed. He selected four ionic solids, namely NaF, KCl, RbBr and CsI. In each salt, as can be seen, *the cation and anion are iso-electronic, i.e.*, they have the same number of electrons which correspond to a noble gas configuration. In NaF, for example, both Na^+ and F^- ions have 10 electrons each and have $1s^2 2s^2 p^6$ configuration which is the same as that of neon. Pauling proposed that in ionic compounds formed by iso-electronic ions, *the ratio of the two ionic radii should be inversely proportional to the ratio of the effective nuclear charges of the two ions.* The effective nuclear charge (Z_{eff}) is obtained by subtracting a screening constant from the actual nuclear charge. The value of screening constant is evaluated from **Slater's rules**, as discussed in details in Chapter 1. According to these rules, the effective nuclear charges of Na^+ and F^- ions at their perpheries come out to be 6·5 and 4·5, respectively. Hence, according to Pauling's rule

$$\frac{r_{Na^+}}{r_{F^-}} = \frac{Z_{eff}(F^-)}{Z_{eff}(Na^+)} = \frac{4{\cdot}5}{6{\cdot}5} \qquad ...(i)$$

Also, we know that $$r_{Na^+} + r_{F^-} = 2{\cdot}31 \text{ Å} \qquad ...(ii)$$

From Eqs. (*i*) and (*ii*) $$r_{Na^+} = 0{\cdot}95 \text{ Å} \quad \text{and} \quad r_{F^-} = 1{\cdot}36 \text{ Å}$$

Following this procedure, the radii of most of the cations and anions have been determined. The radii of some of the univalent cations and anions, thus calculated, are given in Table 3. These values are quite close to the experimentally observed values for these ions (see Table 7, Chapter 2).

TABLE 3

Calculated Radii of Some Univalent Cations and Anions

Ion	Radius (Å)	Ion	Radius (Å)
Li^+	0·60	Au^+	1·37
Na^+	0·95	Ag^+	1·26
K^+	1·33	F^-	1·36
Rb^+	1·48	Cl^-	1·81
Cs^+	1·69	Br^-	1·95
Cu^+	0·96	I^-	2·16

Example 7. The internuclear distance in KCl is 3·44 Å. Calculate the radii of K^+ and Cl^- ions.

Solution : Since K^+ and Cl^- ions are iso-electronic having 18 electrons each, Pauling's rule can be applied.

According to Slater's rules (cf. Chapter 1),

$$Z_{eff}(K^+) \text{ at the periphery of the ion} = 19 - (8\times0{\cdot}35 + 8\times0{\cdot}85 + 2\times1) = 19 - 11{\cdot}60 = 7{\cdot}40$$

$$Z_{eff}(Cl^-) \text{ at the periphery of the ion} = 17 - (8\times0{\cdot}35 + 8\times0{\cdot}85 + 2\times1) = 17 - 11{\cdot}60 = 5{\cdot}40$$

According to Pauling's rule,

$$\frac{r_{K^+}}{r_{Cl^-}} = \frac{Z_{eff}(Cl^-)}{Z_{eff}(K^+)} = \frac{5{\cdot}40}{7{\cdot}40} \quad ...(i)$$

$$r_{K^+} + r_{Cl^-} = 3{\cdot}44 \text{ (given)} \quad ...(ii)$$

From Eqs. (*i*) and (*ii*),

$$r_{K^+} = 1{\cdot}40 \text{ Å and } r_{Cl^-} = 1{\cdot}94 \text{ Å}$$

Radius Ratio Rule and the Shape of Ionic Crystals

As discussed before, in ionic crystals, the coordination numbers of ions as well as the geometric shapes of crystals depend very largely on the relative sizes of the ions, *i.e.*, on their radius ratios.

In order to study the role played by this ratio in determining the coordination number and the shape of an ionic crystal let us suppose that the coordination number of ion A^+ in an ionic compound AX_3 is 3. Thus, three X^- ions will be in contact with one A^+ ion. This may be represented as in Fig. 33(*a*). Such a structure will be quite stable because the positive ion (A^+) finds three negative ions (X^-) immediately in contact with it. The forces of attraction will be quite strong. At the same time, the negative ions are not at all in contact with one another. The forces of repulsion, therefore, will be quite small. The limiting case of stability with coordination number 3 arises when the negative ions (X^- ions) are in contact with each other, as shown in Fig. 33(*b*). The positive ion, no doubt, is still touching the negative ions and the force of attraction is quite strong. But the negative ions are also touching one another and, therefore, the force of repulsion is stronger than before. As already shown, in such a case, the radius ratio r_+/r_- is 0·155. If the ratio r_+/r_- falls below this value (*i.e.*, if A^+ ion becomes still smaller), the structure will be as shown in Fig. 33(*c*). The positive ion is *not* touching any of the negative ions now. The force of attraction, therefore, is weak. At the same time, the negative ions are in direct contact with one another. The force of repulsion, therefore, will be strong. Hence, such a structure is unstable and, therefore, cannot exist. Evidently, for coordination number 3, the lowest, *i.e.*, the limiting radius ratio r_+/r_- is 0·155.

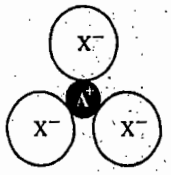

Fig. 33(*a*). A case of stable structure of ionic compound AX_3 with coordination number of A^+ ion 3.

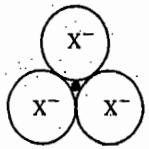

Fig. 33(*b*). Limiting case of stable structure of ionic compound AX_3 with coordination number of A^+ ion 3.

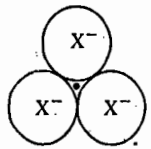

Fig. 33(*c*). Unstable structure of ionic compound AX_3 with coordination number of A^+ ion 3.

Similarly, the limiting radius ratio for the cations to fit in a tetrahedral site is 0·225. In other words, for the radius ratios r_+/r_- ranging between 0·155 to 0·225, trigonal site will be preferred in which the coordination number of cation is 3.

Likewise, as already shown, the limiting radius ratio for the cations to fit into an octahedral site of anions is 0·414. Therefore, tetrahedral sites (C.N. of cation 4) will be preferred between the radius ratio

range 0·255 to 0·414 . In the range 0·414 to 0·732 , octahedral sites (C.N. of cation 6) will be adopted by the cations while above 0·732, cubic sites (C.N. of cation 8) will be favoured.

Thus, *we find that radius ratio is a very important factor in determining the most stable form of arrangement of ions in the crystal lattice of an ionic crystal.*

The permitted coordination numbers and structural arrangements of anions around cations for different r_+/r_- ratios are given in Table 4.

TABLE 4

Limiting Radius Ratios and Shapes of Crystals

Limiting Radius Ratios, r_+/r_-	Permitted Coordination Number	Structural Arrangement	Example
0·155 – 0·225	3	Plane trigonal	Boron oxide
0·255 – 0·414	4	Tetrahedral	ZnS
0·414 – 0·732	6	Octahedral	NaCl
0·732 – 1·00	8	Cubic	CsCl

It would be useful to remember that

In the case of **crystals of the type AB,** if the radius ratios is 0·732 or above, the crystal would have **CsCl type structure,** *i.e., body centred cubic structure in which each ion has a coordination number 8.* If the ratio is less than 0·732 but equal to or greater than 0·414 , the crystal would have **NaCl type structure** *in which each ion has a coordination number 6.* If the ratio is less than 0·414 but equal to or higher than 0·225, the crystal would have a **ZnS type structure** *in which each ion has a coordination number 4.* Lastly, if the ratio is less then 0·225 but equal to or higher than 0·155, the crystal would adopt a **planar trigonal structure** *in which the coordination number of each ion is 3.*

In the case of **crystals of the type AB_2,** if the radius ratio is 0·732 or above, the crystal would have **flourite (CaF_2) type structure** *in which coordination number of cation is 8 and that of anion is 4.* If the ratio lies between 0·414 and 0·732 , the crystal would adopt **rutile (TiO_2) type structure** *in which coordination number of cation is 6 and that of anion is 3.*

Thus, with the help of radius ratios, it is possible to predict the shapes of ionic crystals. Since cations are commonly monovalent and divalent, the ionic crystals are commonly of the type AB and AB_2.

Further Application of Radius Ratio Rule. Some further applications of radius ratio rule have been discussed below.

1. The radius of Na^+ ion is 0·95 Å and that of Cl^- ion is 1·81 Å. Hence, the radius ratio

$$\frac{r_+}{r_-} = \frac{r_{Na^+}}{r_{Cl^-}} = \frac{0{\cdot}95}{1{\cdot}81} = 0{\cdot}524$$

This ratio lies between 0·414 and 0·732 . Hence, Na^+ ions prefer to occupy **octahedral sites** with coordination number 6 in the close-packed lattice of Cl^- ions.

2. The radii of Zn^{2+} and S^{2-} ions are 0·74 Å and 1·84 Å, respectively, so that the radius ratio

$$\frac{r_{Zn^{2+}}}{r_{S^{2-}}} = \frac{0{\cdot}74}{1{\cdot}84} = 0{\cdot}40$$

This radius ratio lies between 0·225 and 0·414 and, therefore, the Zn^{2+} ions prefer to occupy **tetrahedral sites** with coordination number 4 in close-packed lattice of S^{2-} ions.

3. The radii of Cs^+ and Cl^- ions are 1·69 Å and 1·8 Å, respectively, so that the radius ratio

$$\frac{r_{Cs^+}}{r_{Cl^-}} = \frac{1{\cdot}69}{1{\cdot}81} = 0{\cdot}93$$

This suggests that Cs^+ ions perfer to occupy **cubic sites** with coordination number 8.

4. The radii of Mg^{2+} and O^{2-} ions are 0·66 Å and 1·40 Å, respectively, so that the radius ratio

$$\frac{r_{Mg^+}}{r_{O^{2-}}} = \frac{0{\cdot}66}{1{\cdot}40} = 0{\cdot}472$$

This suggests a coordination number 6 for Mg^{2+} ions and they perfer to occupy **octahedral sites.**

5. The radii of B^{3+} and O^{2-} ions are 0·23 Å and 1·40 Å, respectively. Hence, the radius ratio

$$\frac{r_{B^{2+}}}{r_{O^{2-}}} = \frac{0{\cdot}23\ \text{Å}}{1{\cdot}40\ \text{Å}} = 0{\cdot}164$$

The ratio lies between 0·155 and 0·225. Hence, boron oxide would tend to have a **plane trigonal structure** (Table 4).

It may be pointed out pertinently that the radius ratio rule applies to only the packing of rigid spheres. Since larger anions are easily polarised, they do not behave as rigid spheres. Because of polarisation they tend to form covalent bonds which are strongly directional. Such ionic crystals, therefore, do not strictly follow the radius ratio rule.

Structures of Metallic Crystals. The metal atoms in a metallic lattice are all identical and can be assumed to have spherical shape. Metals, therefore, crystallise in three forms, *viz., hexagonal close packing, cubic close packing and body centred cubic arrangement.*

1. Hexagonal close packing. This form has *ABABAB*... type of arrangement of layers of metal atoms. Each metal atom is 'touching' 12 other atoms (6 atoms in its own layer, 3 atoms in the layer above and 3 atoms in the layer below), that is, each metal atom has a coordination number of 12. Approximately 74% of the space is occupied in hexagonal close packing. This arrangement has already been shown in Fig. 20. Metals such as Be, Mg, Ti, etc., have this type of arrangement in their crystals at 25°C.

2. Cubic close packing or face centred cubic arrangement. This form has *ABCABCABC*... type of arrangement of layers of metal atoms. Each metal atom has coordination number 12 as in hexagonal close packing. In this arrangement also, about 74% of space is occupied by cubic close packing. This arrangement has been shown earlier in Fig. 21. Metals such as Ni, Cu, Ag, Au, etc., have this type of arrangement. Due to greater ease of sliding of one layer of atoms over the other in *ccp* arrangement, the metals with *ccp* arrangement are found to be more malleable and ductile than the metals having *hcp* arrangement.

3. Body centred cubic arrangement. In this form, each atom has 8 nearest neighbours and 6 next nearest neighbours that are farther away to the tune of 15 per cent. This form is 92 per cent as dense as the *ccp* and *hcp* forms. The body centred cubic (*bcc*) arrangement has already been shown in Fig. 23*a*. Metals such as Li (and all other alkali metals), Ba, Cr, Fe, etc., have *bcc* structure. The metals having this structure in their crystals are considerably malleable and ductile because *bcc* arrangement can be deformed comparatively easily. These metals have comparatively lower densities because only 68% of the space (as compared to 74% in *ccp* or *hcp* arrangement) is occupied in the *bcc* arrangement.

Some metals crystallise in mixed *hcp-ccp* arrangement of the type *ABCABABCAB*... Examples are metal crystals of La, Co, etc.

Structures of some of the metals at 25°C are presented in Table 5.

TABLE 5

Structures of Metals at 25°C

Metal	Structure	Metal	Structure
Li	*bcc*	Co	*hcp-ccp*
Na	*bcc*	Rh	*ccp*
K	*bcc*	Ir	*ccp*
Rb	*bcc*	Zn	*hcp*
Cs	*bcc*	Cd	*hcp*
Be	*hcp*		
Mg	*hcp*	Ti	*hcp*
Ca	*ccp*	Zr	*hcp*
Sr	*ccp*	Hf	*hcp*
Ba	*bcc*		
Al	*ccp*	V	*bcc*
Tl	*hcp*	Nb	*bcc*
		Ta	*bcc*
		Cr	*bcc*
Pb	*ccp*	Mo	*bcc*
		W	*bcc*
Ni	*ccp*	Te	*hcp*
Pd	*ccp*	Re	*hcp*
Pt	*ccp*		
Cu	*ccp*	Fe	*bcc*
Ag	*ccp*	Ru	*hcp*
Au	*ccp*	Os	*hcp*
Sc	*ccp*		
Y	*hcp*		
La	*hcp-ccp*		

It is evident from Table 5 that it is not easy to frame rules which may predict the type of structure the metals would have in a particular group of the periodic table. The only exception appears to be the group of alkali metals all of which have the same structure. The problem is further complicated by the fact that a large number of metals exhibit polymorphism as a function of temperature, *i.e.*, the same metal may have different structures at different temperatures. This is illustrated in Table 6.

TABLE 6

Structures of Some Metals at Different Temperatures

Metal	Temperature (°C)	Structure
Ca	25	*ccp*
	500	*bcc*
Fe	25	*bcc*
	900	*ccp*
	1400	*bcc*
Sr	25	*ccp*
	350	*hcp*
	600	*bcc*
Li	25	*bcc*
	100	*hcp*

Structures of Ionic Crystals

Ionic crystals, as already explained, consist entirely of positively and negatively charged units called *ions*. It is evident that for *maximum stability* the arrangements of ions in a crystal should be such that *forces of attraction are maximum* and the *forces of repulsion are minimum*.

Hence, for maximum stability, the oppositely charged ions should be as close to one another and similarly charged ions as far away from one another as possible.

The structure of an ionic crystal depends, to a large extent, on relative sizes of the cations and anions concerned. If, for example, anions are larger, they form a close-packed arrangement and the cations just fit into (or occupy) the resulting interstitial sites of tetrahedral or octahedral type, as the case may be.

In the case of a substance of general formula AX, like sodium chloride (NaCl) or zinc sulphide (ZnS), in which the number of each kind of ions is the same, the coordination number of the positive ion is the same as that of the negative ion. But in the case of a substance of general formula AX_2 or A_2X (*e.g.*, $CaCl_2$ or Na_2S) in which the number of each kind is not the same, the coordination number of positive ion is different from that of negative ion. In calcium chloride, for example, chloride ions are twice as many as calcium ions. The coordination number of calcium ion, therefore, is *twice* the coordination number of chloride ion.

Let us discuss the structures of a few common crystals of the formula AX and AX_2. The structures can be described in terms of close-packed arrangements of large anions with small cations occupying the interstitial sites such as tetrahedral or octahedral.

CRYSTALS OF THE TYPE AX

Structure of Sodium Chloride (NaCl). The unit cell of sodium chloride crystal is shown in Fig. 34. In this structure, the sodium ions are represented by hollow circles and chloride ions by solid circles.

The salient features of this structure are as follows :

1. The chloride ions are arranged in *cubic close packing* (*ccp*) arrangement. In this arrangement, there are Cl^- ions at the corners of the cube as well as at the centre of each face (*face centred cubic arrangement*).

2. The sodium ions occupy all the *octahedral sites.*

3. There is only one octahedral site per atom in a close packed lattice. Therefore, there will be one Na^+ ion for every Cl^- ion. This corresponds to 1 : 1 stoichiometry of sodium chloride crystal. This stoichiometry can also be understood by counting the number of Na^+ and Cl^- ions which contribute to the unit cell, as discussed below.

It is clear from Fig. 34 that there are eight Cl^- ions at the corners and six at the faces of the unit cell. We can easily understand from the figure that each ion at the corner is shared between eight unit cells and its contribution per unit cell is 1/8. Similarly, each ion on a face is shared by two unit cells so that its contribution per unit cell is 1/2. Therefore, the number of Cl^- ions for the unit cell is equal to $8\times(1/8) + 6\times(1/2) = 4$. The number of sodium ions can also be calculated in a similar way. There are twelve Na^+ ions on the edges and one inside the cell. It can be easily seen that each ion on the edge is shared by four unit cells and its contribution per unit cell is 1/4 , while the ion at

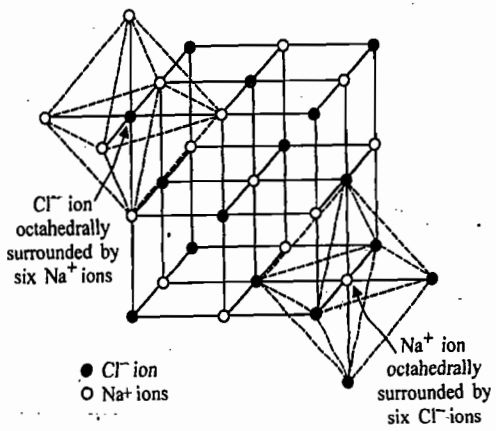

Fig. 34. Unit cell representation of NaCl structure, Hollow circles represent Na^+ ions and solid circles represent Cl^- ions.

the body centre contributes only to one unit cell. Therefore, the number of Na^+ ions for the unit cell is equal to $12 \times (1/4) + 1 = 4$. Thus, the stoichiometry is 1 : 1.

4. In this structure, each Na^+ ion is surrounded by six Cl^- ions which are disposed towards the corners of a regular octahedron. This has also been shown in the figure. Similarly, each Cl^- ion is surrounded by six Na^+ ions. Thus, the coordination number of Na^+ ion as well as that of Cl^- ion is 6.

5. We have seen that for cations to fit into octahedral sites, the radius ratio r_+/r_- should be equal to 0·414 (Table 4). The radius of Na^+ ion is 0·95 Å and that of Cl^- ion is 1·81 Å so that r_{Na^+}/r_{Cl^-} is 0·524 . Therefore, to accommodate somewhat larger sized Na^+ ions, Cl^- ions move apart slightly. In other words, the *ccp* arrangement of Cl^- ions is slightly opened up. This type of structure is adopted by most of the alkali metal halides, the alkaline earth metal oxides and AgF, AgCl, AgBr, NH_4Cl and NH_4 Br, etc.

Structure of Zinc Sulphide (ZnS). It has two types of structures known as

1. Zinc blende Structure *2. Wurtzite Structure*

1. Zinc Blende Structure. The unit cell of zinc blende structure is shown in Fig. 35. In this structure, the zinc ions are represented by hollow circles and the sulphide ions are represented by solid circles. The salient features of this structure are as follows :

1. The sulphide ions are arranged in *ccp* arrangement, *i.e.*, at the corners of the cube and at the centre of each face.

2. The zinc ions occupy half of the tetrahedral sites.

3. Since there are two tetrahedral sites per atom in a close packed lattice, this means that there are two tetrahedral sites per S^{2-} ion. In this arrangement, only half of the tetrahedral sites are occupied by Zn^{2+} ions so that each S^{2-} ion has one Zn^{2+} ion. Therefore, the stoichiometry of the compound is 1 : 1.

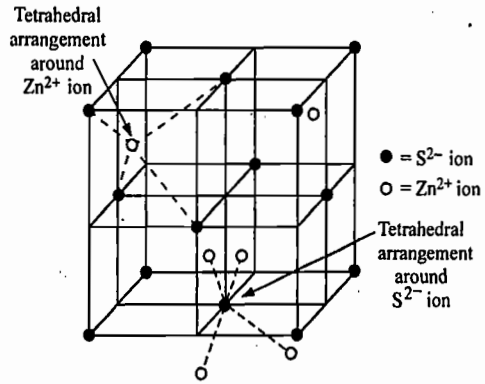

Fig. 35. Unit cell representation of zinc blende structure. Hollow circles represent Zn^{2+} ions and solid circles represent S^{2-} ions.

4. Each zinc ion is surrounded by four sulphide ions which are disposed towards the corners of a regular tetrahedron. Similarly, each S^{2-} ion is surrounded by four Zn^{2+} ions. The arrangement around one Zn^{2+} ion and one S^{2-} ion is also shown in Fig. 35. Thus, the coordination numbers of Zn^{2+} and S^{2-} ions in zinc blende are described as 4 : 4.

5. In zinc sulphide, the radius ratio r_+/r_- is 0·40. This suggests that the coordination number is 4 (Table 4). This supports the structure presented in Fig. 35.

Zinc blende structure is also adopted by some other compounds such as ZnO, CuCl, CuBr, CuI, etc.

2. Wurtzite Structure. The unit cell for wurtzite structure is shown in Fig. 36 in which each Zn^{2+} ion is represented by a hollow circle and each S^{2-} ion is represented by a solid circle. The wurtzite structure may be described as follows :

1. The sulphide ions are arranged in a hexagonal close packed (*hcp*) arrangement.

2. The zinc ions occupy half of the tetrahedral sites.

3. There are two tetrahedral sites for each S^{2-} ion in the lattice. Since only half of them are occupied by Zn^{2+} ions, the stoichiometry of the compound is 1 : 1.

4. Each S^{2-} ion is surrounded by four Zn^{2+} ions which are disposed towards the corners of a regular tetrahedron. Similarly, each Zn^{2+} ion is surrounded by four S^{2-} ions. The arrangement around one Zn^{2+} ion and one S^{2-} ion is shown in Fig. 36. Therefore, the coordination numbers of Zn^{2+} and S^{2-} ions in wurtzite structure are 4 : 4.

5. The radius ratio r_+/r_- in this structure is 0·40 which also suggests that the coordination number is 4 (Table 4) and that the crystal has a tetrahedral structure. Thus, the radius ratio rule supports the above structure. The compounds such as AgI, ZnO, NH_4F and AlN have wurtzite structure.

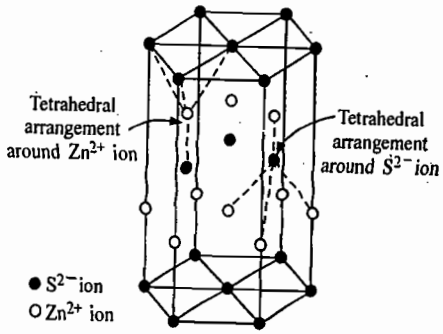

Fig. 36. Unit cell representation of wurtzite structure. S^{2-} ions (solid circles) adopt *hcp* arrangement and Zn^{2+} ions (hollow circles) occupy half of the tetrahedral sites.

It will be noted that the basic difference between *zinc blende* and *wurtzite* structure is that whereas in the former case the sulphide ions are arranged in *ccp* type of packing, in the latter case they are arranged in *hcp* type of packing.

Structure of Cesium Chloride (CsCl). The unit cell of CsCl is shown in Fig. 37. In this structure, cesium ions are represented by hollow circles whereas chloride ions are represented by solid circles. The structure of CsCl may be described as follows :

1. The Cl^- ions form the simple cubic arrangement and the Cs^+ ions occupy the cubic interstitial sites. In other words, the Cl^- ions may be regarded as lying at the corners of a cube and cesium ions are present at the body centre of each cube.

2. Each Cs^+ ion is surrounded by eight Cl^- ions which are disposed towards the corners of a cube. This is clear from Fig. 37(*a*). When the unit cell is extended as shown in Fig. 37 (*b*), it becomes clear that each Cl^- ion is also surrounded by eight Cs^+ ions. Thus, both types of ions are in equivalent positions. Therefore, the coordination numbers of Cs^+ and Cl^- ions are 8 : 8.

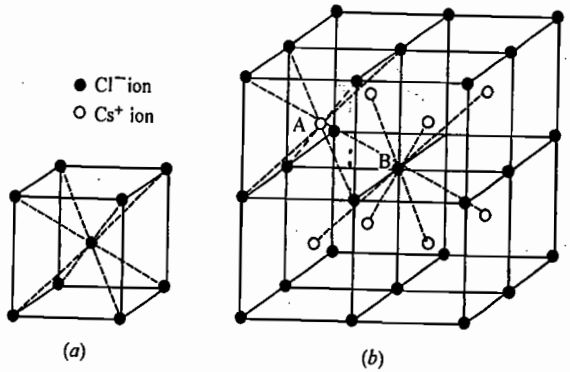

Fig. 37. (*a*) Unit cell representation of CsCl. The Cl^- ions adopt simple cubic arrangement and Cs^+ ions occupy cubic sites. (*b*) The extended unit cell.

The above structure may be described as body centred cubic. But, this would be a misnomer because the body centred cubic structure is one which has the same atoms at the body centre as well as the corners. But in CsCl, the atoms at the corners are different from the atoms at the centre. This type of structure is adopted by CsBr, CsI, TlCl, TlBr, etc.

Since coordination numbers of ions in CsCl (8 : 8) are higher than those in NaCl (6 : 6), we might expect that cesium chloride lattice would be more stable since each ion would have more ions of opposite charge as its neighbours. This is actually the case. The cesium chloride lattice is 1 per cent more stable than the sodium chloride lattice.

Here question arises that if CsCl lattice is more stable then why do the halides of Li, Na, K and Rb not have this lattice ? The answer lies in the radius ratio effect. The radius ratio in the halides of Li, Na,

K and Rb lies between 0·73 and 0·41 and, therefore, the coordination number has to be 6 (Table 4). If an attempt is made to pack 8 halide ions around a *smaller* positive ion, say, Na^+ ion, then some of the negative ions will touch each other sooner than they can approach a positive ion, as shown in Fig. 38. The lattice would thus be unstable. This difficulty can be overcome by packing 6 negative ions around the central positive ion. Hence, the coordination number of 6 is preferred.

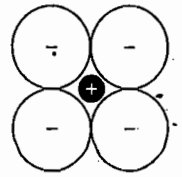

Fig. 38. Cross-section of unstable structure with 8 halide ions around an alkali metal ion other than Cs^+.

CRYSTALS OF THE TYPE AX_2

Structure of Calcium Fluoride (CaF_2). The unit cell of CaF_2 is shown in Fig. 39. The calcium ions are represented by hollow circles and fluoride ions are represented by solid circles. The CaF_2 structure may be described as follows :

1. The Ca^{2+} ions are arranged in *ccp* arrangement so that there are Ca^{2+} ions at all the corners and at the centre of each face of the cube. The fluoride ions occupy all the tetrahedral sites.

2. Since there are two tetrahedral sites for each Ca^{2+} ion and F^- ions occupy all the tetrahedral sites, there will be two F^- ions for each Ca^{2+} ion. Thus, the stoichiometry of the compound is 1 : 2.

3. In this arrangement, each F^- ion is surrounded by four Ca^{2+} ions whereas each Ca^{2+} ion is surrounded by eight F^- ions. Thus, the coordination numbers of Ca^{2+} and F^- ions are 8 : 4.

This structure is adopted by a large number of fluorides such as BaF_2, SrF_2, PbF_2, HgF_2, CuF_2, etc.

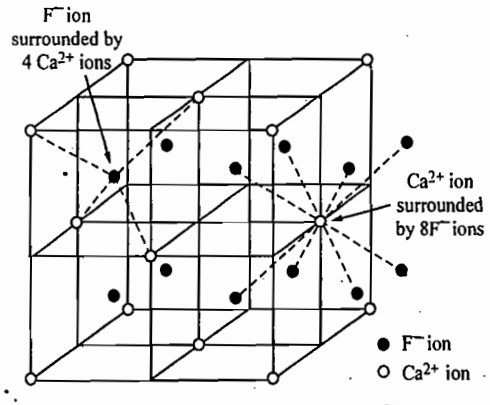

Fig. 39. Unit cell representation of CaF_2. The Ca^{2+} ions adopt *ccp* arrangement and F^- ions occupy all the tetrahedral sites.

Structure of Titanium Dioxide, TiO_2 (Rutile Structure). The unit cell of rutile structure is shown in Fig. 40 in which titanium ions are represented by hollow circles and oxide ions are represented by solid circles.

The structure may be described as follows :

1. The titanium ions are arranged in a *distorted body centred cubic arrangement* in which these ions are present at all the corners and at the centre of the distorted cube. This structure cannot be described as cubic because one of the axes is shorter than the other by 30 per cent. The structure is, therefore, described as **distorted cubic**.

2. As shown in Fig. 40, each titanium ion is surrounded octahedrally by six oxide ions, as, for example, the titanium ion marked A in the figure. On the other hand, each oxide ion is surrounded by three titanium ions disposed towards the corners of an equilateral triangle. Thus, the coordination numbers of Ti^{4+} and O^{2-} ions are 6 : 3.

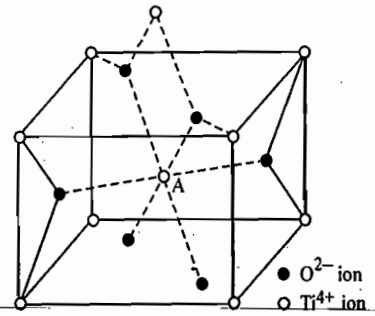

Fig. 40. Structure of titanium dioxide.

Structure of Calcium Carbide (CaC_2). The unit cell of calcium carbide is shown in Fig. 41. The structure of calcium carbide is similar to that of sodium chloride (Fig. 34). Here sodium ions are replaced by

calcium ions and chloride ions by C_2 groups. The carbon atoms are associated in pairs, as shown in Fig. 41, forming the C_2 groups. The C_2 groups are aligned in parallels as shown. The cubic symmetry observed in sodium chloride is, however, distorted considerably in the case of calcium carbide for obvious reasons.

The structure of FeS_2 is similar to that of CaC_2. However, the S_2 units are not aligned in parallels as are the C_2 units in the case of CaC_2.

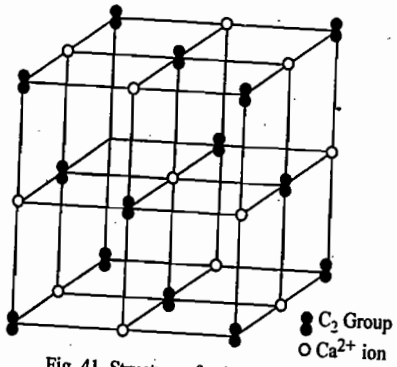

Fig. 41. Structure of calcium carbide.

Structure of Cadmium Iodide (CdI_2) The unit cell of cadmium iodide is shown in Fig. 42 in which Cd^{2+} ions are represented by hollow circles and iodide ions are represented by solid circles.

The salient features of this structure are described below :

1. The iodide ions are arranged in a *hexagonal close packed* (*hcp*) arrangement while cadmium ions lie in *octahedral sites between every two layers of iodide ions*.

2. Each Cd^{2+} ion is surrounded octahedrally by six I^- ions, as shown in Fig. 42. On the other hand, each I^- ion has three Cd^{2+} ions as nearest neighbours. The three Cd^{2+} ions surround the I^- ion in an arrangement in which Cd^{2+} ions form the base of a trigonal pyramid whose apex is the I^- ion.

3. The arrangement of the three layers corresponds to the composition CdI_2.

This arrangement is continued as shown and the structure is referred to as a layer lattice. The forces operating in between the I – Cd – I layers to hold them together are weak. As a result, this compound is flaky and can be easily cleaved.

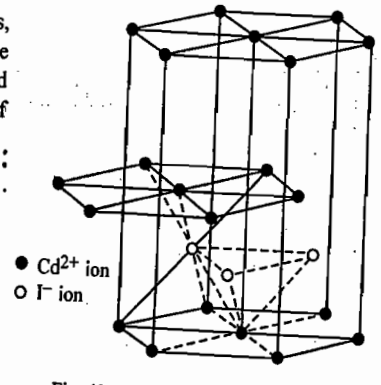

Fig. 42. Structure of cadmium iodide.

Lattice Energy of an Ionic Crystal

The **lattice energy *U* of an ionic crystal** is defined *as the amount of energy released when cations and anions in their gaseous states are brought from infinity to their respective lattice sites in a crystal to form one mole of the ionic crystal.*

The formation of a mole of an ionic crystal from the constituent gaseous ions may be represented as follows :

$$A^+(g) + B^-(g) \xrightarrow{-U} A^+B^-(s) \; ; \qquad U = \text{Lattice energy}$$

With the coming together of positive and negative ions, there is a considerable decrease in potential energy of the system. Hence, in the formation of an ionic crystal from the constituent gaseous ions, as in the above example, there is considerable *release of energy in the form of heat.* Hence, *U* is negative.

It is obvious that the greater the magnitude of the lattice energy of an ionic crystal, the greater would be its stability. Lattice energies of a few ionic crystals are given in Table 7.

TABLE 7

Lattice Energies of Some Common Ionic crystals

Uni-Univalent Crystals		Bi-Bivalent Crystals	
Ionic Crystal	**Lattice Energy (kJ mol^{-1})**	**Ionic Crystal**	**Lattice Energy (kJ mol^{-1})**
LiF	– 1033	CaF_2	– 2581
CsF	– 748	MgF_2	– 2882
NaCl	– 778	MgO	– 3932
LiI	– 140	BeO	– 3125
CsI	– 601	MgS	– 3254
AgCl	– 895	ZnO	– 4032

As can be seen, lattice energies of ionic crystals are quite high. This is on account of strong electrostatic attraction between oppositely charged ions present in the crystals. Since coulombic forces of attraction vary directly as the product of the charges, it follows that the higher the valency (charge) of the ions, the greater would be the lattice energy of the ionic crystals. Thus, lattice energy increases as we move from uni–univalent ionic crystals to uni-bivalent ionic crystals and then to bi-bivalent ionic crystals.

Calculation of Lattice Energies of Ionic Crystals

The lattice energy of ionic crystals can be calculated theoretically on the basis of coulombic interactions between the ions present in the crystals. There are two types of interactions :

1. *Attractive interactions between oppositely charged ions.*
2. *Repulsive interactions because of interpenetration of electron charge clouds.*

1. Attractive Interactions between Oppositely Charged Ions. The potential energy (*P.E.*) of a pair of ions of opposite charges varies inversely as the distance *r* between the ions. This may be expressed as

$$P.E.\ (\text{attraction}) = z_1 z_2 \frac{(+e)(-e)}{r} = -\frac{z_1 z_2 e^2}{r} \qquad ...(2)$$

where *e* is the electronic charge and z_1 and z_2 are the charges on the oppositely charged ions (being, for example, 1 and 1 in the case of NaCl and 2 and 1 in the case of $CaCl_2$).

2. Repulsive Interactions due to Interpenetration of Electron Charge Clouds. As a cation and an anion come very close to each other, there is repulsion between them because of interpenetration of similarly charged electron charge clouds. The potential energy due to this repulsion has been shown to be inversely proportional to the *n*th power of the distance between the ions, *i.e.*,

$$P.E.\ (\text{repulsion}) = b\, e^2 / r^n \qquad ...(3)$$

when *n* is called *Born exponent* while *b* is a constant termed as *repulsion coefficient*. The value of *n* increases with increase in electron charge density around the ions. In the case of ions having Ne configuration (*e.g.*, Na^+ and F^- ions), $n = 7$ while in the case of ions having Ar, Kr and Xe configurations, $n = 9$, 10 and 12, respectively.

The net potential energy for a pair of ions of opposite charges is thus given by combining Eqs. 2 and 3, *i.e.*,

$$P.E.\ (\text{net}) = -z_1 z_2 e^2/r + be^2/r^n \qquad ...(4)$$

Eq. 4 is known as **Born equation.** It gives the potential energy of a system comprising of a cation and an anion which carry z_1 and z_2 as integral charges, as explained above.

It will be seen that the second term, be^2/r^n, *viz.*, the repulsion term in Eq. 4 increases more rapidly than the first term with decrease in the interionic distance r. Born equation gives the *energy released* when a cation and an anion separated by an infinite distance in gaseous state are brought closer together in a crystal at a distance r from each other.

The **application of Born equation** may be illustrated by considering the forces of attraction and repulsion involved in a crystal of sodium chloride. In a crystal, there is not one cation and one anion. Instead, there is a large number of cations and anions arranged together according to a certain specific geometry. It is necessary, therefore, to consider forces of attraction and repulsion between all of them. Thus, in a crystal of sodium chloride (Fig. 43), each sodium ion is surrounded by

(*i*) 6 chloride ions at a distance r

(*ii*) 12 other sodium ions at a distance $\sqrt{2}\,r$

(*iii*) 8 more chloride ions at a distance $\sqrt{3}\,r$

(*iv*) 6 more sodium ions at a distance $\sqrt{4}\,r$

(*v*) 24 more chloride ions at a distance $\sqrt{5}\,r$

(*vi*) 24 more sodium ions at a distance $\sqrt{6}r$, and so on and so forth.

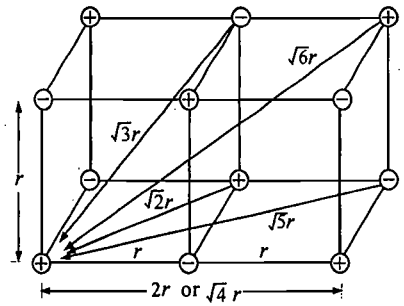

Fig. 43. Interionic distance in NaCl crystal.

The *first term* in Born equation may be calculated from the above data. It is useful to remember that since attraction leads to *fall* and repulsion leads to *rise* in potential energy, the potential energy due to attraction is given a negative sign while that due to repulsion is given a positive sign. Keeping this in view, the potential energy due to the first term in Born equation is obtained by adding up the effect of all the interactions. Thus,

$$(P.E.)_1 = -\frac{6z_1z_2e^2}{r} + \frac{12z_1z_2e^2}{\sqrt{2}r} - \frac{8z_1z_2e^2}{\sqrt{3}r} + \frac{6z_1z_2e^2}{\sqrt{4}r} - \frac{24z_1z_2e^2}{\sqrt{5}r} + \frac{24z_1z_2e^2}{\sqrt{6}r} - \ldots\ldots$$

$$= -\frac{z_1z_2e^2}{r}\left[6 - \frac{12}{\sqrt{2}} + \frac{8}{\sqrt{3}} - \frac{6}{\sqrt{4}} + \frac{24}{\sqrt{5}} - \frac{24}{\sqrt{6}} \ldots\right]$$

For NaCl, a uni-univalent electrolyte, both z_1 and z_2 are equal to unity. The quantity in the brackets is thus summation of an infinite series and is known as the **Madelung constant** for the sodium chloride structure. Its value comes out to be 1·747558. Madelung constant is generally denoted by the symbol A. Any other salt having the same geometrical arrangement of ions as sodium chloride will have the same value of Madelung constant. If it is required to calculate the value in the case of some other salts, it is possible to do so provided the geometrical arrangement of the ions in their crystals is known. Thus, the *first term* may be expressed as

$$(P.E.)_1 = -A\,z_1\,z_2\,e^2/r \qquad \ldots(5)$$

The values of Madelung constants for some of the typical crystal structures are given in Table 8.

TABLE 8

Madelung Constants for Some Typical Crystal Structures

Crystal Structure	Examples of Compounds	Coordination Numbers of Ions	Madelung Constant
Sodium chloride	NaCl	Na^+ : 6 ; Cl^- : 6	1·7475
Cesium chloride	CsCl	Cs^+ : 8 ; Cl^- : 8	1·7627
Zinc blende	ZnS	Zn^{2+} : 4 ; S^{2-} : 4	1·6381
Wurtzite	ZnS	Zn^{2+} : 4 ; S^{2-} : 4	1·6410
Fluorite	CaF_2	Ca^{2+} : 8 ; F^- : 4	5·0388
Rutile	TiO_2	Ti^{2+} : 6 ; O^{2-} : 3	4·8160
Cadmium iodide	CdI_2	Cd^{2+} : 6 ; I^- : 3	4·7100

The *second term* in Born equation may now be considered. As already mentioned, it arises from repulsion between a cation and an anion due to interpenetration of similarly charged electron charge clouds. Since this term varies inversely as r^n, it is enough to consider nearest neighbours only. Others which are farther away will not have any significant effect. In the case of sodium chloride crystal, each sodium ion is surrounded by six chloride ions. The repulsion energy term, therefore, becomes $6be^2/r^n$. The term $6be^2$ is generally replaced by B where B is, evidently, the product of be^2 and the number of nearest neighbours. Therefore, the *second term* becomes B/r^n.

Considering interionic force due to all the neighbouring ions, the potential energy of an ion in a crystal may be written as

$$P.E. = -Az^2e^2/r + B/r^n \qquad \ldots(6)$$

where A is Madelung constant and z^2 has replaced z_1z_2 because $z_1 = z_2 = z$. It is the highest common factor of the ionic charges. The value of n in many common ions varies from 7 to 12.

It is possible to eliminate B from the above equation by realising that an *ion will be in stable equilibrium position when attractive and repulsive forces acting on it are equally balanced.* The potential energy of the ion is then a minimum and $d(P.E.)/dr = 0$. The interionic distance r may then be taken as r_0. By differentiating potential energy with respect to r and equating it to zero, we can eliminate the constant B as follows :

$$P.E. = -Az^2e^2r^{-1} + Br^{-n} \qquad \text{(Eq. 6)}$$

$$d(P.E.)/dr = -Az^2e^2(-1)\,r^{-2} + B(-n)\,r^{(-n-1)}$$

$$= Az^2e^2r^{-2} - nBr^{(-n-1)}$$

Equating $d(P.E.)/dr = 0$ when r is denoted as r_0, we get

$$Az^2e^2r_0^{-2} - nBr_0^{(-n-1)} = 0$$

or $$Az^2e^2r_0^{-2} = n\,Br_0^{(-n-1)}$$

or $$r_0^{n-1} = \frac{nB}{Az^2e^2}$$

or $$r_0 = \left(\frac{nB}{Az^2e^2}\right)^{1/(n-1)} \qquad \ldots(7)$$

and $$B = Az^2r_0^{n-1}e^2/n \qquad \ldots(8)$$

Substituting the value of B in Eq. 6, we have

$$(P.E.)_0 = -\frac{Ae^2z^2}{r_0} + \frac{Az^2e^2}{nr_0^n} r_0^{n-1} = \frac{-Az^2e^2}{r_0} + \frac{Az^2e^2}{nr_0}$$

$$= \frac{Az^2e^2}{r_0}\left(\frac{1}{n} - 1\right) \qquad ...(9)$$

The lattice energy U_0 is defined as the amount of energy released in the formation of a *mole* of a crystal from the constituent gaseous ions separated at infinite distance from one another. Thus,

$$U_0 = N_A \times \text{(Potential energy)} = \frac{N_A Az^2e^2}{r_0}\left(\frac{1}{n} - 1\right) \qquad ...(10)$$

Since n is always more than 1, U_0 would be negative, as expected.

In the above equation, all the quantities are known for a given crystal except the value of n which can be calculated from the compressibility of the crystal if the crystal spacing parameters are known.

The values of lattice energies calculated by means of this equation have been found to be in good agreement with those obtained experimentally, as shown for some of the compounds in Table 9.

TABLE 9

Lattice Energies of Some Common Compounds

Compound	Lattice Energy (kJ mol^{-1})	
	Experimental	Theoretical
MgF_2	– 2882	– 2920
CaF_2	– 2581	– 2585
AgCl	– 895	– 849
AgBr	– 883	– 824
AgI	– 870	– 795

The Born equation leads to the following conclusions :

1. The higher the charge on cation and anion, the greater would be the magnitude of lattice energy and, therefore, the greater would be the stability of the crystal.

2. Since lattice energy is inversely proportional to the interionic distance which is taken as the sum of the radii of the cation and the anion, hence the smaller the size of the ions, the smaller would be the interionic distance, the higher would be the magnitude of lattice energy and the greater would be the stability of the ionic crystal.

3. The lattice energy and hence stability of an ionic crystal is directly proportional to the Madelung constant which depends upon the coordination number of each ion and the geometric pattern of the ions in the crystal lattice of the crystal.

Experimental Determination of Lattice Energy. The Born-Haber Cycle. Since direct experimental determination of lattice energies is not so easy, these are determined indirectly with the help of a thermo-chemical cyclic process known as **Born-Haber cycle**. We would illustrate this by taking into consideration the determination of the lattice energy of NaCl.

The various steps involved in the formation of NaCl (s) in crystalline state are as follows :

1. Conversion of Metallic Sodium into Gaseous Sodium Atoms. The energy required for the conversion of one mole of metallic sodium into gaseous sodium atoms is called **sublimation energy**. It is represented by S.

$$\underset{1\text{ mole}}{Na\,(s)} + S \longrightarrow Na\,(g)\,; \qquad S = \text{Sublimation energy}$$

2. Dissociation of Gaseous Chlorine Molecules into Gaseous Chlorine Atoms. This step involves the dissociation of gaseous chlorine molecules into gaseous chlorine atoms. The amount of energy required to dissociate one mole of gaseous chlorine molecules into gaseous atoms is called **dissociation energy**. It is represented by D.

$$\underset{1\text{ mole}}{Cl_2\,(g)} + D \longrightarrow 2Cl\,(g)\,; \qquad D = \text{Dissociation energy}$$

Evidently, the energy required to produce one mole of gaseous chlorine atoms would be $D/2$.

3. Conversion of Gaseous Sodium Atoms into Sodium Ions. The amount of energy required to convert one mole of gaseous sodium atoms into sodium ions in the gaseous state is called **ionisation energy**. This may be represented by IE.

$$Na(g) + IE \longrightarrow Na^+(g) + e^-\,; \qquad IE = \text{Ionisation energy}$$

4. Conversion of Gaseous Chlorine Atoms into Chloride Ions. The amount of energy released when one mole of gaseous chlorine atoms are converted into chloride ions in the gaseous state is called **electron affinity.** It is represented by EA.

$$Cl\,(g) + e^- \longrightarrow Cl^-\,(g) + EA\,; \qquad EA = \text{Electron affinity}$$

5. Combination of Gaseous Ions to form a Solid Crystal. This step invsolves the combination of gaseous Na^+ and Cl^- ions to give one mole of sodium chloride crystal. The amount of energy released when one mole of solid crystalline compound is formed from gaseous ions of opposite charges is called **lattice energy.** It is denoted by U.

$$Na^+\,(g) + Cl^-(g) \longrightarrow NaCl\,(s) + U\,; \qquad U = \text{Lattice energy}$$

The *overall change* may be represented as

$$Na\,(s) + 1/2\,Cl_2\,(g) \longrightarrow NaCl\,(s)\,; \qquad \Delta H_f = ?$$

The enthalpy change for this reaction is called **enthalpy of formation** of sodium chloride and may be denoted as ΔH_f.

The various steps may be represented in the form of **Born-Haber cycle,** as shown in Fig. 44.

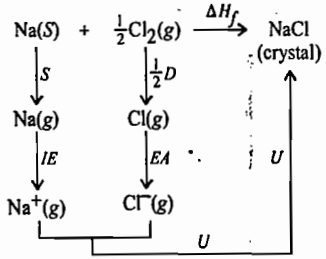

Fig. 44. Born-Haber cycle for the formation of NaCl.

According to Hess's law, the enthalpy of formation of sodium chloride should be the same irrespective of the fact whether it takes place directly in one step or through a number of steps, as illustrated above. Hence,

$$\Delta H_f = S + (1/2)\,D + IE + EA + U$$

Using positive sign for energy *absorbed* and negative sign for *energy released*, we have

Heat of sublimation of sodium (S) = 108·5 kJ mol^{-1}

Dissociation energy of Cl_2 (D) = 243·0 kJ mol^{-1}

Ionisation energy of sodium (IE) = 495·2 kJ mol^{-1}

Electron affinity of chlorine (EA) = – 348·3 kJ mol^{-1}

Enthalpy of formation of NaCl (ΔH_f) = – 381·8 kJ mol^{-1}

Substituting the various values in the above equation, we get

$$-381{\cdot}8\text{ kJ mol}^{-1} = 108{\cdot}5\text{ kJ mol}^{-1} + 1/2\,(243{\cdot}0)\text{ kJ mol}^{-1} + 495{\cdot}2\text{ kJ mol}^{-1} - 348{\cdot}3\text{ kJ mol}^{-1} + U$$

$\therefore$ **Lattice energy of sodium chloride,** $U = -758{\cdot}7$ **kJ mol^{-1}**

Explanation of Some Properties of Ionic Crystals on the Basis of Lattice Energy

1. Solubility of Ionic Crystals in Various Solvents. When an ionic solid goes into solution, *its crystal lattice gets ruptured.* The ions which occupied certain fixed positions in the crystal now move farther apart in the solution. The *question* arises. *How is the energy required to cause the rupture of the lattice obtained ?* The answer is not far to seek. There is a *strong interaction between the solvent and the ions* resulting in the *solvation of the ions.* If water is the solvent, the process is called *hydration of the ions.* The ionic solvation or hydration is an exothermic process releasing a considerable amount of

energy. *It is this energy which is utilised in causing rupture of the crystal lattice.* The liquids which cause solvation of ions and are, therefore, good solvents for ionic solids, have *high dielectric constants.* Thus, water, liquid ammonia, hydrogen fluoride, etc., are good solvents for ionic solids. Liquids with low dielectric constants, such as benzene, carbon tetrachloride, etc., do not solvate the ions and are, therefore, not good solvents for ionic solids. Since solvation of ions does not occur, no energy is released to break down the lattice.

The salts of alkaline earth metals (Mg, Ca, Ba, etc.,) with polyvalent anions such as sulphate, oxalate, phosphate, etc., are much less soluble than the corresponding salts of alkali metals. This has been attributed to their higher lattice energies. The energy released in the solvation of the ions is not sufficiently large to break their crystal lattice to an appreciable extent.

2. Stability of Ionic Compounds. The higher the magnitude of lattice energy, the greater would be the stability of the ionic compound. The higher magnitude of lattice energy means larger energy of attraction between the cations and the anions. The magnitude of properties such as melting point, boiling point, enthalpy of formation, enthalpy of sublimation would be high for ionic compounds having high magnitude of lattice energy.

DEFECT STRUCTURES IN CRYSTALS

The structures of ionic solids described in the preceding pages relate only to *ideal crystals.* An **ideal crystal** *is the one which has the same unit cell and contains the same lattice points throughout the crystal.*

At absolute zero, all ionic crystals show well-ordered arrangements of ions and there are no defects. With rise in temperature, however, there is a chance that one or more of the lattice sites may remain unoccupied by the ions. This constitutes a defect. The number n of such defects per cm^3, at a given temperature T on the absolute scale, is given by the equation

$$n = Ne^{-w/2RT} \qquad ...(11)$$

where N is the total number of sites per cm^3 of the crystal and w is the work (energy) required to produce a defect ; R is the gas constant.

Defects in crystals may be discussed under two heads :

A. Defects in Stoichiometric Crystals

B. Defects in Non-Stoichiometric Crystals.

A. Defects in Stoichiometric Crystals

Stoichiometric crystals are those in which the number of positive and negative ions are exactly in the ratios indicated by their chemical formulae. For simplicity, we can consider the crystals of the type AB having equal number of A^+ and B^- ions. In these crystals, two types of defects are generally observed. These are called (1) Schottky defect and (2) Frenkel defect.

1. Schottky Defect. This defect arises if *some of the lattice points are unoccupied.* The points which are unoccupied are called *lattice vacancies* or *'holes'*. The existence of two holes, one due to a missing positive ion and the other due to a missing negative ion in a crystal lattice, is illustrated in Fig. 45. It may be noted that the crystal, as a whole, remains neutral because the number of missing positive and negative ions is the same.

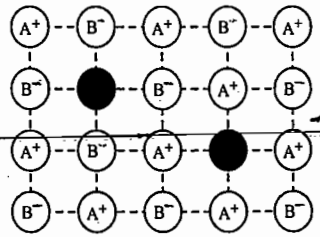

Fig. 45. The Schottky defect in crystals.

Schottky defect appears generally in ionic compounds having a high coordination number and in which the radius ratio, r_+/r_-, is not far below unity, *i.e.*, in which the positive and negative ions do not differ very much in size. Sodium chloride and cesium chloride

which have coordination numbers of 6 and 8, respectively, furnish good examples of ionic crystals in which Schottky defect appears.

2. Frenkel Defect. This defect arises when an ion occupies an interstitial position between the lattice points. This is shown in Fig. 46. It is seen that one of the positive ions occupies a position in the interstitial space rather than at its own appropriate site in the lattice. A 'hole' is thus created in the lattice as shown. It may be noted again that the crystal remains neutral since the number of positive ions is the same as that of the negative ions. Positive ions being smaller are more likely to occupy interstitial positions than the negative ions.

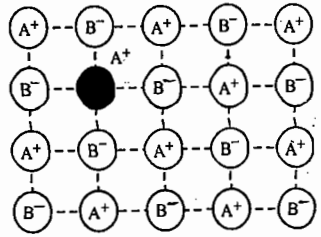

Fig. 46. The Frenkel defect in crystals.

Frenkel defect appears generally in compounds in which the negative ions are much larger than the positive ions, *i.e.*, the radius ratio, r_+/r_-, is low. The coordination number in such compounds is also low (Table 4). Hence, fewer attractive forces between oppositely charged ions have to be broken in causing movement of a positive ion from its appropriate site to the interstitial position.

In silver bromide, AgBr, some of the Ag^+ ions are generally missing from their regular positions and occupy positions in between the other ions in the lattice. The presence of Ag^+ ions in the interstitial spaces of the silver bromide crystal is responsible for the formation of a photographic image on exposure of silver bromide crystals (*i.e.*, photographic plate) to light. Zinc sulphide is another substance in which Frenkel defect appears. Zn^{2+} ions are entrapped in the interstitial spaces leaving 'holes' in the lattice.

Lattice vacancies ('holes') occur in almost all types of ionic crystals. However, Schottky defect appears more often than Frenkel defect. The reason is that the *energy needed to form a Schottky defect is much less than that needed to form a Frenkel defect.* In sodium chloride, the energy required to form a Schottky defect is about 170 kJ per mole. The lattice energy of sodium chloride is – 758·7 kJ per mole so that the energy required to break the NaCl lattice is 758·7 kJ per mole. It is, therefore, far easier to produce a Schottky defect than to break the lattice. The number of Schottky defects increases exponentially with rise in temperature. Thus, as revealed by X–ray diffraction of sodium chloride, while at room temperature this substance has one Schottky defect for 10^{15} lattice sites, the number of defects for the same number of lattice sites rises to such a high value as 10^6 at 500°C and 10^{11} at 800°C.

Consequences of Schottky and Frenkel Defects. Schottky and Frenkel defects in crystals lead to some interesting consequences.

1. The closeness of similar charges brought about by the Frenkel defect (Fig. 46) tends *to increase the dielectric constant of the crystals.*

2. A consequence of both types of defects is that the *crystal is able to conduct electricity to a small extent* by an ionic mechanism. It happens like this. As an electric field is applied, a nearby ion moves from its lattice site to occupy a 'hole'. This results in creating a new 'hole' and another nearby ion moves into it, and so on. This process continues and a 'hole', thereby, migrates from one end to the other end. Thus, it conducts electricity across the whole of the crystal.

3. The presence of 'holes' *lowers the density of the crystal,* as expected.

4. The presence of 'holes' also *lowers the lattice energy* or *the stability of the crystal.* The presence of too many 'holes' may cause a partial collapse of the lattice.

B. Defects in Non-Stoichiometric Crystals

Non-stoichiometric crystals do not obey strictly the law of constant proportions. The numbers of positive and negative ions present in such compounds are different from those expected from their ideal chemical formulae. In other words, there is excess of either positive charge or negative charge in the crystal. However, the crystal as a whole is neutral. If positive charge is in excess, it is balanced by the presence of *extra electrons.* If negative charge is in excess, it is balanced by the presence of *extra positive ions.* The crystal structure, therefore, becomes irregular and this implies the presence of defects. Such

defects are called **non-stoichiometric defects.** These defects may exist in a crystal in addition to Schottky and Frenkel defects already discussed.

Non-stoichiometric defects, evidently, are of two types depending upon whether *positive ions are in excess* or *negative ions are in excess*. These are known as **metal excess defects** and **metal deficiency defects,** respectively.

Metal Excess Defects. In these defects, positive ions are in excess. These defects may arise in *two ways*.

1. A negative ion may be missing from its lattice site leaving a 'hole' which is occupied by an extra electron to maintain the electrical balance, as shown in Fig. 47. There is, evidently, an excess of positive (metal) ions, although the crystal, as a whole, is neutral.

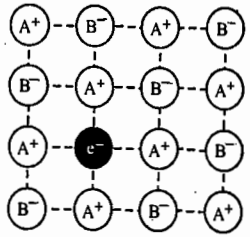

Fig. 47. Metal excess defect casued by a missing negative ion.

This defect is somewhat similar to Schottky defect but differs in having only one 'hole' and not a pair as in the latter case. This type of defect is not very common. It has been observed in those crystals which are likely to form Schottky defect. For example, when sodium chloride is treated with sodium vapour, a *yellow* non-stoichiometric form of sodium chloride is obtained in which there is excess of sodium ions. Similarly, if potassium chloride is exposed to potassium vapour, a *lilac* coloured non-stoichiometric form of potassium chloride is obtained in which there is excess of potassium ions. In each case, the extra positive charge due to extra metal ion is balanced by the presence of a free electron in the lattice.

2. *An extra positive ion occupies an interstitial position in the lattice and to maintain electrical neutrality, an electron also finds a place in the interstitial space*, as shown in Fig. 48.

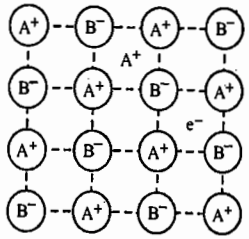

Fig. 48. Metal excess defect due to extra positive ion.

This type of metal excess defect is somewhat similar to Frenkel defect but differs in having no 'holes' and in having interstitial electrons. This kind of defect is more common than the first kind of metal excess defect. It is formed in crystals which are likely to develop Frenkel defect. Zinc oxide crystal is a good example.

Consequences of Metal Excess Defects. 1. The crystals associated with metal excess defects of the first kind or second kind, *contain free electrons* (Figs. 47 and 48). Since these electrons can migrate in an electric field, *such crystals can conduct electricity.* However, since the number of defects and, therefore, the number of electrons is very small, these crystals can conduct only small amounts of current, very much smaller than the current conducted by metals, fused salts or salts dissolved in water. These materials are, therefore, termed as **semiconductors.** Since current, howsoever small, is carried by electrons in *normal way*, these substances are called ***n*-type semiconductors.**

2. The crystals with metal excess defects are generally coloured. This, again, is due to the presence of free electrons. These electrons get excited easily to higher energy levels by absorption of certain wave lengths from the visible white light and, therefore, the compounds appear coloured. Thus, non-stoichiometric sodium chloride is *yellow*, non-stoichiometric potassium chloride is *lilac* in colour. Zinc oxide which is white in cold, *appears yellow when hot.*

Metal Deficiency Defects. There are *two possible ways* in which metal deficiency defects can occur.

1. In the first way, one of the positive ions may be missing from its lattice site. The extra negative charge may be balanced by some nearby metal ion by acquiring an additional positive charge. This is represented in Fig. 49. The metal, obviously, must be in a position to exhibit variable valency. This

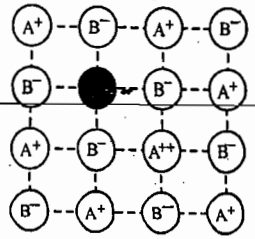

Fig. 49. Metal deficiency defect due to a missing positive ion.

type of defect, therefore, is generally found amongst the compounds of transition metals. Crystals of ferrous oxide, FeO, ferrous sulphide, FeS and nickel oxide, NiO, show this type of defect.

2. In the second way, an extra negative ion may occupy an interstitial position. The extra negative charge is balanced again by means of an extra charge on one of the adjacent metal ions, as shown in Fig. 50. *The metal* in this case also, *should be capable of exhibiting variable valency, i.e.,* it should be one of the transition metals. However, since the negative ions are usually very large, it is not expected that they would be able to fit into the interstitial positions. As a matter of fact, no crystal showing this type of metal deficiency defect is known. The structure represented in Fig. 50, therefore, remains merely a *theoretical possibility.*

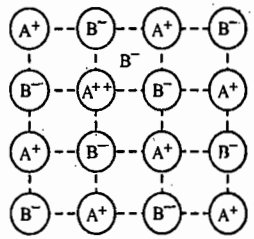

Fig. 49. Metal deficiency defect due to a negative ion.

Consequences of Metal Deficiency Defects. Crystals with metal deficiency defects can also be semiconductors. This property arises from the movement of an electron from one ion to another ion. In this way, the ion, say, A^+, changes into A^{++}. Thus, the movement of an electron from A^+ ion is *an apparent movement of* A^{++} *ion*. This is called *movement of positive 'hole'* and the substances permitting this type of movement are known as ***p*-type semiconductors.**

Thermal Defects. Intrinsic Conduction. Atoms of both germanium and silicon have four electrons in the outer shell. Each atom, therefore, is covalently bonded with four neighbouring atoms through sp^3 hybrid bonds, giving rise to a highly stable tetrahedral structure as in diamond. There are no free or conducting electrons as we have in metals. The electrical conductance, therefore, is very low. Now, suppose a sufficient amount of energy, say, in the form of heat, is supplied to the crystal as a result of which one of the covalent bonds gets broken and the electrons are released. The electrons, thus released, can migrate leaving behind a positive charge, *i.e.,* a 'positive hole', at the site of the missing bond. *The crystal will now be able to conduct electricity* because, when electric field is applied, the electrons migrate in one direction and the 'positive holes' in the other. This type of conduction in known as **intrinsic conduction** as it can be introduced in the crystal without adding an external substance.

Impurity Defects. Certain defects in crystals arise from the presence of chemical impurities. These are known as **impurity defects.** One important application of these defects lies in the use of externally added metal impurities to germanium and silicon crystals to make them act as **semiconductors.** Germanium and silicon belong to Group 14 of the periodic table. These elements, in pure state, have very low electrical conductivity. However, on adding even traces of an element belonging to Group 13 or 15, the electrical conductivity is greatly enhanced. This may be explained as follows :

Suppose, in the first instance, a Group 15 element, like arsenic, is added to a germanium crystal. As a germanium atom is substituted by an atom of arsenic, four of the electrons in arsenic form covalent bonds with the surrounding germanium atoms but the *fifth electron remains free.* In this way, an extra electron, over and above the number required for forming four covalent bonds, gets introduced into the crystal. This extra electron can serve to conduct electricity, *i.e.,* it behaves like a conductor-electron as in metals. Thus, germanium containing traces of arsenic (known as ***arsenic-doped germanium***) begins to exhibit fairly high electrical conductivity. This type of conduction is known as **extrinsic conduction.** It is much greater than the intrinsic conduction discussed above. Since, in this type of conduction, current is carried by excess electrons in the *normal way*, it is called ***n*-type semiconduction.**

Now, suppose a Group 13 element, like indium, having only three electrons in the outer shell, is added in small traces to, say, pure germanium. The atoms of indium, evidently, are not able to complete tetrahedral covalent structures of Group 14 elements because they are one electron short of the requirement. Hence, some of the sites normally occupied by electrons will be left empty. This gives rise to *electron-vacancies.*

The electron-vacant sites are known as 'positive holes' because the net charge at these sites is positive. When electric field is applied, adjacent electrons move into the positive holes and in this way other electron-vacancies (or positive holes) are formed. The migration of positive holes thus continues and current is carried thereby throughout the crystal.

Thus, doping of germanium with traces of indium increases the electrical conductivity of germanium crystal. Since the current, in the present case, is carried by *positive holes*, this type of conduction is called ***p*-type semiconduction.**

It is clear from the above discussion that while doping germanium (or silicon) with arsenic (an element of Group 15) gives rise to *n-type* of semi-conduction, that with indium (an element of Group 13) gives rise to *p-type* of semiconduction. It may be noted that *n-type* as well as *p-type* of semiconductors are electrically neutral because each atom of impurity added is neutral in itself containing, as it does, equal number of protons and electrons. There is, no doubt, a surplus or shortage of one valency electron depending on whether an element of Group 15 or Group 13 is added, but the overall number of electrons remains equal to the number of positive nuclear charges.

Effect of temperature on the conductivity of semiconductors. *The conductivity of semiconductors, unlike that of metals, increases with rise in temperature.* This is due to the fact that extra electron or positive hole, as the case may be, is bound, though weakly, with the crystal and, therefore, some energy in the form of heat is needed to free it from the crystal lattice for the conduction of electricity.

Applications of Semiconductors. The combination of *n* and *p*-type semiconductors (known as ***n–p* junctions**), finds interesting applications in the **fabrication of transistors.** This device can conduct electric current more easily in one particular direction than in the reverse direction and, therefore, can be used as **a rectifier** for changing alternating current into direct current. The device is schematically represented in Fig. 51. The material on the left side of each junction is *n*-type conductor obtained by doping germanium with, say, arsenic. The minus signs represent extra electrons. The material on the right side of the junction is *p*-type conductor obtained by doping germanium with, say, indium. The positive signs represent 'positive holes' arising from the deficiency of electrons at the indium impurity centres. When an external voltage is applied in such a way as to cause motion of electrons (*n*-current) from left to right and motion of positive holes (*p*-current) from right to left (Fig. 51*a*), current is readily conducted. If direction of voltage is reversed so that there is separation of electrons and positive holes as shown in Fig. 51(*b*), there is cancellation of *n* and *p*-currents and hence the conduction stops. Thus, the *n–p* junction permits the current from an outside source to flow *in one direction only.*

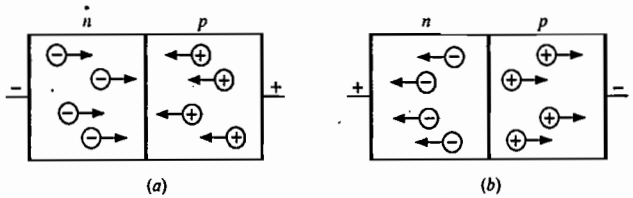

Fig. 51. Semiconductors acting as rectifier.

Fabrication of Transistors

Transistors are obtained either by putting a very thin layer of *n*-type semiconductors between two much thicker layers of *p*-type semiconductors or by putting a very thin layer of *p*-type semiconductors between two much thicker layers of *n*-type semiconductors. The first type is known as *p–n–p* transistors and the second type is known as *n–p–n* transistors.

The fabrication of an *n–p–n* type transistor, for illustration, is described below. It involves the following steps :

1. A small chip of a single *n*-type silicon crystal is oxidised in air or steam to produce a thin coating of SiO_2 over its surface.

2. The SiO_2 film is then coated with a film of a *photosensitive material* known as *'photo-resist'*.

3. A thin film of a *masking material* is then applied over that portion of the photo-resist which is required to be 'protected'. The crystal is then exposed to ultraviolet light which attacks only the unprotected, *i.e.*, the unmasked region. The exposed part of the photo-resist is removed by treatment with an acid. The masked region remains unaffected.

4. The unprotected surface of the crystal is then etched with HF to remove the SiO_2 layer and washed.

5. The etched surface is then exposed to the vapours of a Group 13 element (*e.g.*, indium) so that its atoms diffuse through the exposed silicon surface to form ***p*-type silicon**. The vapours will not diffuse through silicon surface protected by SiO_2.

6. Steps 1 – 4 are repeated using a different mask to selectively expose the desired new areas on the surface of the crystal. The newly exposed areas are then exposed to vapours of a Group 15 element (*e.g.*, arsenic) to produce patterned layers of ***n*-type silicon.**

7. The resulting material is an ***n–p–n* transistor.**

By employing similar technique, we can fabricate ***p–n–p* type transistors.**

A transistor can act as a triode and can thus be used as an *amplifier*, as an *oscillator* and also as a *rectifier.*

QUESTIONS

1. (*a*) How will you distinguish a crystalline solid from an amorphous solid ?
   (*b*) What is meant by elements of symmetry of a crystal ? Discuss the various elements of symmetry in a cubic crystal.
2. (*a*) Explain the terms : isotropy, anisotropy and interfacial angles with respect to crystals.
   (*b*) Explain the difference between cubic and hexagonal close packing.
   (*c*) Represent diagrammatically the unit cells for
   (*i*) a simple cubic lattice (*ii*) face centred cubic lattice (*iii*) body centred cubic lattice
   How many atoms are present per unit cell in these arrangements ? **[Ans. (*i*) 1 (*ii*) 4 (*iii*) 2]**
3. (*a*) What do you understand by axis of rotation ? Show the following axes of rotation in a cubic unit cell :
   (*i*) one 2-fold axis (*ii*) one 3-fold axis (*iii*) one 4-fold axis
   (*b*) Show that the volume of space occupied for a cubic close packed lattice of spheres is 74%.
   (*c*) Out of the seven basic crystal systems which one has (*i*) maximum and (*ii*) minimum symmetry ? **[Ans. (*i*) cubic (*ii*) triclinic]**
4. Calculate the maximum radius ratio r_A/r_B for an atom A to fit in the simple cubic lattice of atom B. **[Ans. 0·732]**
5. Discuss the structure of a compound in which the cation and the anion have 6 coordination numbers.
   (*a*) Calculate the size of tetrahedral and octahedral sites in closed packed structures.
   (*b*) In a close packed array of *N* spheres, how many (*i*) octahedral and (*ii*) tetrahedral sites are present ? **[Ans. (*i*) *N* (*ii*) 2*N*]**
   (*c*) A compound consisting of cation A of radius 0·97 Å and anion B of radius 2·51 Å will probably crystallise in the NaCl form. Is this statement correct ? Justify. **[Ans. Incorrect]**
6. (*a*) Define and explain the terms unit cell and space lattice.
   (*b*) Describe the three types of cubic unit cells among the Bravais lattices ? Calculate the number of atoms per unit cell in each case.
   (*c*) Sketch a two-dimensional lattice of closest packed identical spheres and indicate a suitable unit cell.
7. (*a*) Discuss the classification of crystals on the basis of bonding between the constituent units.
   (*b*) Discuss the radius ratio rule for determining the shapes of ionic crystals.
   (*c*) Sodium chloride has *fcc* structure. How many Na^+ and Cl^- ions are there in the unit cell ? **[Ans. Na^+ = 4, Cl^- = 4]**
8. (*a*) Discuss in details the close packing of identical solid spheres. What is meant by *hcp* and *ccp*?
   (*b*) Draw neat diagrams for NaCl and CsCl structures. What is the basic difference between the two structures ?
   (*c*) At room temperature, sodium crystallises in a body centred cubic lattice with *a* = 4·24 Å. Calculate the theoretical density of sodium. Molar mass of sodium = 23·0 g mol^{-1} **[Ans. 1·0 g mol^{-3}]**
9. (*a*) What is coordination number ? Calculate the coordination number of an atom in
   (*i*) a primitive cubic unit cell (*ii*) a body centred cubic unit cell and
   (*iii*) a face centred cubic unit cell.

(*b*) Show with the help of a diagram that a face centred tetragonal structure is actually a body centred tetragonal structure.

(*c*) Iron (α-Fe) crystallises in a *bcc* system with $a = 2{\cdot}86$ Å. The atomic mass of iron is $55{\cdot}85$ g mol^{-1}. Calculate the density of iron. **[Ans. 7·92 g cm^{-3}]**

10. What are Miller indices ? Sketch the planes in a cube having the Miller indices (*i*) 010 (*ii*) 112 (*iii*) 312 (*iv*) 111

11. Discuss the following structures with diagrams :

(*i*) Rutile structure (*ii*) Calcium fluoride structure

(*iii*) Calcium carbide structure (*iv*) Cadmium iodide structure

12. The ionic radii of Rb^+, Br^- and I^- ions are 1·47, 1·95 and 2·16 Å, respectively. Predict the most probable type of geometry exhibited by RbBr and RbI on the basis of radius ratio rule.

13. (*a*) Draw the structures of zinc blende and wurtzite and show the coordination around each type of ion in these structures. What is the basic difference in these two types of ZnS structures ?

(*b*) If the radius of each close packed sphere is *R*, calculate the radius *r* of the largest sphere that can pack into a tetrahedral hole without disturbing the close packed spheres.

(*c*) What is Madelung constant ? Is the Madelung constant same or different for NaCl and CsCl structures ? **[Ans. Different]**

14. Discuss Born equation for theoretical calculation of lattice energies. What conclusions can be drawn from this equation ?

15. Discuss in details the Born-Haber cycle for experimental determination of lattice energy.

16. What is lattice energy ? How does the solubility of an ionic solid depend upon its lattice energy ?

17. What types of defect are commonly produced in crystals ? Discuss in details the following types of defects in crystals :

(*i*) Schottky defect (*ii*) Frenkel defect (*iii*) Metal deficiency defect (*iv*) Metal excess defect.

18. (*a*) What are non-stoichiometric compounds ? Discuss the defects observed in their structures.

19. (*a*) What type of lattice defects are possible in non-stoichiometric compounds of the type *AB* ? What is the effect of increase in temperature on these detects ?

20. (*a*) What are semiconductors ? Explain what is meant by *n*-type and *p*-type semiconduction. What is the effect sof temperature on semiconduction ?

(*b*) Describe the principle of working and fabrication of a transistor.

7 NON-AQUEOUS SOLVENTS

Solvent. A solvent is defined as a substance which has the power of dissolving other substances. Water is an excellent solvent. On account of its high dielectric constant, it is capable of reducing forces of electrostatic attraction binding the charged ions in electrolytes in the solid state. Thus, salts and other electrolytes get dissociated into ions when they dissolve in water and the solutions conduct electricity. Water has a long liquid range (0° to 100°C) and hence is liquid at ordinary temperatures. It is most easily available and can be easily purified. It is neutral, odourless, non-toxic and non-poisonous. It can, therefore, be handled safely. Due to all these characteristics, water serves as the most useful solvent.

Attempts have been made to find out some other common substances which could serve as good solvents like water and could also have sizeable dielectric constants so that they could have high ionising capacities. Liquid ammonia, liquid sulphur dioxide, anhydrous hydrogen fluoride, anhydrous sulphuric acid and liquid dinitrogen tetroxide are some such solvents.

Classification of Solvents. The various solvents are generally classified as follows :

1. Protonic and aprotic solvents. Solvents from which protons (*i.e.*, H^+ ions) can be derived are called protonic solvents. Common examples are : H_2O, NH_3, HF, etc. Solvents from which protons cannot be ordinarily derived are called aprotic solvents. Examples are : CCl_4, C_6H_6, acetonitrile, etc.

2. Acid solvents, basic solvents and amphiprotic solvents. Solvents which have a strong tendency to give protons are also called acid solvents, *e.g.*, liquid hydrogen fluoride, sulphuric acid and acetic acid. Solvents which have strong affinity for protons are called basic solvents, *e.g.*, liquid ammonia, pyridine, hydrazine, etc. Amphiprotic solvents are those which neither have a strong tendency to gain nor a strong tendency to lose protons. Examples are : water, methyl alcohol, ethyl alcohol, etc.

3. Ionising and non-ionising solvents. Ionising solvents are those which are capable of undergoing auto or self-ionisation. Examples are : water, ammonia, sulphur dioxide, etc. These solvents ionise as follows :

$$H_2O + H_2O \rightleftharpoons H_3O^+ + OH^-$$

$$NH_3 + NH_3 \rightleftharpoons NH_4^+ + NH_2^-$$

$$SO_2 + SO_2 \rightleftharpoons SO^{2+} + SO_3^{2-}$$

Solvents which do not ionise at all are non-ionising solvents. Ionising solvents have high dielectric constants and are polar. Non-ionising solvents have low dielectric constants and are non-polar.

Characteristic Properties of a Solvent. Some characteristic physical and chemical properties of a solvent which govern its usefulness as a solvent are given below.

1. Melting point and boiling point. The melting and boiling points of a solvent indicate the range of temperature over which it can exist in the liquid state under atmospheric pressure. The melting and boiling points of various solvents alongwith their critical temperatures and critical pressures are given in Table 1.

TABLE 1

Melting Points, Boiling Points and Critical Constants of Various Solvents

Solvent	M.P./F.P. (°C)	B.P. (°C)	Critical temperature (°C)	Critical pressure (atm)
Sulphuric acid	10·4	300·0	–	–
Water	0	100·0	374·0	217·7
Ammonia	– 77·7	– 33·5	132·4	112·0
Sulphur dioxide	– 75·5	– 10·1	157·5	77·8
Hydrogen fluoride	– 89·4	19·5	230·2	–
Dinitrogen tetroxide	– 11·2	21·1	–	–

Because of the above values while water exists as liquid at ordinary temperature and pressure, ammonia, sulphur dioxide and dinitrogen tetroxide exist as gases under these conditions. These gases, therefore, act as solvents only at low temperatures.

2. Heats of fusion and vaporisation. The heat absorbed by one mole of a substance to change from solid to liquid state is called its molar heat of fusion. Likewise, the heat absorbed by one mole of a substance to change from liquid to vapour state is called its molar heat of vaporisation. These constants for water, ammonia, sulphur dioxide and hydrogen fluoride are given in Table 2.

TABLE 2

Molar Heats of Fusion and Vaporisation of Some Solvents

Solvents	Molar heat of fusion (kJ mol^{-1})	Molar heat of vaporisation at boiling point (kJ mol^{-1})
Water	6·02	40·65
Ammonia	5·65	23·34
Sulphur dioxide	7·40	24·93
Hydrogen fluoride	4·58	30·28

The heats of fusion and vaporisation indicate the nature and strength of forces with which the molecules of the solvent are held together in the solid or the liquid state. A high heat of vaporisation of a liquid indicates that the intermolecular forces in it are strong. A better idea of the intermolecular forces is obtained by dividing the heat of vaporisation by the boiling point. For normal liquids, the ratio of the heat of vaporisation expressed in joules to the boiling point (K) is a constant known as **Trouton constant.** This constant is about 90 J K^{-1} mol^{-1} for normal liquids. Such liquids have single molecules without any bonds between them. A higher value of the constant indicates association of molecules. The molecules of liquids which undergo association are polar. The common solvents like water, ammonia, hydrogen fluoride and alcohols are all associated liquids.

It is evident from Table 2 that heats of fusion for water and ammonia are very nearly the same. This indicates that the forces which hold molecules together in water and ammonia are of the same magnitude. The heat of fusion of sulphur dioxide is comparatively high while that of hydrogen fluoride is comparatively low indicating that while the force holding SO_2 molecules together is stronger, the force holding HF molecules is weaker.

TABLE 3

Dipole Moments and Dielectric Constants of Some Solvents

Solvent	Dipole Moment (Debye Units)	Dielectric Constant
Water	1·85	78·5 (25°C)
Ammonia	1·47	22·0 (– 33·5°C)
Sulphur dioxide	1·61	17·4 (– 20°C)
Hydrogen fluoride	1·90	83·6 (0°C)
Dinitrogen tetroxide	—	2·42 (0°C)

3. Dielectric constant. The coulombic force F between a cation and an anion is given by the expression $F = q_1q_2 / [\varepsilon (r_1+r_2)^2]$ where q_1 and q_2 are the charges for cations and anions, respectively ; r_1 and r_2 are the radii of the two ions and ε is the dielectric constant. A high value of ε indicates that a small

amount of energy will be required to separate the ions and hence it will be easy to dissolve an ionic solute. Thus, dielectric constant, in general, determines the ability of a solvent to dissolve ionic compounds. For example, solvents such as anhydrous hydrogen fluoride and water, which have high dielectric constants, are the best solvents for ionic and polar compounds. On the other hand, solvents like liquid ammonia and liquid sulphur dioxide with low dielectric constants show decreased ability to dissolve ionic compounds especially those containing multi-charged ions. Thus, carbonates, sulphates and phosphates are practically insoluble in liquid ammonia and liquid sulphur dioxide.

The dielectric constant and the polarity of a solvent are closely related. An ionising solvent not only has a large dipole moment but also has a large dielectric constant. This is evident from the data given in Table 3.

Some important **non-aqueous solvents** are described below.

LIQUID AMMONIA

Liquid ammonia is one of the most extensively studied non-aqueous solvents. It is a protonic solvent and its water-like properties have made it a highly useful solvent and a reaction medium for carrying out several types of organic and inorganic reactions.

Liquid ammonia shows a striking resemblance with water in its solvent action. Ammonia molecules are, however, less strongly associated through hydrogen bonding in liquid ammonia. Consequently, the freezing and boiling points of liquid ammonia are lower than those of water. Another similarity with water is the polarity of the ammonia molecule. It has a pyramidal structure which makes it polar. A third similarity is autoionisation of liquid ammonia, similar to the autoionisation of water. Both liquid ammonia and water show comparable autoionisation, represented as below :

$$H_2O \rightleftharpoons H^+ + OH^-$$
$$H^+ + H_2O \rightleftharpoons H_3O^+$$
$$2H_2O \rightleftharpoons \underset{\text{Hydronium ion}}{H_3O^+} + \underset{\text{Hydroxyl ion}}{OH^-}$$

$$K_w = [H_3O^+][OH^-] = 1{\cdot}0\times10^{-14} \text{ at } 25°C$$

$$NH_3 \rightleftharpoons H^+ + NH_2^-$$
$$H^+ + NH_3 \rightleftharpoons NH_4^+$$
$$\underset{\text{Liquid ammonia}}{2NH_3} \rightleftharpoons \underset{\text{Ammonium ion}}{NH_4^+} + \underset{\text{Amide ion}}{NH_2^-}$$

$$K_b = [NH_4^+][NH_2^-] = 1{\cdot}9\times10^{-33} \text{ at } -50°C.$$

However, the extent of autoionisation of liquid ammonia is much less than that of water (compare the values of K_w and K_b).

Ammonia can, therefore, conduct electricity only to a feeble extent. The dielectric constant of liquid ammonia (22) is much smaller than that of water (78·5) . The lower dielectric constant results in a generally decreased ability of liquid ammonia to dissolve ionic compounds. Liquid ammonia is, therefore, a poor solvent for ionic substances. However, low viscosity of ammonia (0·254 centipoise at – 33·5°C) compared to that of water (0·959 centipoise at 25°C) is expected to promote greater ionic mobilities and thereby compensate to some extent the effect of the comparatively low dielectric constant. The physical properties of water and liquid ammonia are given in Table 4.

TABLE 4

Physical Properties of Water and Ammonia

Properties	Water	Ammonia
Boiling point	100°C	−33·5°C
Freezing point	0°C	−77·7°C
Density	1·0 g ml^{-1} (4°C)	0·68 g ml^{-1} (−33·5°C)
Dielectric constant	78·5 (25°C)	22·0 (−33·5°C)
Specific conductance (ohm^{-1} cm^{-1})	$6{\cdot}0\times10^{-8}$ (25°C)	1×10^{-11} (− 33·5°C)
Viscosity (centipoise)	0·959 (25°C)	0·254 (− 33·5°C)
Dipole moment (Debye)	1·85	1·47
Trouton constant (J K^{-1} mol^{-1})	109	101·2

Chemical Reactions in Liquid Ammonia

As mentioned above, liquid ammonia has water–like properties and hence the reactions which take place in aqueous solutions can also occur in liquid ammonia solutions. Chemical reactions that take place in liquid ammonia are of the following types.

1. Precipitation Reactions. Precipitation reactions normally involve double decomposition. The solubilities of various substances in liquid ammonia and water are different and hence many reactions which are not normally possible in water have been reported to occur in liquid ammonia. Some of these reactions are discussed below.

a. Consider the precipitation of silver chloride in aqueous medium.

$$KCl + AgNO_3 \longrightarrow AgCl\downarrow + KNO_3$$

In liquid ammonia, the direction of the reaction is reversed.

$$AgCl + KNO_3 \xrightarrow{\text{liq. } NH_3} KCl\downarrow + AgNO_3$$

Similarly, a white precipitate of $BaCl_2$ is produced when solutions of silver chloride and barium nitrate in liquid ammonia are brought together.

$$AgCl + Ba(NO_3)_2 \xrightarrow{\text{liq. } NH_3} BaCl_2\downarrow + 2AgNO_3$$

b. Iodides and bromides get precipitated when solutions of various metal nitrates and ammonium halides in liquid ammonia are mixed together.

$$Sr(NO_3)_2 + 2NH_4Br \xrightarrow{\text{liq. } NH_3} SrBr_2\downarrow + 2NH_4NO_3$$

$$Zn(NO_3)_2 + 2NH_4I \xrightarrow{\text{liq. } NH_3} ZnI_2\downarrow + 2NH_4NO_3$$

c. Ammonium sulphide in liquid ammonia is capable of precipitating many metal sulphides from the solutions of nitrates of the metals.

$$(NH_4)_2S + 2AgNO_3 \xrightarrow{\text{liq. } NH_3} Ag_2S\downarrow + 2NH_4NO_3$$

$$(NH_4)_2S + Cu(NO_3)_2 \xrightarrow{\text{liq. } NH_3} CuS\downarrow + 2NH_4NO_3$$

$$(NH_4)_2S + Cd(NO_3)_2 \xrightarrow{\text{liq. } NH_3} CdS\downarrow + 2NH_4NO_3$$

2. Acid–Base Reactions in Liquid Ammonia. There is an interesting comparison between neutralisation reactions in aqueous solution and in liquid ammonia solution. Hydrochloric acid gas dissolves in liquid ammonia giving NH_4^+ ions and Cl^- ions.

$$HCl(g) + NH_3 \longrightarrow NH_4^+ + Cl^-$$

A similar reaction takes place in the case of water.

$$HCl(g) + H_2O \longrightarrow H_3O^+ + Cl^-$$

In aqueous solution, the process of neutralisation of a strong acid by a strong base involves the combination of H_3O^+ and OH^- ions to form practically un-ionised H_2O, the anion of the acid and the cation of the base remaining unchanged. For instance, the neutralisation of hydrochloric acid with potassium hydroxide may be represented as

$$HCl + H_2O \longrightarrow H_3O^+ + Cl^-$$

$$KOH \longrightarrow OH^- + K^+$$

$$H_3O^+ + OH^- \longrightarrow 2H_2O \text{ (Neutralisation)}$$

A similar thing happens in the case of liquid ammonia solution. The process of neutralisation involves combination of NH_4^+ and NH_2^- ions to form un–ionised NH_3. For instance, the neutralisation of ammonium chloride with potassium amide may be represented as

$$NH_4Cl \longrightarrow NH_4^+ + Cl^-$$

$$KNH_2 \longrightarrow NH_2^- + K^+$$

$$NH_4^+ + NH_2^- \longrightarrow 2NH_3 \text{ (Neutralisation)}$$

Obviously, the role of NH_4Cl in liquid ammonia solution is the same as that of HCl in aqueous solution. Similarly, the role of KNH_2 in liquid ammonia solution is the same as that of KOH in aqueous solution. Thus, NH_4Cl may be regarded as a strong acid and KNH_2 as a strong base in liquid ammonia solution. They are termed as ammono acids and ammono bases, respectively. Some typical reactions of ammono acids and ammono bases are given below.

a. Reactions of Ammono Acids. Ammono acid is a substance which in liquid ammonia furnishes NH_4^+ ion. The following reactions show their behaviour to be similar to that of aqua acids.

1. Neutralisation. This has already been discussed above.

2. Replacement of protons by reactive metals. Acids give out hydrogen with metals in aqueous solutions. Likewise, the solutions of ammonium salts in liquid ammonia react with alkali and other metals to give hydrogen.

$$Na + NH_4^+ \xrightarrow{\text{liq. } NH_3} Na^+ + NH_3 + 1/2\,H_2$$

$$Co + 2NH_4NO_3 \xrightarrow{\text{liq. } NH_3} Co(NO_3)_2 + 2NH_3 + H_2$$

This is analogous to the reaction :

$$Co + H_2SO_4 \longrightarrow CoSO_4 + H_2$$

Ammonium salts decolourise blue solutions of alkali metals in liquid ammonia.

3. Protolysis. Certain compounds like urea, acetamide, sulphamide, etc., which are incapable of donating protons to water, can readily undergo protolysis in liquid ammonia, *i.e.*, they can donate protons to NH_3 in liquid ammonia. Hence organic amides act as acids in liquid ammonia, as illustrated by the following reactions:

$$H_2N(CO)NH_2 + NH_3 \longrightarrow H\bar{N}(CO)NH_2 + NH_4^+$$

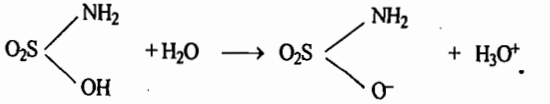
$$H_3C(CO)NH_2 + NH_3 \longrightarrow H_3C(CO)\bar{N}H + NH_4^+$$

$$H_2N(SO_2)NH_2 + NH_3 \longrightarrow H_2N(SO_2)\bar{N}H + NH_4^+$$

Similarly, sulphamic acid behaves as a dibasic acid in liquid ammonia.

$$H_2N(SO_2)OH + 2NH_3 \longrightarrow \bar{O}(SO_2)\bar{N}H + 2NH_4^+$$

However, it acts as a monobasic acid in aqueous solution. This is because NH_2 group cannot donate a proton to water.



h. Reactions of Ammono Bases. Ammono base is a substance which in liquid ammonia furnishes NH_2^- ion. Consequently, amides ($-NH_2$), imides ($=NH$) and nitrides ($\equiv N$) behave as bases in liquid ammonia, as shown below :

$$-NH_2 + NH_3 \longrightarrow -NH_3^+ + NH_2^-$$
$$=NH + NH_3 \longrightarrow =NH_2^+ + NH_2^-$$
$$\equiv N + NH_3 \longrightarrow \equiv NH^+ + NH_2^-$$

Since in all the above reactions, the NH_2^- ion is released, the amide, imide and nitride all behave as ammono bases.

Several species that are considered as strong bases in water, behave as weak bases in liquid ammonia. Extremely strong bases such as H^- and O^{2-} are levelled to NH_2^- ion in liquid ammonia.

$$H^- + NH_3 \longrightarrow \bar{N}H_2 + H_2$$
$$O^{2-} + NH_3 \longrightarrow \bar{N}H_2 + \bar{O}H$$

Since alkaline earth amides and lithium and sodium amides have very low solubility, potassium amide (KNH_2), which is much more soluble, is usually employed as an ammono base. Thus, salts of metals in liquid ammonia are precipitated as amides, imides and nitrides by the addition of a solution of KNH_2.

$$AgNO_3 + KNH_2 \xrightarrow{\text{liq. } NH_3} KNO_3 + AgNH_2 \downarrow$$
$$PbI_2 + KNH_2 \xrightarrow{\text{liq. } NH_3} KI + HI + Pb(NH) \downarrow$$
$$BiI_3 + KNH_2 \xrightarrow{\text{liq. } NH_3} KI + 2HI + BiN \downarrow$$

3. Amphoterism. A compound that dissolves both in acids and bases is said to be amphoteric in character. In aqueous medium, zinc and aluminium hydroxides are amphoteric. In liquid ammonia, zinc amide shows amphoteric behaviour. This is illustrated by the following reactions :

$$Zn(OH)_2 + 2HCl \xrightarrow{H_2O} ZnCl_2 + 2H_2O$$
$$Zn(NH_2)_2 + 2NH_4Cl \xrightarrow{\text{liq. } NH_3} ZnCl_2 + 4NH_3$$
$$Zn(OH)_2 + 2NaOH \xrightarrow{H_2O} Na_2ZnO_2 + 2H_2O$$
$$Zn(NH_2)_2 + 2NaNH_2 \xrightarrow{\text{liq. } NH_3} Na_2Zn(NH)_2 + 2NH_3$$

4. Ammonolysis. Ammonolysis in liquid ammonia is similar to hydrolysis in aqueous medium. Just as in hydrolysis, the concentration of H^+ or OH^- ions increases due to interaction of cations or anions of a salt with H^+ or OH^- ions furnished by autoionizaion of H_2O, in ammonolysis, the concentration of either NH_4^+ or NH_2^- ions increases due to interaction of cations or anions of a salt with NH_4^+ or NH_2^- ions furnished by autoionisation of NH_3. Consider the hydrolysis of $CuSO_4$ and ammonolysis of $SnCl_4$:

$$CuSO_4 \longrightarrow Cu^{2+} + SO_4^{2-}$$
$$2H_2O + 2H_2O \rightleftharpoons 2H_3O^+ + 2OH^-$$
$$Cu^{2+} + 2OH^- \longrightarrow Cu(OH)_2$$
$$CuSO_4 + 4H_2O \rightleftharpoons \underset{\text{Weak base}}{Cu(OH)_2} + SO_4^{2-} + 2H_3O^+$$

$$SnCl_4 \longrightarrow Sn^{4+} + 4Cl^-$$
$$4NH_3 + 4NH_3 \rightleftharpoons 4NH_4^+ + 4NH_2^-$$
$$Sn^{4+} + 4NH_2^- \longrightarrow Sn(NH_2)_4$$
$$SnCl_4 + 8NH_3 \rightleftharpoons \underset{\text{Weak base}}{Sn(NH_2)_4} + 4NH_4^+ + 4Cl^-$$

In ammonolysis, the atom or ion from the compound undergoing ammonolysis is replaced by $-NH_2$ or $=NH$ or $\equiv N$ group. For example, in excess of liquid ammonia, the ammonolysis of $TiCl_4$ takes place in steps as follows :

$$TiCl_4 \xrightarrow[-HCl]{\text{liq. } NH_3} TiCl_3(NH_2) \xrightarrow[-HCl]{\text{liq. } NH_3} TiCl_2(NH_2)_2 \xrightarrow[-HCl]{\text{liq. } NH_3} TiCl(NH_2)_3 \xrightarrow[-HCl]{\text{liq. } NH_3} Ti(NH_2)_4$$

In the case of organic halides which undergo slow ammonolysis at the boiling point of liquid ammonia, mixtures of primary, secondary and tertiary amines are formed.

$$RX + 2NH_3 \longrightarrow RNH_2 + NH_4X$$
$$RX + RNH_2 + NH_3 \longrightarrow R_2NH + NH_4X$$
$$RX + R_2NH + NH_3 \longrightarrow R_3N + NH_4X$$

where X = Cl, Br or I.

Alkali metal hydrides and oxides also undergo ammonolysis to give amides.

$$NaH + NH_3 \longrightarrow NaNH_2 + H_2$$
$$Na_2O + 2NH_3 \longrightarrow 2NaNH_2 + H_2O$$

5. Ammonation and formation of Ammoniates. Ammonation is a type of solvation reaction in which liquid ammonia is used as a solvent and in which one or more ammonia molecules are attached to a solute species (a cation, an anion or a neutral molecule) by a chemical bond. The products of solvation are called solvates and in the case of ammonation they are known as ammoniates. Solvation in water is called hydration and the products are known as hydrates.

Formation of typical ammoniates is shown below :

$$SO_3 + 2NH_3 \longrightarrow SO_3.2NH_3 \qquad 1:2 \text{ adduct}$$
$$SiF_4 + 2NH_3 \longrightarrow SiF_4.2NH_3 \qquad 1:2 \text{ adduct}$$
$$BF_3 + NH_3 \longrightarrow BF_3.NH_3 \qquad 1:1 \text{ adduct}$$

6. Complex Formation Reactions. Several complex formation reactions in liquid ammonia are known. These are similar to reactions occurring in aqueous systems. The following reactions are given for illustration:

Aqueous System :

$$Zn(NO_3)_2 + 2NaOH \xrightarrow{H_2O} \underset{\text{Insoluble}}{Zn(OH)_2} + 2NaNO_3$$
$$Zn(OH)_2 + 2NaOH \xrightarrow{H_2O} \underset{\text{Soluble hydroxo complex}}{Na_2[Zn(OH)_4]}$$

Liquid Ammonia System :

$$Zn(NO_3)_2 + 2KNH_2 \xrightarrow{\text{liq. } NH_3} \underset{\text{Insoluble}}{Zn(NH_2)_2} + 2KNO_3$$
$$Zn(NH_2)_2 + 2KNH_2 \xrightarrow{\text{liq. } NH_3} \underset{\text{Soluble amide complex}}{K_2[Zn(NH_2)_4]}$$

Similarly, many metal amides, imides and nitrides dissolve in a solution of potassium amide in liquid ammonia forming soluble amide complexes.

$$AgNH_2 + KNH_2 \xrightarrow{liq.\,NH_3} \underset{\text{Soluble amide complex}}{K[Ag(NH_2)_2]}$$

Aluminium salts react with potassium amide solution in liquid ammonia forming soluble amide complexes. Thus,

$$AlCl_3 + 3KNH_2 \xrightarrow{liq.\,NH_3} \underset{\text{Insoluble}}{Al(NH_2)_3} + 3KCl$$

$$Al(NH_2)_3 + KNH_2 \xrightarrow{liq.\,NH_3} \underset{\text{Soluble amide complex}}{K[Al(NH_2)_4]}$$

7. Reduction Reactions. Liquid ammonia serves as an excellent medium for reduction reactions involving inorganic species. For instance, alkali metals dissolve in liquid ammonia giving blue coloured solutions which are strong reducing agents as they can readily supply electrons for reduction processes. Sodium metal in liquid ammonia, for instance, reduces CuI to Cu.

$$CuI + Na \xrightarrow{liq.\,NH_3} Cu + NaI$$

8. Oxidation Reactions. Oxidising action of various oxidising agents is weaker in liquid ammonia than in aqueous solutions. For instance, HNO_3 in liquid ammonia does not act as an oxidising agent. Similarly, $KMnO_4$ in liquid ammonia acts as a very weak oxidising agent. $KMnO_4$ is reduced by a solution of potassium in liquid ammonia to K_2MnO_4 and finally to MnO.

$$K + NH_3 \longrightarrow KNH_2 + 1/2\,H_2$$

$$6KMnO_4 + 6KNH_2 \longrightarrow 6K_2MnO_4 + 4NH_3 + N_2$$

$$K_2MnO_4 + 4K + 3NH_3 \longrightarrow MnO + 3KNH_2 + 3KOH$$

9. Solubility of Substances in Liquid Ammonia. As expected from its very low dielectric constant, liquid ammonia is a poor solvent for ionic substances. Amongst the **inorganic compounds,** nitrates, thiocyanates, perchlorates and most of the cyanides are soluble in liquid ammonia. Oxides, hydroxides, carbonates, phosphates, sulphates and most of the sulphides are insoluble. Most of the iodides are soluble and bromides are less soluble. Fluorides and chlorides (except Be^{2+} and Na^+ chlorides) are practically insoluble. Most of the ammonium salts such as NH_4NO_3, NH_4SCN, CH_3COONH_4 are soluble in liquid ammonia. Most of the metal amides, except those of alkali metals, are insoluble.

Amongst the **organic compounds,** halogen compounds, alcohols, ketones, esters, simple ethers, phenol and its derivatives are soluble. Aromatic hydrocarbons are sparingly soluble. Alkanes are insoluble. Alkenes and alkynes are slightly soluble.

Amongst the **elements,** metals like Mg, Al, Zn, Ca, La, Ce, Mn, etc., have low solubilities in liquid ammonia. Alkali metals and alkaline earth metals are highly soluble in liquid ammonia. The non-metals like sulphur, phosphorus, iodine are soluble and they react with the solvent.

Solutions of Alkali Metals in Liquid Ammonia. The ability to dissolve the alkali metals is one of the striking features of liquid ammonia as a solvent. The alkali metal solutions in liquid ammonia are blue in colour. The **blue solution** is characterised by

(*i*) its colour which is independent of the metal involved.

(*ii*) its density which is similar to that of pure liquid ammonia.

(*iii*) its conductivity which is in the range of conductivities of electrolytes dissolved in liquid ammonia, and

(*iv*) its paramagnetism (*i.e.*, these solutions when placed in a magnetic field are attracted into the field) which indicates the presence of a large number of unpaired electrons.

The alkali metal solutions dissociate to form alkali metal cations and ammoniated electrons.

The dissociation into cation and ammoniated electron accounts for the electrolytic conductivity of the blue coloured dilute solutions. As the concentration of the solution is increased, M^+ and e^--species associate resulting in a decrease of conductivity.

Very dilute solutions of alkali metals in liquid ammonia are metastable and when catalysed they undergo decomposition.

$$[e(NH_3)_x]^- \xrightarrow{Fe_2O_3} NH_2^- + 1/2H_2 + (x-1)NH_3$$

As the concentration of metal increases, the blue colour changes to bronze and finally the colour disappears altogether. On evaporating the alkali metal–ammonia solutions, the alkali metal can be recovered.

The blue colour of dilute metal-ammonia solutions is attributed to the presence of ammoniated cation as well as ammoniated electron.

$$M^+ + xNH_3 \rightleftharpoons \underset{\text{Ammoniated cation}}{M(NH_3)_x^+}$$

$$e^- + yNH_3 \rightleftharpoons \underset{\text{Ammoniated electron}}{e(NH_3)_y^-}$$

Advantages of Liquid Ammonia as a Solvent

1. Dissolution of alkali metals in liquid ammonia without chemical reaction is the greatest advantage of using liquid ammonia as a solvent. The dissolved alkali metals can be recovered from the solution by evaporation.
2. The alkali metal solutions in liquid ammonia are strong reducing agents, even stronger than hydrogen.
3. Ammonium salts dissolved in liquid ammonia find application in preparative chemistry. They can be used to precipitate sulphides, halides, sulphates and alcoholates.
4. The tendency for solvolysis is less in liquid ammonia than in water.

Limitations of Liquid Ammonia as a Solvent

1. Low temperature or high pressure is necessary while working with liquid ammonia. This is because the liquid range for liquid ammonia is from – 33·5°C to – 77·7°C.
2. Liquid ammonia is hygroscopic in nature. Hence, all the reactions are to be carried out in sealed tubes.
3. The use of liquid ammonia as a solvent and as a reaction medium requires special technique as it has an offensive odour.

ANHYDROUS HYDROGEN FLUORIDE

Hydrogen fluoride is one of the most water-like solvents since it is **liquid** at temperatures below 19·4°C upto – 89·4°C. Its boiling point (+ 19·4°C) is very high as compared to the boiling points of other non-aqueous solvents. Its dipole moment (1·90 D) and dielectric constant (83·6 at 0°C) are also quite close to those of water. Because of its high dielectric constant, it serves as an excellent ionising solvent.

However, its use as a non-aqueous solvent has been quite limited because it is poisonous, its specific conductance is low and it can dissolve only a few substances without reacting with them.

The characteristic physical properties of liquid hydrogen fluoride are given in Table 5.

TABLE 5

Some Characteristic Physical Properties of Anhydrous Hydrogen Fluoride

Property	Values
Freezing point	– 89·4°C
Boiling point	19·4°C
Density	0·99 g ml^{-1}
Dielectric constant	83·6 (0°C)
Dipole moment	1·90 D
Viscosity	0·256 centipoise (15°C)
Specific conductance	$1{\cdot}4\times10^{-5}$ ohm^{-1} cm^{-1} (15°C)

Chemical Reactions in Liquid Hydrogen Fluoride. Some of the important chemical reactions taking place in anhydrous hydrogen fluoride are discussed below briefly.

1. Precipitation Reactions. Sulphates, perchlorates and periodates of non-alkali metals get precipitated when their fluorides dissolved in liquid hydrogen fluoride are treated with solutions of sulphates, perchlorates and periodates of alkali metals.

$$Na_2SO_4 + NiF_2 \longrightarrow \underset{\text{Ppt.}}{NiSO_4} + 2NaF$$

$$NaClO_4 + TlF \longrightarrow \underset{\text{Ppt.}}{TlClO_4} + NaF$$

$$KIO_4 + AgF \longrightarrow \underset{\text{Ppt.}}{AgIO_4} + KF$$

Another important precipitation reaction involves the precipitation of $AgBF_4$.

$$AgNO_3 + BF_3 + 2HF \longrightarrow \underset{\text{Ppt.}}{AgBF_4} + H_2NO_3F$$

2. Acid-Base Reactions. The high specific conductance of anhydrous hydrogen fluoride suggests a relatively large degree of its autoionisation :

$$3HF \rightleftharpoons \underset{\text{(Acid)}}{H_2F^+} + \underset{\text{(Base)}}{HF_2^-}$$

Thus, any substance which can yield H_2F^+ ion would behave as an acid and any substance which can yield HF_2^- or F^- ion would behave as a base. Accordingly, *even strong acids* such as HNO_3 and H_2SO_4 *behave as bases* in hydrogen fluoride since they release F^- ions.

$$\underset{\text{Base}}{HNO_3} + \underset{\text{Acid}}{HF} \longrightarrow H_2NO_3^+ + F^-$$

$$\underset{\text{Base}}{H_2SO_4} + \underset{\text{Acid}}{HF} \longrightarrow H_3SO_4^+ + F^-$$

Perchloric acid, which behaves as the strongest acid in aqueous solution, exhibits an amphoteric character in liquid hydrogen fluoride. Thus,

$$\underset{\text{Base}}{HClO_4} + HF \longrightarrow H_2ClO_4^+ + F^-$$

$$\underset{\text{Acid}}{HClO_4} + HF \longrightarrow ClO_4^- + (H_2F)^+$$

Only a few substances such as BF_3, AsF_5, SbF_5 and SnF_4, which behave as Lewis acids in aqueous solutions, function as acids in anhydrous hydrogen fluoride. Thus,

$$\underset{\text{Acid}}{SbF_5} + 2HF \longrightarrow SbF_6^- + H_2F^+$$

$$\underset{\text{Acid}}{BF_3} + 2HF \longrightarrow BF_4^- + (H_2F)^+$$

$$\underset{\text{Acid}}{SnF_4} + 4HF \longrightarrow SnF_6^{2-} + 2(H_2F)^+$$

3. Protonation of Organic Compounds. Organic compounds such as benzene, ethanol, alkanes get protonated when dissolved in HF. Thus,

$$C_6H_6 + HF \longrightarrow C_6H_7^+ + F^-$$

$$C_2H_5OH + HF \longrightarrow C_2H_5OH_2^+ + F^-$$

(*i*) $$(CH_3)_3CCH_3 + HF \longrightarrow (CH_3)_3CCH_4^+ + F^-$$

(*ii*) $$(CH_3)_3CCH_4^+ \longrightarrow (CH_3)_3C^+ + CH_4$$

Because of the formation of ions, organic compounds mentioned as above, give conducting solutions in HF. The aromatic hydrocarbons give coloured solutions in HF and their solubilities can be increased further by adding fluoride acceptors such as BF_3 and SbF_5. The protonated species can be isolated as crystalline salts of BF_4^- and SbF_6^-.

4. Formation of Addition Compounds. Metallic fluorides form addition compounds with HF. Examples are : *KF.2HF*, *KF.3HF*, *NH_4F.HF*, etc.

ANHYDROUS SULPHURIC ACID

The characteristic physical properties of non-aqueous sulphuric acid are given in Table 6.

The viscosity of anhydrous H_2SO_4 is about 25 times higher than that of water. Therefore, solutes dissolve very slowly in sulphuric acid and are also difficult to crystallise from H_2SO_4.

TABLE 6

Some Characteristic Physical Properties of Sulphuric Acid

Properties	Values
Freezing point	10·4°C
Boiling point	300°C
Density	1·84 ml^{-1} (25°C)
Dielectric constant	110
Viscosity (centipoise)	24·54 (20°C)

Chemical Reactions of anhydrous Sulphuric Acid

1. Autoionisation. Anhydrous sulphuric acid autoionises to give $H_3SO_4^+$ and HSO_4^- ions :

$$2\,H_2SO_4 \rightleftharpoons H_3SO_4^+ + HSO_4^-$$

Therefore, any chemical species producing HSO_4^- ions will act as a base and any chemical species producing $H_3SO_4^+$ ion acts as an acid in H_2SO_4.

2. Acid–Base Reactions. Some typical acid–base reactions of anhydrous H_2SO_4 are given below :

(*a*) $KHSO_4$ acts as a base in anhydrous sulphuric acid.

$$KHSO_4 \rightleftharpoons K^+ + HSO_4^-$$

(*b*) Species that are basic in water are also basic in H_2SO_4.

$$OH^- + 2H_2SO_4 \longrightarrow 2HSO_4^- + H_3O^+$$

$$NH_3 + H_2SO_4 \longrightarrow NH_4^+ + HSO_4^-$$

(*c*) Water behaves as a base in anhydrous sulphuric acid.

$$H_2O + H_2SO_4 \longrightarrow HSO_4^- + H_3O^+$$

(*d*) Species containing lone pair of electrons easily accept a proton from H_2SO_4 and act as bases. Thus, amides (like urea, etc). which act as acids in liquid NH_3, are neutral in water and behave as bases in anhydrous H_2SO_4.

$$H_2N(CO)NH_2 + H_2SO_4 \longrightarrow HSO_4^- + [H_2N(CO)NH_3^+]$$

(*e*) Acids which behave as weak acids or even as strong acids in water behave as bases in anhydrous H_2SO_4.

$$CH_3COOH + H_2SO_4 \longrightarrow HSO_4^- + CH_3COOH_2^+$$

$$HNO_3 + 2H_2SO_4 \longrightarrow 2HSO_4^- + NO_2^+ + H_3O^+$$

(*f*) Even very strong acids like perchloric acid behave as weak acids in anhydrous H_2SO_4.

$$HClO_4 + H_2SO_4 \longrightarrow H_3SO_4^+ + ClO_4^-$$

3. Dehydrating Action. H_2SO_4 acts as a strong dehydrating agent and extracts water even from chemical compounds. Thus,

$$C_{12}H_{22}O_{11} \xrightarrow[-11\,H_2O]{H_2SO_4} 12C$$

4. Super Acids. The acids which behave as *strong acids* in strong acid solvents are termed as super acids. For example, $[HB(HSO_4)_4]$, hydrogen [tetrakis(hydrogen sulphato) borate] whose solutions can be prepared in sulphuric acid, behaves as an exceptionally strong acid.

The super acid $HB(HSO_4)_4$ has not been isolated as such. Only its solutions can be prepared. The other super acids are $H_2Sn(HSO_4)_4$ and $H_2Pb(HSO_4)_4$ in H_2SO_4 solution.

LIQUID DINITROGEN TETROXIDE

Dinitrogen tetroxide, N_2O_4, has been studied extensively as a non-protonic non-aqueous solvent. The physical properties of this solvent are given in Table 7.

Much of the chemistry in this solvent can be rationalised in terms of an autoionisation equilibrium of the type

$$N_2O_4 \rightleftharpoons NO^+ + NO_3^-$$

Although there is no physical evidence for the above type of autoionization occurring in N_2O_4, it has been found that the electrical conductance of N_2O_4 increases on adding a donor or a polar solvent to it. This may perhaps be due to increased stabilisation of cations and anions (NO^+ and NO_3^-) of N_2O_4 as a result of the ion–dipole interaction of these ions with the molecules of the added donor or polar solvent.

TABLE 7

Some Characteristic Physical Properties of Liquid Dinitrogen tetroxide

Properties	Values
Freezing point	– 11·2°C
Boiling point	21·1°C
Density	1·493 g ml^{-1} (0°C)
Dielectric constant	2·42
Viscosity	0·527 centipoise (0°C)
Specific conductance	$1{\cdot}3\times10^{-13}$ ohm^{-1} cm^{-1} (0°C)

Thus, assuming that N_2O_4 undergoes autoionisation as mentioned above, it can be said that any chemical species which gives the cation NO^+ in this solvent will behave as an acid and any chemical species which gives the anion NO_3^- in this solvent will behave as a base. Thus, NOCl behaves as an acid in N_2O_4, as is evident from the following reaction :

$$2NOCl \xrightleftharpoons{N_2O_4} 2NO^+ + 2Cl^-$$
$$2NO^+ + Sn \rightleftharpoons 2NO + Sn^{2+}$$
$$Sn^{2+} + 2Cl^- \rightleftharpoons SnCl_2$$
$$\overline{2NOCl + Sn \rightleftharpoons 2NO + SnCl_2}$$

Thus, the acid behaviour of NOCl in N_2O_4, when it reacts with Sn, is parallel to the behaviour of HCl in water when it reacts with Zn as is apparent from the following reaction :

$$2HCl + 2H_2O \xrightleftharpoons{H_2O} 2H_3O^+ + 2Cl^-$$
$$2H_3O^+ + Zn \rightleftharpoons Zn^{2+} + 2H_2O + H_2$$
$$Zn^{2+} + 2Cl^- \rightleftharpoons ZnCl_2$$
$$\overline{Zn + 2HCl \rightleftharpoons ZnCl_2 + H_2}$$

The compound $[EtNH_3]^+[NO_3]^-$ releases NO_3^- anion in N_2O_4. It, therefore, acts as a base in N_2O_4. A

typical reaction of $[EtNH_3]^+[NO_3^-]$ with zinc metal in N_2O_4 is similar to the reaction of zinc with $NaNH_2$ in liquid ammonia, as is evident from the following reactions :

$$2N_2O_4 \rightleftharpoons 2NO^+ + 2NO_3^- \text{ (autoionisation)}$$
$$Zn + 2NO^+ \rightleftharpoons Zn^{2+} + 2NO$$
$$\overline{2\,[EtNH_3]^+[NO_3]^- + Zn^{2+} + 2NO_3^- \rightleftharpoons [EtNH_3]_2^+[Zn(NO_3]^{2-} + 2NO}$$
$$Zn + 2N_2O_4 + 2[EtNH_3]^+[NO_3]^- \rightleftharpoons [EtNH_3]_2^+[Zn(NO_3)_4]^{2-} + 2NO$$
$$4NH_3 \rightleftharpoons 2NH_4^+ + 2NH_2^- \text{ (autoionisation)}$$
$$Zn + 2NH_4^+ \rightleftharpoons 2NH_3 + H_2 + Zn^{2+}$$
$$Zn^{2+} + 2NaNH_2 + 2NH_2^- \rightleftharpoons Na_2[Zn(NH_2)_4]$$
$$\overline{Zn + 2NH_3 + 2NaNH_2 \rightleftharpoons Na_2[Zn(NH_2)_4] + H_2}$$

The solvolysis of metal oxides in N_2O_4 is similar to their solvolysis in liquid ammonia, as shown below :

$$2N_2O_4 \rightleftharpoons 2NO^+ + NO_3^- \text{ (autoionisation)}$$
$$CaO + 2NO^+ \rightleftharpoons Ca^{2+} + N_2O_3$$
$$Ca^{2+} + 2NO_3^- \rightleftharpoons Ca(NO_3)_2$$
$$\overline{CaO + 2N_2O_4 \rightleftharpoons Ca(NO_3)_2 + N_2O_3}$$
$$4NH_3 \rightleftharpoons 2NH_4^+ + 2NH_2^- \text{ (autoionization)}$$
$$Na_2O + 2NH_4^+ \rightleftharpoons 2NH_3 + H_2O + 2Na^+$$
$$2Na^+ + 2NH_2^- \rightleftharpoons 2NaNH_2$$
$$\overline{Na_2O + 4NH_3 \rightleftharpoons 2NaNH_2 + 2NH_3 + H_2O}$$

In fact, solvolysis of the halides of metals in N_2O_4 provides an excellent method for preparing anhydrous metal nitrates which are otherwise extremely difficult to prepare. Thus,

$$2N_2O_4 \rightleftharpoons 2NO^+ + 2NO_3^-$$
$$ZnX_2 + 2NO^+ \rightleftharpoons 2NOX + Zn^{2+}$$
$$Zn^{2+} + 2NO_3^- \rightleftharpoons Zn(NO_3)_2$$

The NOX produced in the reaction decomposes to NO and X_2 and, therefore, it does not participate in the reverse equilibrium reaction. The overall reaction is, thus,

$$2N_2O_4 + ZnX_2 \rightleftharpoons 2NO + X_2 + \underset{\text{(anhydrous)}}{Zn(NO_3)_2}$$

Several metal carbonyls are also solvolysed in a similar manner. Thus,

$$N_2O_4 \rightleftharpoons NO^+ + NO_3^-$$
$$\overline{(OC)_5Mn\text{–}Mn(CO)_5 + NO^+ + NO_3^- \rightleftharpoons Mn(CO)_5(NO_3) + Mn(CO)_4NO + CO}$$
$$(OC)_5Mn\text{–}Mn(CO)_5 + N_2O_4 \rightleftharpoons Mn(CO)_5NO_3 + Mn(CO)_4NO + CO$$

Similarly,

$$3N_2O_4 \rightleftharpoons 3NO^+ + 3NO_3^-$$

$$Fe(CO)_5 + 3NO_3^- \rightleftharpoons Fe(NO_3)_3 + 5CO + 3e^-$$

$$3NO^+ + 3e^- \rightleftharpoons 3NO$$

$$Fe(CO)_5 + 3N_2O_4 \rightleftharpoons Fe(NO_3)_3 + 5CO + 3NO$$

N_2O_4 is also known to form solvated species of the type shown below :

$$2N_2O_4 \rightleftharpoons 2NO^+ + 2NO_3^-$$

$$Ca + 2NO^+ + 2NO_3^- + N_2O_4 \longrightarrow [Ca(NO_3)_2.N_2O_4] + 2NO$$

$$Ca + 3N_2O_4 \longrightarrow [Ca(NO_3)_2.N_2O_4] + 2NO$$

Quite often, however, the solvated species formed as above are found to be nitrosonium nitrate compounds. For example, $Sc(NO_3)_3.2N_2O_4$ and $2Fe(NO_3)_3.3N_2O_4$ are actually $[NO^+]_2[Sc(NO_3)_5]^{2-}$ and $[NO^+]_3[Fe(NO_3)_4]_2^-[NO_3]^-$, respectively.

There are certain reactions which cannot be explained on the basis of the autoionisation of N_2O_4 proposed as above. For instance, the reaction of N_2O_4 with BF_3 yields $[NO_2]^+[ONOBF_3]^-$ and $[NO_2]^+[F_3BONOBF_3]^-$, which can be explained better by assuming the following autoionisation of N_2O_4 :

$$N_2O_4 \rightleftharpoons NO_2^+ + NO_2^-$$

It is worthwhile mentioning here that neither the two proposed ionisations of N_2O_4 nor the partial equations written for various chemical reactions occurring in liquid N_2O_4 are essentially an experimental reality. Nevertheless, the two proposed auto-ionisations and the various partial equations described as above do explain satisfactorily the chemistry of reactions occurring in liquid dinitrogen tetroxide.

LIQUID SULPHUR DIOXIDE

Liquid sulphur dioxide is also a non-protonic solvent as it does not yield a proton (H^+) on ionisation. It is widely used for carrying out a number of chemical reactions.

Under normal temperature and pressure, sulphur dioxide is a gas but it can be readily liquefied. It has a wide liquid range (– 10·°C to – 75·5°C) and hence can serve as a good solvent. Its use as a non-aqueous solvent is rapidly increasing due to its low cost and ease of its handling. Its dielectric constant is small (17·4 at – 20·0°C) which makes it a good solvent for covalent compounds but a poor solvent for electrovalent compounds.

The characteristic physical properties of liquid sulphur dioxide are given in Table 8.

TABLE 8
Some Characteristic Physical Properties of Liquid Sulphur Dioxide

Properties	Values
Freezing point	– 75·5°C
Boiling point	–10·1°C
Density	1·46 g ml^{-1} (– 10°C)
Dielectric constant	17·4 (– 20°C)
Dipole moment	1·61 Debye
Viscosity	0·428 centipoise (– 10°C)
Specific conductance	4×10^{-8} ohm^{-1} cm^{-1} (– 10°C)

Autoionisation. By analogy with water and liquid ammonia, autoionisation of sulphur dioxide takes place as under :

$$SO_2 + SO_2 \rightleftharpoons SO^{2+} + SO_3^{2-}$$

The thionyl ion (SO^{2+}) is analogous to the hydronium ion (H_3O^+) and ammonium ion (NH_4^+) while sulphite ion (SO_3^{2-}) corresponds to hydroxyl ion (OH^-) and amide ion (NH_2^-) of the aqueous and liquid ammonia systems, respectively.

Sulphur dioxide solutions are not as good electrical conductors as are liquid ammonia solutions or aqueous solutions.

Solubility of Substances in Liquid Sulphur Dioxide. Amongst the **inorganic compounds**, iodides and thiocyanates are the most soluble. Metal sulphates, sulphides, oxides and hydroxides are practically insoluble. Many of the ammonium, thallium and mercuric salts are soluble. Liquid sulphur dioxide is an excellent solvent for covalent compounds. Substances such as IBr, PBr_3, CCl_4, $SiCl_4$, $SnCl_4$ are soluble in it. **Metals** are insoluble in liquid sulphur dioxide.

Amongst the **organic compounds**, benzene and alkenes dissolve in it freely. Pyridine, quinoline, ethers, halogen derivatives and acid chlorides also dissolve in liquid sulphur dioxide. Alkanes are insoluble.

Reactions in Liquid Sulphur Dioxide. Chemical reactions that occur in liquid sulphur dioxide are of the following types :

1. Acid–base Reactions or Neutralisation Reactions. Comparing the autoionisation of liquid sulphur dioxide with that of water, it can be seen that thionyl ion (SO^{2+}) is analogous to hydronium ion (H_3O^+) and sulphite ion SO_3^{2-} is analogous to hydroxyl ion (OH^-). Hence, all compounds containing or making available SO_3^{2-} ions in liquid sulphur dioxide will act as bases in this medium. Similarly, all compounds which make available SO^{2+} ions in liquid sulphur dioxide will act as typical acids in liquid sulphur dioxide.

Typical acid–base or neutralisation reactions in liquid sulphur dioxide are given below.

Reaction between thionyl chloride and cesium sulphite :

$$\underset{\text{Acid}}{SOCl_2} + \underset{\text{Base}}{Cs_2SO_3} \xrightarrow{liq.SO_2} \underset{\text{Salt}}{2CsCl} + \underset{\text{Solvent}}{2SO_2}$$

Reaction between thionyl thiocynate and potassium sulphite.

$$\underset{\text{Acid}}{SO(SCN)_2} + \underset{\text{Base}}{K_2SO_3} \xrightarrow{liq.SO_2} \underset{\text{Salt}}{2K(SCN)} + \underset{\text{Solvent}}{2SO_2}$$

2. Solvolytic Reactions. Only a limited number of salts undergo solvolysis in liquid sulphur dioxide. Some common reactions are given below.

Ammonium acetate is solvolysed in liquid sulphur dioxide.

$$2CH_3COONH_4 + 2SO_2 \longrightarrow (NH_4)_2SO_3 + (CH_3COO)_2SO$$

$$(CH_3COO)_2SO \longrightarrow SO_2 + (CH_3CO)_2O$$

Binary halides such as PCl_5, UCl_6, WCl_6 undergo solvolysis in liquid sulphur dioxide.

$$PCl_5 + SO_2 \longrightarrow POCl_3 + SOCl_2$$

$$UCl_6 + 2SO_2 \longrightarrow UO_2Cl_2 + 2SOCl_2$$

$$WCl_6 + SO_2 \longrightarrow WOCl_4 + SOCl_2$$

The formaion of solvates, *i.e.*, the addition compounds with the solvent, is also known. Typical solvates formed are $NaI.4SO_2$, $RbI.4SO_2$, $KBr.4SO_2$, $CaI_2.4SO_2$, $BaI_2.4SO_2$, $SrI_2.4SO_2$, $AlCl_3.2SO_2$, etc.

3. Precipitation Reactions. A large number of precipitation reactions can be carried out in liquid sulphur dioxide due to specific solubility relationships. Some of these reactions are given below.

$$2CH_3COOAg + SOCl_2 \xrightarrow{liq.SO_2} 2AgCl\downarrow + \underset{\text{Thionyl acetate}}{SO(CH_3COO)_2}$$

$$2KI + SOCl_2 \xrightarrow{liq.SO_2} 2KCl\downarrow + SOI_2$$

$$SbCl_3 + 3LiI \xrightarrow{liq.SO_2} SbI_3\downarrow + 3LiCl$$

$$PbF_2 + Li_2SO_4 \xrightarrow{liq.SO_2} PbSO_4\downarrow + 2LiF$$

$$AlCl_3 + 3NaI \xrightarrow{liq.SO_2} 3NaCl\downarrow + AlI_3$$

4. Complex Formation Reactions. A large number of complex formation reactions of liquid sulphur dioxide have been reported. For instance, the solubility of iodine in liquid sulphur dioxide is greatly increased by the addition of potassium or rubidium iodide. This is due to the formation of the complex KI_3 or RbI_3.

$$KI + I_2 \xrightarrow{liq.SO_2} KI_3$$

$$RbI + I_2 \xrightarrow{liq.SO_2} RbI_3$$

Similarly, the increase in the solubility of cadmium iodide and mercuric iodide in liquid sulphur dioxide is attributed to the formation of complexes.

$$HgI_2 + 2KI \xrightarrow{liq.SO_2} K_2[HgI_4]$$

Some other examples of complex formation are as follows :

$AlCl_3$ reacts with SO_3^{2-} ions to form a precipitate of $Al_2(SO_3)_3$ which redissolves in excess of SO_3^{2-} ions forming the complex ion $[Al(SO_3)_3]^{3-}$.

$$2AlCl_3 + 3SO_3^{2-} \rightleftharpoons Al_2(SO_3)_3\downarrow + 6Cl^-$$

$$Al_2(SO_3)_3 + 3SO_3^{2-} \rightleftharpoons \underset{\text{Soluble complex ion}}{2[Al(SO_3)_3]^{3-}}$$

Similarly,

$$SbCl_3 + 3KCl \xrightarrow{liq.SO_2} K_3[SbCl_6]$$

$$SbCl_5 + KCl \xrightarrow{liq.SO_2} K[SbCl_6]$$

$$SbCl_5 + NOCl \xrightarrow{liq.SO_2} NO[SbCl_6]$$

5. Amphoteric Behaviour. Various salts show amphoteric behaviour in liquid sulphur dioxide. The reaction of $AlCl_3$ with NaOH in aqueous medium can be compared with the reaction of $AlCl_3$ with tetramethyl ammonium sulphite in liquid sulphur dioxide. In aqueous solution, the reaction takes place as follows.

$$AlCl_3 + 3NaOH \xrightarrow{H_2O} \underset{\text{Gelatinous ppt.}}{Al(OH)_3} + 3NaCl$$

$$Al(OH)_3 + NaOH \xrightarrow{H_2O} \underset{\text{Soluble complex}}{Na[Al(OH)_4]}$$

From the soluble complex, $Al(OH)_3$ can be reprecipitated by the addition of HCl.

$$Na[Al(OH)_4] + HCl \longrightarrow NaCl + H_2O + Al(OH)_3\downarrow$$

In liquid sulphur dioxide medium, an identical reaction takes place between $AlCl_3$ and tetramethyl ammonium sulphite :

$$2AlCl_3 + 3[N(CH_3)_4]_2SO_3 \xrightarrow{liq.SO_2} 6[N(CH_3)_4]Cl + \underset{\text{Gelatinous ppt.}}{Al_2(SO_3)_3}$$

$$Al_2(SO_3)_3 + 3[N(CH_3)_4]_2SO_3 \xrightarrow{liq.SO_2} \underset{\text{Soluble complex}}{2[N(CH_3)_4]_3[Al(SO_3)_3]}$$

From the soluble complex, $Al_2(SO_3)_3$ can be reprecipitated by adding the acid, $SOCl_2$.

$$2[N[CH_3)_4]_3[Al(SO_3)_3] + 3SOCl_2 \xrightarrow{liq.SO_2} 6[N(CH_3)_4]Cl + 6SO_2 + Al_2(SO_3)_3\downarrow$$

The behaviour of $GaCl_3$ is similar to that of $AlCl_3$.

6. Redox Reactions. Liquid sulphur dioxide does not have any strong oxidising or reducing properties. It serves only as a medium for redox reactions. For instance, liquid sulphur dioxide cannot reduce iodine. However, a sulphite in liquid sulphur dioxide reduces iodine to iodide. Thus,

$$I_2 + 2K_2SO_3 \xrightarrow{liq.SO_2} K_2SO_4 + 2KI + SO_2$$

KI is oxidised to free iodine by $SbCl_5$ in liquid sulphur dioxide.

$$6KI + 3SbCl_5 \xrightarrow{liq.SO_2} 3I_2 + SbCl_3 + 2K_3[SbCl_6]$$

MOLTEN SALTS AS NON-AQUEOUS SOLVENTS

The molten salts which act as non-aqueous solvents can be divided into two categories, *viz.*,

1. High Temperature Molten Salts *2. Room Temperature Molten Salts*

1. High Temperature Molten Salts. This category contains melts of compounds containing mainly ionic bonds, *e.g.*, alkali halides. The coordination number of the ions drops from 6 in solids to 4 in their melts. The long range lattice symmetry is destroyed in the molten state of such salts but the short range symmetry around the ions still exists. Ionic compounds can be dissolved in such melts giving rise to highly conducting solutions. The cryoscopic technique can be applied to determine the number of ions of the solute. For example, the number of ions of KF in molten sodium chloride is 2 and of BaF_2 is 3. But the number of ions of NaF in molten NaCl comes out to be 1 by the cryoscopic method because the Na^+ ion of solute is common with the Na^+ ion of molten NaCl solvent.

Another type of molten salts are melts of covalently bonded compounds although some autoionisation may occur in such compounds also. The example is the autoionisation of molten HgX_2 :

$$2HgX_2 \rightleftharpoons HgX^+ + HgX_3^-$$

Thus, any substance which increases the concentration of HgX^+ behaves as an acid and any substance which increases the concentration of HgX_3^- behaves as a base. Other examples are :

$$Hg(ClO_4)_2 + HgX_2 \longrightarrow 2\,HgX^+ + 2ClO_4^- \qquad (Hg(ClO_4)_2 \text{ acts as an acid})$$

$$KX + HgX_2 \longrightarrow K^+ + HgX_3^- \qquad (KX \text{ acts as a base})$$

$$Hg(ClO_4)_2 + 2KX \longrightarrow 2K^+ + 2ClO_4^- + HgX_2 \qquad (\text{neutralisation})$$

2. Room Temperature Molten Salts. Some chloroaluminates such as  $AlCl_4^-$ are liquids at

room temperature and can be used as solvents for many ionic compounds. But a serious limitation of such liquid chloroaluminate solvents is that they are highly hygroscopic and hydrolyse readily. The hydrolysed chloroaluminates may further react with the dissolved salts to produce their oxidised products.

$$AlCl_4^- + H_2O \longrightarrow [AlCl_2O]^- + 2HCl$$

$$[AlCl_2O]^- + [TiCl_6]^{2-} \longrightarrow [TiOCl_4]^{2-} + AlCl_4^-$$

However, the oxygen of the oxidised product can be quantitatively removed by passing phosgene into the solution of the salt in the chloroaluminate melt.

$$[TiOCl_4]^{2-} + COCl_2 \longrightarrow TiCl_6^{2-} + CO_2 \uparrow$$

Another salt which is liquid at room temperature is obtained by reacting $Et_2NH^+Cl^-$ with CuCl.

$$Et_2NH^+Cl^- + CuCl \longrightarrow Et_2NH^+[CuCl_2]^- \xrightarrow{Et_2NH^+Cl^-} (Et_2NH)_2[CuCl_3]^{2-}$$

$$\xrightarrow{CuCl} (Et_2NH)[Cu_2Cl_3]^-$$

The low melting point of the product obtained by the above reaction is due to the presence of a mixture of salts such as $Et_2NH^+[CuCl_2]^-$, $(Et_2NH^+)_2[CuCl_3]^{2-}$, in the product. This solvent can be easily reduced and can also be easily oxidised.

$$CuCl_2^- + e^- \longrightarrow Cu + 2Cl^-$$

$$CuCl_2^- \longrightarrow CuCl_2 + e^-$$

Therefore, the species which are even mildly oxidising or mildly reducing cannot be studied in this solvent. Moreover, all reactions to be studied in this solvent have to be carried out in the absence of air.

Utility of Molten Salts as Solvents

1. The highly reacting solutes which cannot be studied in reactive solvents can be studied in molten salts. For example, the halogens which cannot be studied in water can be conveniently studied in molten halides.

2. Molten halides are used for the production of halogens.

$$NaCl\ (molten) \xrightarrow{Electrolysis} Na + 1/2\ Cl_2$$

3. Molten salts are used in metallurgy to remove silica as slag which is in molten state at the temperature required for extraction of the metal.

$$CaO\ (flux) + SiO_2\ (impurity) \longrightarrow CaSiO_3\ (slag)$$

4. Molten alkali metal halides can dissolve any amount of the corresponding alkali metal. However, molten halides of Zn, Cd, Hg dissolve the corresponding metal to a smaller extent. It is assumed that the metal dissolved in metal halides loses electrons so that the solution becomes reducing. That is why Cd and Hg reduce a part of molten $HgCl_2$ and $CdCl_2$.

$$Hg + HgCl_2 \longrightarrow Hg_2Cl_2$$

$$Cd + CdCl_2 \longrightarrow Cd_2Cl_2$$

5. The molten salts provide a medium in which the concentration of anionic ligands can be much more than is possible in their aqueous solutions. For example, $CrCl_6^{3-}$, $TiCl_6^{3-}$ cannot be isolated from aqueous solutions as these species *immediately* hydrolyse. But, these species can be easily prepared by using molten metal chlorides as solvent medium.

$$CrCl_3 + 3Cl^- \longrightarrow [CrCl_6]^{3-}$$

$$TiCl_4 + 2Cl^- \longrightarrow [TiCl_6]^{2-}$$

QUESTIONS

1. (*a*) What do you understand by ionising and non-ionising solvents ? Give examples.
2. (*a*) Discuss the chemistry of liquid ammonia as a solvent.
   (*b*) What are the advantages and disadvantages of liquid ammonia as solvent ?
3. Describe the following reactions in liquid ammonia giving suitable examples : (*i*) Acid–base reactions (*ii*) Precipitation reactions (*iii*) Complex formation reactions (*iv*) Ammonolysis.
4. Discuss the nature and applications of metal ammonia solutions.
5. Compare the acid–base neutralisation and protolysis reactions of liquid ammonia and water.
6. What are protic and aprotic solvents ? Give examples. Is liquid HF a protic or an aprotic solvent ?
7. Discuss the merits and demerits of liquid hydrogen fluoride as a non-aqueous solvent. Discuss briefly the chemical reactions which take place in this solvent.
8. Discuss briefly the reactions which take place in non-aqueous sulphuric acid.
9. Give the important physical constants of liquid N_2O_4. Discuss the various reactions which occur in this solvent.
10. (*a*) Discuss the following reactions in liquid sulphur dioxide giving two examples of each type :
    (*i*) Acid–base reactions (*ii*) Solvolytic reactions (*iii*) Complex formation reactions
    (*b*) What are the advantages and disadvantages of liquid SO_2 as a solvent ?
11. "Dielectric constants, dipole moments and autoionisation play a significant role in explaining solubilities of substances in various solvents." Discuss.
12. Explain giving reasons :
    (*i*) Strong oxidising agents do not exist in liquid ammonia.
    (*ii*) Solutions of alkali metals in liquid ammonia are coloured.
    (*iii*) A strong acid like HNO_3 behaves as a base in hydrogen fluoride.
    (*iv*) Covalent compounds such as C_6H_6 and C_2H_5OH give conducting solutions in liquid hydrogen fluoride.
13. Discuss the role played by molten salts as non-aqueous solvents.

8 ACIDS AND BASES

Different concepts have been put forth by different investigators to characterise acids and bases. While some of the concepts are quite narrow in their approach, others are fairly comprehensive. Some important concepts of acids and bases are discussed below.

Arrhenius Concept

According to Arrhenius concept, *an* **acid** *is a substance that dissociates to give hydrogen ions when dissolved in water.* Thus, hydrogen chloride gas is an acid because when dissolved in water, it gives hydrogen ions.

$$HCl\,(g) + \text{water} \rightleftharpoons H^+\,(aq) + Cl^-\,(aq)$$

The symbol *aq* indicates that the ions are hydrated, *i.e.*, associated with one or more molecules of water.

According to Arrhenius concept, *a* **base** *is a substance which dissociates into hydroxyl ions when dissolved in water.* Thus, NaOH is a base because it furnishes hydroxyl ions in aqueous solution.

$$NaOH + \text{water} \rightleftharpoons Na^+\,(aq) + OH^-\,(aq)$$

The high dielectric constant of water lowers the force of attraction between the oppositely charged ions and thus causes the dissociation of the electrolyte.

Hydronium ion. Hydrogen ion is merely a proton. It is a unique ion in the sense that it has no electron. It is the smallest ion known and, therefore, has a strong tendency to get hydrated. It exists largely as attached to a molecule of water forming H_3O^+ ion, *viz.*, the **hydronium ion.**

Although the proton in aqueous solution is known to be largely hydrated, with H_3O^+ as its probable structure, it is customary to represent it as $H^+\,(aq)$, for the sake of convenience.

Due to simplicity, Arrhenius concept was widely accepted and used. However, this concept has a serious limitation that it can be applied only to aqueous solutions. It fails to account for the behaviour of acids and bases in solvents other than water, *viz.*, non-aqueous solvents.

Proton Transfer Theory. Concept of Lowry and Bronsted

Lowry and Bronsted suggested a more general definition of acids and bases which applies to aqueous as well as to non-aqueous solutions. According to this concept, an **acid** is defined as a substance which has a tendency to donate a proton to any other substance and a **base** as a substance which has a tendency to accept a proton from any other substance. In other words, an **acid** is a proton-donor and a **base** is a proton-acceptor.

When an acid loses a proton, the residual part of it has a tendency to regain the proton. Therefore, it behaves as a base. An acid and a base may, therefore, be defined by the general equation

$$\text{Acid} \rightleftharpoons H^+ + \text{Base}$$

Consider ionisation of acetic acid in water which may be represented as

$$\underset{\text{Acid}}{CH_3COOH} + \underset{\text{Base}}{H_2O} \rightleftharpoons \underset{\text{Acid}}{H_3O^+} + \underset{\text{Base}}{CH_3COO^-}$$

It is evident that acetic acid *donates a proton* to water and thus acts as an *acid*. Water *accepts* a proton and, therefore, acts as a *base*. In the reverse reaction, hydronium ion (H_3O^+) *donates* a proton to the acetate ion and, therefore, acts as an *acid*. The acetate ion *accepts* a proton and, therefore, behaves as a *base*.

Such pairs of substances which can be formed from one another by the gain or loss of a proton are known as **conjugate acid–base pairs.** Thus, acetic acid is the conjugate acid of acetate ion and acetate ion is the conjugate base of acetic acid. Similarly, water is the conjugate base of hydronium ion and hydronium ion is the conjugate acid of water.

The ionisation of hydrochloric acid in water may be represented as

$$\underset{\text{Acid}}{HCl} + \underset{\text{Base}}{H_2O} \rightleftharpoons \underset{\text{Acid}}{H_3O^+} + \underset{\text{Base}}{Cl^-}$$

Evidently, hydrochloric acid is the conjugate acid of chloride ion and chloride ion is the conjugate base of hydrochloric acid.

The following points emerge out of the above discussion :

1. Firstly, it is evident that a substance is able to show its acidic character only if another substance capable of accepting a proton (i.e., a base) is present. For example, acetic acid or hydrogen chloride solution in benzene is not acidic because benzene is not in a position to take up protons. But, a solvent like water can take up protons and, therefore, acetic acid or hydrochloric acid can ionise in water, as shown in the above examples.

2. Secondly, hydrogen ion in aqueous solution does not exist as H^+ ion but as hydrated ion, H_3O^+.

3. Thirdly, not only molecules but even ions may act as acids or bases. Thus, in the above examples, acetate (or chloride) ion acts as a base as it can accept a proton to form acetic acid (or hydrochloric acid). In fact, anion of any acid is the conjugate base of the acid.

As can be seen from the ionisation of acetic acid or hydrochloric acid represented above, there is one acid and one base on each side of the equation. Suppose, acetic acid is designated as $Acid_1$, then the acetate ion, its conjugate base, may be designated as $Base_1$. Similarly, if water is referred to as $Base_2$, then the hydronium ion, its conjugate acid, may be designated as $Acid_2$. The ionization of acetic acid in water may thus be represented as

$$Acid_1 + Base_2 \rightleftharpoons Acid_2 + Base_1 \qquad ...(4)$$

$Acid_1$ and $Base_1$ is a **conjugate acid–base pair** and so is the pair of $Acid_2$ and $Base_2$.

In general, the ionisation of an acid HA in water may be represented as

$$HA + H_2O \rightleftharpoons H_3O^+ + A^-$$

Just as an acid requires a solvent that can take up a proton (*i.e.*, can act as a base) for its ionization, a base requires a solvent that can give up a proton (*i.e.*, that can act as an acid) for its ionization. Water possesses both basic and acidic properties. Therefore, acids as well as bases can ionize in water. Thus, water acts as an acid (a proton-donor) towards ammonia and as a base (a proton-acceptor) towards acetic acid. Such substances are said to be **amphiprotic.**

Consider ionisation of ammonia in water which may be represented as

$$\underset{Base_1}{NH_3} + \underset{Acid_2}{H_2O} \rightleftharpoons \underset{Acid_1}{NH_4^+} + \underset{Base_2}{OH^-}$$

Now ammonium ion (NH_4^+) is the conjugate acid (say, Acid $_1$) to the base NH_3 (Base$_1$) and hydroxyl ion (OH^-) is the conjugate base (Base$_2$) to the acid H_2O (Acid$_2$).

Relative Strengths of Acid–Base Pairs. The *strength of an acid*, according to the above concept of Lowry and Bronsted, depends upon its *tendency to lose protons* and the *strength of a base* depends upon its *tendency to gain protons*. If an acid, such as hydrochloric acid, is a strong acid, it will have a strong tendency to donate protons. Thus, the equilibrium

$$HCl + H_2O \rightleftharpoons H_3O^+ + Cl^-$$

lies very much to the right and the reverse reaction, representing the gain of protons by the chloride ions leading to the reformation of HCl, takes place to a very small extent. Accordingly, Cl^- ion is a weaker base than H_2O since the latter has a greater tendency to take up a proton.

Acetic acid, on the other hand, has considerably less tendency to donate protons and is, therefore, a much weaker acid. It ionises to a small extent, *i.e.*, the equilibrium

$$CH_3COOH + H_2O \rightleftharpoons H_3O^+ + CH_3COO^-$$

lies mostly towards the left. It follows, therefore, that CH_3COO^- ion has a much greater tendency to gain protons and hence it is a much stronger base than H_2O.

In the above reaction, acetic acid and hydronium ion may be regarded as two acids competing with each other to donate protons. Again, since the equilibrium is known to lie towards the left, it follows that hydronium ion is more successful in this attempt than acetic acid. Hence, the former is a stronger acid. In short, while acetate ion is a stronger base than water, its conjugate acid, acetic acid, is a weaker acid than hydronium ion.

Thus, as a general rule, *the stronger an acid, the weaker must be its conjugate base and vice versa.* If an acid (*e.g.*, HCl) is strong, its conjugate base (Cl^- ion) is weak. If a base (*e.g.*, CH_3COO^-) is strong, its conjugate acid (CH_3COOH) is weak.

Water is a weak base because its conjugate acid, hydronium ion (H_3O^+), is a strong acid. At the same time, water is a very weak acid because its conjugate base, hydroxide ion (OH^-), is a very strong base.

It may be pointed out that while strong acids like HCl, HNO_3, H_2SO_4, etc., being *covalent* compounds, get ionised only in a solvent like water which can take up protons, strong bases such as NaOH, KOH, $Ba(OH)_2$, etc., being *electrovalent* compounds, exist as ions even in the solid state. The basic character of these compounds is exclusively due to the presence of hydroxyl ion which is always there (even without a solvent) and, therefore, no interaction with a solvent like water is necessary in such cases.

Lux–Flood Concept

This concept was proposed by Lux and extended by Flood. It considers the acid–base reaction in terms of the specific reaction of the oxide ion and is mainly used for molten oxides at high temperatures. According to this concept, an **acid** is a substance which accepts the oxide ion and a **base** is a substance which donates the oxide ion. In other words, an **acid** is an oxide ion-acceptor and a **base** is an oxide ion-donor. For example, in the reaction

$$\underset{\text{Base}}{CaO} + \underset{\text{Acid}}{SiO_2} \longrightarrow CaSiO_3,$$

calcium oxide is a base and silicon dioxide is an acid. Similarly, in the reaction

$$PbO + SO_3 \longrightarrow PbSO_4$$

PbO is a base while SO_3 is an acid.

This concept, however, has only a limited scope.

The Solvent–System (or Autoionization) Concept

According to solvent–system concept put forth by Fanklin, an **acid** is a substance which, in a solvent, increases the concentration of a cation charateristic of that solvent and a **base** is a substance which, in a solvent, increases the concentration of an anion characteristic of that solvent. The characteristic cations and anions of the solvent are the ions produced during its autoionization.

Autoionization of water, for instance, is represented as

$$2H_2O \rightleftharpoons \underset{\text{Solvent cation}}{H_3O^+} + \underset{\text{Solvent anion}}{OH^-}$$

Thus, in water, substances giving H_3O^+ ions are acids and those giving OH^- ions are bases.

Liquid ammonia undergoes autoionization as follows :

$$2NH_3 \rightleftharpoons \underset{\text{Solvent cation}}{NH_4^+} + \underset{\text{Solvent anion}}{NH_2^-}$$

According to solvent–system concept, in liquid ammonia, substances which give ammonium ions (NH_4^+) act as acids while those giving amide ions (NH_2^-) act as bases. For example, ammonium chloride acts as an acid while potassium amide acts as a base in liquid ammonia.

$$NH_4Cl \overset{\text{liq. } NH_3}{\rightleftharpoons} NH_4^+ + Cl^-$$

$$KNH_2 \overset{\text{liq. } NH_3}{\rightleftharpoons} K^+ + NH_2^-$$

The acid–base neutralisation reaction of NH_4Cl and KNH_2 in liquid NH_3 is analogous to that of HCl and NaOH in water.

$$NH_4Cl + KNH_2 \longrightarrow KCl + 2NH_3$$

$$HCl + NaOH \longrightarrow NaCl + H_2O$$

Consider the autoionization of liquid nitrogen tetroxide :

$$N_2O_4 \rightleftharpoons \underset{\text{Solvent cation}}{NO^+} + \underset{\text{Solvent anion}}{NO_3^-}$$

According to solvent–system concept, in liquid nitrogen tetroxide, the substances which furnish nitrosyl ions (NO^+) behave as acids and those which furnish nitrate ions (NO_3^-) behave as bases. Accordingly, NOCl behaves as an acid and $NaNO_3$ behaves as a base, in this solvent.

$$NOCl \overset{\text{liq. } N_2O_4}{\rightleftharpoons} NO^+ + Cl^-$$

$$NaNO_3 \overset{\text{liq. } N_2O_4}{\rightleftharpoons} Na^+ + NO_3^-$$

Autoionization of sulphuric acid is represented as

$$2H_2SO_4 \rightleftharpoons H_3SO_4^+ + HSO_4^-$$

Thus, any species giving $H_3SO_4^+$ ion acts as an acid and any species giving HSO_4^- ion acts as a base.

Just as ionic product of H_2O is written as $K_w = [H_3O^+][OH^-]$, similarly, the ionic product of any solvent AB ionising as $AB \rightleftharpoons A^+ + B^-$, may be written as $K_{AB} = [A^+][B^-]$. Just as the convenient scale for indicating H^+ ion concentration in aqueous media is the ***p*H scale** and the point of neutrality is given by $-1/2 \log K_w$ (*i.e.*, $pH = 7$), similarly, we can construct a convenient scale for indicating the acidity of the solvent AB, the point of neutrality being given by $-1/2 \log K_{AB}$.

Limitations of Solvent–System (or Autoionization) Concept. The solvent–system concept lays too much stress on ionic reactions and chemical properties of the solvent. This concept totally ignores the physical properties of the solvent. The limitations of the concept can be understood more clearly by taking into consideration certain specific examples.

Solvent $POCl_3$ undergoes autoionization as

$$POCl_3 \rightleftharpoons \underset{\text{Acid ion}}{POCl_2^+} + \underset{\text{Base ion}}{Cl^-}$$

In $POCl_3$, $(CH_3)_4N^+Cl^-$ and $FeCl_3$ ionise as follows :

$$(CH_3)_4N^+Cl^- \longrightarrow (CH_3)_4N^+ + Cl^-$$

$$FeCl_3 + POCl_3 \longrightarrow FeCl_4^- + POCl_2^+$$

According to the solvent–system concept, therefore, $(CH_3)_4N^+Cl^-$ is a *base* and $FeCl_3$ is an *acid* in $POCl_3$ and the net reaction between these two species is a typical neutralisation reaction which may be represented as

$$\underset{\text{Acid ion}}{POCl_2^+} + \underset{\text{Base ion}}{Cl^-} \longrightarrow POCl_3$$

The above view receives support from the fact that $FeCl_3$ can be titrated quantitatively against $(CH_3)_4N^+Cl^-$ in $POCl_3$ as the solvent conductometrically as well as spectrophotometrically and the *end point is sharp.*

The same reaction occurs between $FeCl_3$ and $(CH_3)_4N^+Cl^-$ in $OP(OEt)_3$ as the solvent giving the same product $FeCl_4^-$. However, this solvent cannot autoionize to give Cl^- ion. In fact, there is no evidence for the autoionization of the solvent $OP(OEt)_3$ at all. The solvent–system concept thus fails to explain the reaction between $FeCl_3$ and $(CH_3)_4N^+Cl^-$ in $OP(OEt)_3$.

Autoionization of liquid SO_2 is supposed to occur as follows :

$$2SO_2 \rightleftharpoons \underset{\text{Acid ion}}{SO^{2+}} + \underset{\text{Base ion}}{SO_3^{2-}}$$

The compound $SOCl_2$ is supposed to ionize in liquid SO_2 as follows :

$$SOCl_2 \overset{\text{liq. } SO_2}{\rightleftharpoons} SO^{2+} + 2Cl^-$$

According to the solvent–system concept, therefore, $SOCl_2$ is an acid.

Cs_2SO_3 ionises in liquid SO_2 as follows :

$$Cs_2SO_3 \overset{\text{liq. } SO_2}{\rightleftharpoons} 2Cs^+ + SO_3^{2-}$$

According to the solvent–system concept, therefore, Cs_2SO_3 is a *base.*

Evidently, the net reaction between $SOCl_2$ and a sulphite would be a neutralisation reaction as per the solvent–system concept.

$$SO^{2+} + SO_3^{2-} \rightleftharpoons 2SO_2$$

Such a reaction does occur between $SOCl_2$ and Cs_2SO_3 .

The explanation for the above reaction is, obviously, based on the autoionization of liquid SO_2. But, autoionization of liquid SO_2 has not been established at all. Liquid SO_2 has a very low dielectric constant which does not favour its ionization. Nonionization of liquid SO_2 is fully supported by the following experiment :

$SOCl_2$ is dissolved in liquid SO_2 labelled with radioactive ^{35}S. According to the solvent–system concept, the following reactions are supposed to occur :

$$2\,{}^{35}SO_2 \rightleftharpoons {}^{35}SO^{2+} + {}^{35}SO_3^{2-}$$
$$SOCl_2 \rightleftharpoons SO^{2+} + 2Cl^-$$
$${}^{35}SO^{2+} + 2Cl^- \rightleftharpoons {}^{35}SOCl_2$$

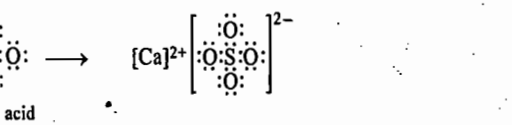
If autoionization of liquid SO_2 actually occurs, the labelled and unlabelled SO^{2+} ions would compete with each other to combine with the Cl^- ion to form $SOCl_2$. As a result, a considerable amount of ^{35}S would get incorporated in $SOCl_2$ within a very short time. But this does not happen. The half-life for the exchange of ^{35}S in this reaction is found to be about 2 years ! This rules out the possibility of autoionization of liquid SO_2. In other words, the reaction between $SOCl_2$ and Cs_2SO_3 cannot be explained on the basis of solvent–system concept.

It may thus be concluded that the solvent–system concept is useful only when the ionic species formed in solution are definitely known. The concept should not be stretched for solvents which are not conducive towards ion formation and also for solvents the nature of whose ions or even the existence of whose ions is not definitely known.

Lewis Concept

In 1923, G.N. Lewis, in order to cover all types of neutralization reactions, gave more broad based definitions of acids and bases. According to Lewis concept, a **base** is defined as a substance which can donate electrons whereas an **acid** is a substance which can accept electrons. In other words, while a **base** is an electron-donor, an **acid** is an electron-acceptor.

In the light of these definitions, the combination of calcium oxide with sulphur trioxide to form calcium sulphate is represented as below :



Lewis base Lewis acid

A lone pair of electrons from oxide ion of calcium oxide is donated to sulphur trioxide.

Lewis definition of a base covers all substances which have unshared electrons in the outer energy levels. These would also be classed as bases according to Lowry–Bronsted's concept. On the other hand, Lewis acids include all substances which have vacant orbitals to accept electrons. These include the following types of substances :

1. *All cations are regarded as Lewis acids* because they can accept electrons. While larger cations such as Na^+, K^+, Ba^{2+}, Ca^{2+}, etc., behave as weak Lewis acids, smaller cations such as H^+, Ag^+, Fe^{2+}, etc., behave as strong Lewis acids. The smallest cation, *viz.*, H^+ ion, behaves as the strongest Lewis acid.

$$H^+ + NH_3 \longrightarrow NH_4^+$$

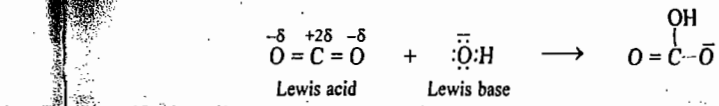
2. *Electron-deficient compounds in which the central atoms can expand their valence shells are regarded as Lewis acids.* For example, in molecules such as BF_3, BCl_3, $AlCl_3$, etc., the central atoms have only six electrons around them and, therefore, have a tendency to accept an electron pair to complete their octet. For example,

$$F_3B + :NH_3 \longrightarrow F_3B:NH_3$$

3. *Molecules in which the central atoms have vacant d orbitals may also behave as Lewis acids by extending their valency shells beyond the octet.* For example, in molecules such as $SnCl_4$, SiF_4, SbF_5, etc., the central atoms have vacant *d* orbitals and, therefore, they extend their valency shells beyond the octet, as shown below :

$$\underset{\text{Lewis acid}}{SiF_4} + \underset{\text{Lewis base}}{2F^-} \longrightarrow [SiF_6]^{2-}$$
$$SnCl_4 + 2Cl^- \longrightarrow [SnCl_6]^{2-}$$
$$SbF_5 + F^- \longrightarrow [SbF_6]^-$$

4. *Molecules in which the central atom is bonded to atoms of different electronegativities through one or more multiple bonds also behave as Lewis acids.* For example, C atom in CO_2 behaves as a Lewis acid because in this molecule, carbon is bonded to more electronegative oxygen atoms through double bonds. As the Lewis base approaches the less electronegative carbon atom, the pi electron charge density gets displaced away from the carbon atom towards oxygen atoms. This results in development of a partial positive charge on carbon atom and a partial negative charge on oxygen atoms. In other words, the electron charge density on carbon atom decreases and, therefore, carbon atom in carbon dioxide acts as an electron-acceptor.



Lewis acid Lewis base

Similarly, S atom in SO_2 acts as a Lewis acid towards OH^- ion.

Sulphur trioxide also acts as a Lewis acid. Its electronic structure is as shown before. It has a double bond between S and one of the O atoms. The oxygen atom, being more electronegative than sulphur atom, pulls the pi electrons towards itself leaving a partial positive charge on sulphur atom which, thereby, acts as an *electron-deficient centre.* As a result, a Lewis base like O^{2-} would donate its electron pair to S atom of SO_3 leading to the formation of SO_4^{2-} ion, as mentioned before.

Limitations of Lewis Concept. The Lewis concept has several limitations, the most significant of which are discussed below :

1. The Lewis concept is *too general* and includes all reactants which can form coordination bonds. Even metals in their zero oxidation state (*e.g.,* Fe, Ni, Co, Mn) are termed as Lewis acids in their complexes with pi acceptor ligands such as CO, cyclopentadiene and olefins.

2. The relative strengths of acids and bases cannot be explained on the basis of Lewis concept.

RELATIVE STRENGTHS OF ACIDS AND BASES

There are several factors which affect the relative strengths of acids and bases. The effects of some of these factors are discussed below.

1. Effect of Solvent on Relative Strengths of Acids and Bases

Effect of Solvent on Acid Strength. *Acid strength* is a relative term. According to the concept of Lowry and Bronsted, the strength of an acid depends on the substance which acts as a base. Consider the general equation

$$\text{Acid}_1 + \text{Base}_2 \rightleftharpoons \text{Acid}_2 + \text{Base}_1$$

Evidently, the capacity of the acid to ionise (*i.e.*, to donate protons) depends upon the base strength (*i.e.*, the capacity to accept protons) of the solvent which acts as a base. To illustrate this point, ionization in three solvents, namely, glacial acetic acid, water and liquid ammonia of increasing basic character may be considered.

Ionization in acetic acid. Although acetic acid is normally an acid, it is also able, to some extent, to accept a proton and thus act as a base as well. The ionization of a strong acid HA in this medium may thus be represented as

$$\underset{\text{Acid}}{HA} + \underset{\text{Base}}{CH_3COOH} \rightleftharpoons \underset{\text{Acid}}{CH_3COOH_2^+} + \underset{\text{Base}}{A^-}$$

But, the equilibrium cannot lie very much to the right since acetic acid has only a small tendency to accept protons. Therefore, *even strong acids are only feebly ionised in acetic acid.*

The degrees of ionization of a number of acids when dissolved in glacial acetic acid have been determined from conductance measurements. Taking these as a measure of their relative strengths, some of the common acids have been arranged in the following order of decreasing strength :

$$HClO_4 > HBr > H_2SO_4 > HCl > HNO_3$$

This is the correct order of decreasing strengths of these acids.

Ionisation in water. Water is a much stronger base than acetic acid, *i.e.,* it has a much greater tendency to accept protons than acetic acid. Therefore, the ionisation equilibrium of a strong acid in water, represented as

$$\underset{\text{Acid}}{HA} + \underset{\text{Base}}{H_2O} \rightleftharpoons \underset{\text{Acid}}{H_3O^+} + \underset{\text{Base}}{A^-}$$

lies very much to the right. All the five acids mentioned in the above series, therefore, react almost completely with water to form, in every case, hydronium ion, H_3O^+. Therefore, *all strong acids in aqueous solutions appear almost equally strong.* Obviously, their relative strengths in aqueous solutions cannot be compared. This phenomenon is known as the **levelling effect.**

However, the ionic equilibria do not proceed that far in the case of weak acids like formic, acetic, propionic, lactic, tartaric and phosphoric acids. It is, therefore, possible to distinguish between their relative strengths, as will be shown a little later.

Ionisation in liquid ammonia. Liquid ammonia has such a strong basic character (*i.e.,* it has such a strong tendency to take up protons) that even a weak acid, like acetic acid, ionises to a considerable extent in liquid ammonia and thus behaves as a strong acid. The ionic equilibrium represented below, lies very much to the right :

$$\underset{\text{Acid}}{CH_3COOH} + \underset{\text{Base}}{NH_3} \rightleftharpoons \underset{\text{Acid}}{NH_4^+} + \underset{\text{Base}}{CH_3COO^-}$$

By conductance measurements it has been found that all acids, which in aqueous solution behave stronger than acetic acid, appear to be of about the same strength when dissolved in liquid ammonia. Thus, such strong acids as hydrochloric and nitric and such weak acids as acetic and propionic, appear to be of almost equal strength when dissolved in liquid ammonia.

Ionisation in hydrogen fluoride. Hydrogen fluoride has strong acidic properties and no basic, *i.e.,* proton-accepting, properties at all. Consequently, even the strongest acid is incapable of ionising as an acid when dissolved in hydrogen fluoride. As a matter of fact, many substances, which are normally acids but have some tendency to accept protons as well under certain conditions, ionise as bases when dissolved in hydrogen fluoride. Thus, nitric acid ionises slightly as a base in hydrogen fluoride solution :

$$\underset{\text{Base}}{HNO_3} + \underset{\text{Acid}}{HF} \rightleftharpoons \underset{\text{Acid}}{H_2NO_3^+} + \underset{\text{Base}}{F^-}$$

It is thus interesting to note that even *a strong acid* like HNO_3 *behaves as a base* (a very weak base though) when dissolved in HF.

Acetic acid, which has comparatively greater tendency to accept a proton, ionises comparatively more readily as a base in hydrogen fluoride solution :

$$\underset{\text{Base}}{CH_3COOH} + \underset{\text{Acid}}{HF} \rightleftharpoons \underset{\text{Acid}}{CH_3COOH_2^+} + \underset{\text{Base}}{F^-}$$

Thus, acetic acid behaves as a stronger base than nitric acid when dissolved in hydrogen fluroride.

Effect of Solvent on Base Strength. The nature of the solvent plays an equally important role in the ionization and relative strengths of bases as well. If the solvent is a weak acid, such as water, it will be possible to compare the strengths of different bases as they will ionise to different extents. But if the solvent is even a slightly stronger acid, *e.g.,* acetic acid, it will not be possible to distinguish between the strengths of different bases.

For example, aniline, a very weak base and sodium hydroxide, a very strong base in water, *appear to be equally strong when acetic acid is used as the solvent* **(levelling effect).** Sometimes advantage is taken of this fact in volumetric estimations of bases which are too weak in aqueous solution to be titrated against acids.

Explanation of levelling effect on the basis of solvent–system concept. The levelling effect can be explained by invoking the solvent–system concept of acids and bases. According to this concept, *all acids and bases stronger than the characteristic cation and the anion of the solvent would be levelled to the characteristic cation and anion of the solvent. Acids and bases weaker than the characteristic cation and anion of the solvent would remain in equilibrium with them.* The above concept would become clear from the following illustration.

The three strong acids, $HClO_4$, HCl and HNO_3 ionise in water as follows :

$$HClO_4 + H_2O \longrightarrow H_3O^+ + ClO_4^-$$

$$HCl + H_2O \longrightarrow H_3O^+ + Cl^-$$

$$HNO_3 + H_2O \longrightarrow H_3O^+ + NO_3^-$$

All the three acids are stronger acids than the characteristic cation of the solvent (water), *viz.,* the H_3O^+ ion. These acids would, therefore, be *completely levelled* (or converted) to the characteristic cation H_3O^+ of the solvent and thus behave as being equally strong. A solvent in which various strong acids appear equally strong is known as a **levelling solvent.**

Now consider an acid such as CH_3COOH which is weaker than H_3O^+, in water. It would remain in equilibrium with H_3O^+, as shown below :

$$CH_3COOH + H_2O \rightleftharpoons CH_3COO^- + H_3O^+$$

The strength of such an acid would depend upon the concentration of the characteristic cation of water, *viz.*, the H_3O^+ ion at equilibrium.

For measuring relative strengths of strong acids, we must select a solvent whose characteristic cation is a stronger acid than the acids whose strengths are to be measured. One such solvent is CH_3COOH. Consider autoionization of acetic acid represented as

$$2CH_3COOH \rightleftharpoons CH_3COOH_2^+ + CH_3COO^-$$

The strong acid HA dissociates in acetic acid as follows :

$$HA + CH_3COOH \rightleftharpoons CH_3COOH_2^+ + A^-$$

The characteristic cation of acetic acid, *viz.*, $CH_3COOH_2^+$ ion, is stronger than HA. Hence, HA and $CH_3COOCH_2^+$ ion will remain in equilibrium. The strength of HA in acetic acid would thus be determined by the concentration of $CH_3COOH_2^+$ ion at equilibrium.

The solvents in which strong acids ionise to different extents so that the relative strengths of these acids can be measured, are known as **differentiating solvents.** Thus, acetic acid is a *differentiating solvent* while water is a *levelling solvent* for strong acids such as $HClO_4$, HBr, H_2SO_4, HCl, HNO_3.

Levelling effect is observed in the case of strong bases as well. If a base is stronger than the characteristic anion of the solvent, it would be levelled (or converted) into the anion of the solvent. Thus, all strong bases would appear to be equally strong in water as they get completely converted into OH^- ion, the characteristic anion of the solvent (water).

According to the solvent-system concept, the behaviour of a species as an acid or a base would depend upon the *acidic* or *basic nature of the solvent.* For example, acetic acid behaves as a weak acid in water, a strong acid in ammonia and as a base in sulphuric acid, as illustrated below :

In water :

$$CH_3COOH + H_2O \rightleftharpoons H_3O^+ + CH_3COO^-$$

There is only a small concentration of H_3O^+ ions in solution. Therefore, acetic acid behaves as a weak acid in water.

In ammonia :

$$CH_3COOH + NH_3 \longrightarrow NH_4^+ + CH_3COO^-$$

Acetic acid is almost completely converted to NH_4^+ ion which is a characteristic cation of the solvent. Therefore, acetic acid behaves as a strong acid in ammonia.

In sulphuric acid :

$$CH_3COOH + H_2SO_4 \rightleftharpoons CH_3COOH_2^+ + HSO_4^-$$

There is considerable concentration of HSO_4^- in solution which is the characteristic anion of sulphuric acid. Hence, acetic acid behaves as a base in sulphuric acid.

Similarly, urea behaves as a weak acid in ammonia but as a strong base in concentrated sulphuric acid, as illustrated below :

$$H_2NCONH_2 + NH_3 \rightleftharpoons H_2NCONH^- + NH_4^+$$
$$H_2NCONH_2 + H_2SO_4 \longrightarrow H_2NCONH_3^+ + HSO_4^-$$

Sulphuric acid is such a strong acid solvent that even a strong acid like HNO_3 behaves as a base (though very weak) in it according to the equation

$$HNO_3 + H_2SO_4 \rightleftharpoons HSO_4^- + H_2O + NO_2^+$$

2. Effect of Polarity and Dielectric Constant on Relative Strengths of Acids and Bases

The polarity and dielectric constant of a solvent influence considerably the acidic and basic strength of ionic species dissolved in that solvent. According to Coulomb's law, the force of attraction between two oppositely charged ions is given by

$$F = q_1q_2/\varepsilon r^2 \quad ...(1)$$

where q_1 and q_2 are the charges on the ions, r is the distance between the two ions and ε is the dielectric constant of the solvent. The higher the dielectric constant of the solvent, the lower is the magnitude of F. In solvents with low dielectric constants, the force of attraction between the ions of the solute will be relatively large and consequently the dissociation (separation of ions) of the solute would be small. In solvents with high dielectric constants, the force of attraction between the ions would be small and the extent of dissociation would be large. In other words, the acidic or basic strength of a species would increase with an increase in the dielectric constant of the solvent. The dielectric constant and the dipole moment are known to be directly related. Hence, the greater the polarity of a solvent, the greater would be the acidic or basic strength of the species dissolved in that solvent.

3. Effect of Substituents on Relative Strengths of Acids and Bases

The substituents present in acids and bases have a marked effect on their relative strengths. The increase or decrease in acid or base strength depends upon the nature of the substituents, their number and the type of bonding involved in them. This is illustrated below.

a. Electron-releasing or Electron-withdrawing Nature of Substituents. Since an acid is an electron-acceptor and a base is an electron-donor, the nature of substituents (whether electron-releasing or electron-withdrawing) present in them would affect their acidic or basic strength considerably. An electron-withdrawing substituent would increase and an electron-releasing substituent would decrease the acid strength of a species . Thus, chloroacetic acid is stronger than acetic acid while propionic acid is weaker than acetic acid. This is because Cl is an electron-withdrawing and CH_3 is an electron-releasing group.

Similarly, an electron-releasing substituent would increase and an electron-withdrawing substituent would decrease the basic strength of a species. Thus, while NH_3 is basic, NF_3 is almost neutral. Likewise, $(CH_3)_2NH$ is more basic than CH_3NH_2 and NH_3. The CH_3 group, being electron-releasing, increases the basic character of ammonia.

The inductive effect decreases as the substituent moves away from the COOH group. This is the reason why 1-chloro propionic acid ($CH_3CHClCOOH$) is a stronger acid than 2-chloropropionic acid ($ClCH_2CH_2COOH$).

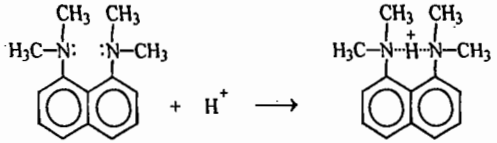
b. Steric and Solvation Effects. The inherent basic character of a species in gas phase is determined from its proton affinity. The proton affinities (kJ/mol) of NH_3, CH_3NH_2, $(CH_3)_2NH$ and $(CH_3)_3N$ are 870, 920, 950 and 970, respectively. Proton affinity of a species is defined as the amount of *energy released* when one mole of H^+ ions get attached to one mole of the base. It is always taken as a positive quantity. Therefore, basicity increases in the order : $NH_3 < CH_3NH_2 < (CH_3)_2NH < (CH_3)_3N$ in *gas* phase, as expected from electron-releasing nature of CH_3 group.

In trisubstituted amines in the gas phase, the basicity decreases with increase in the bulk of the substituent. Thus, the basicity of trialkyl amines decreases in the order :

$$N(CH_3)_3 > N(CH_2CH_3)_3 > N(CH(CH_3)_2)_3$$

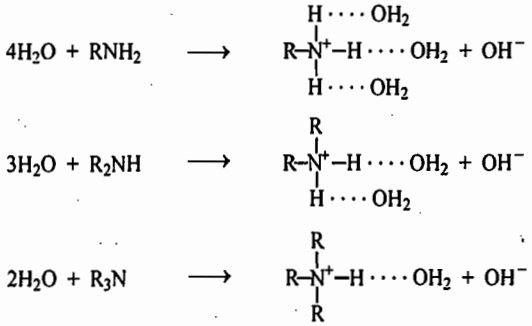
As the bulk of the substituent goes on increasing, the approach of an electron acceptor (acid) towards the electron pair on N atom of amine goes on becoming more and more difficult due to more and more steric evercrowding around the electron pair. *It is to be emphasised here that the same base may act in different ways while reacting with acids having substituents of different bulk.* Thus, $N(CH_2CH_3)_3$ will behave as a weaker base towards $B(CH_2CH_3)_3$ than towards $B(CH_3)_3$ because the bulkier C_2H_5 groups of $B(C_2H_5)_3$ will face more steric hindrance from the substituents on N atom of the base than the CH_3 groups of $B(CH_3)_3$, making the approach of the electron-acceptor B atom of $B(C_2H_5)_3$ more difficult than the approach of B atom of $B(CH_3)_3$ towards the electron pair on N atom of the base.

However, there are some compounds in which the steric effects stabilise the H^+–base adduct. For example, the four methyl groups of bis (dimethylamino) naphthalene sterically hinder one another. Also, the lone pairs of electrons on the two N atoms are too close and repel each other. Both these factors destabilise the base. The reaction of such a base with H^+ ion gives high stability to the adduct in the following manner :



Such compounds are highly basic and are termed as **'proton sponges'** because it is very difficult to remove protons from such adducts.

The order of basicities of amines in water is different from the order observed in gas phase. This is because of the reason that apart from the electronic effects which determine the basicity of amines in gas phase, the solvation effects also determine their basicities. It can be seen from the following reactions that the extent of hydration of amines through hydrogen bonding is in the order : $RNH_2 > R_2NH > R_3N$.



(Water in the above reactions also acts as an acid towards amines. R stands for CH_3 group)

Since solvation releases energy and stabilises the amine, it follows that solvation will stabilise primary amines to the maximum extent and tertiary amines to the minimum extent. Thus, the electronic factors (as in gas phase) and the solvation factors (as in solution phase) impart opposite order to the basicities of amines in water.

The combination of the two factors renders R_3N least basic and R_2NH most basic in water (R is CH_3) . Thus, the true order of the basicities of methyl substituted amines in water is observed to be :

$$(CH_3)_3N < CH_3NH_2 < (CH_3)_2NH$$

c. Type of Bonding Involved in Substituents. The presence of a pi bond in a substituent alters the acidic or basic character of the species. For instance, although fluorine is more electron-withdrawing than chlorine or bromine yet BF_3 is *less acidic* than BCl_3 or BBr_3 . This may be explained as follows : In a B–F bond in BF_3, one of the filled *p* orbitals of fluorine of proper symmetry forms a pi bond by overlapping with a vacant *p* orbital of boron, causing a shift of electronic charge from fluorine to boron. This decreases the electron-accepting power of boron in BF_3 . The *p* orbitals of Cl or Br are much higher in energy and are not suited for pi bonding with boron. Thus, the shift of electronic charge from Cl or Br to boron is much less. Therefore, the electron-accepting power of boron in BCl_3 or BBr_3 is more than that in BF_3 .

4. Additional Factors Influencing Relative Strengths of Acids and Bases

The influence of solvents as well as the effect of substituents on relative strengths of acids and bases

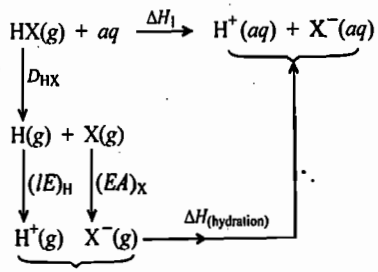
have been discussed above in some details. Apart from these, the following factors also influence the relative strengths of acids and bases :

a. Charge on the species. All other factors remaining constant, an increase in the positive charge would increase the acidic strength of the species and an increase in the negative charge would increase the basic strength of the species. This is because an increase in positive charge increases the electron-accepting capacity and an increase in negative charge increases the electron-donating capacity of the species.

b. Electronegativity. *In the species HX, the higher the electronegativity (electron-pulling capacity) of X, the easier would be the release of proton (H^+) from HX. In other words, the acid strength (proton-releasing capacity) of HX would increase with increase in the electronegativity of X. For example, the electronegativity of non-metals of the second period are in the order C < N < O < F . The acid strength of their hydrides also varies in the same order, i.e., $CH_4 < NH_3 < H_2O < HF$. Thus, within a period of the periodic table, the higher the electronegativity of a non-metal X, the greater would be the acid strength of HX.*

c. Hydration and other energy factors. Electronegativity is not the sole factor which determines the acid strength of a species. On the basis of electronegativities of the halogens, the strength of the halogen acids should change in the order HI < HBr < HCl < HF. But, actual order is just the reverse, *i.e.*, HF < HCl < HBr < HI . This anomaly may be explained as follows :

The ionization of HX (X = halogen) in an aqueous solution, in fact, involves a number of energy factors. We can write the following cycle similar to Born–Haber cycle, for the ionization of HX into $H^+(aq)$ and $X^-(aq)$ ions :



From Hess's law,

$$\Delta H_1 = D_{HX} + (IE)_H - (EA)_X - \Delta H_{hydration}$$

where ΔH_1 = Enthalphy of ionization of HX in water

D_{HX} = Dissociation energy of HX(*g*)

$(IE)_H$ = Ionization energy of H atom

$(EA)_X$ = Electron affinity of X atom

$\Delta H_{hydration}$ = Enthalpy of hydration of H^+ and X^- ions.

Both $(EA)_X$ and $\Delta H_{hydration}$ are energy-releasing processes and are written with negative signs in the Hess's law expression for ΔH_1.

Evidently, the ionization of HX, *i.e.*, the acid strength of HX, would be favoured if ΔH_1 has a large negative value. To this end, while D_{HX} should be small, $(EA)_X$ and $\Delta H_{hydration}$ should be large since $(IE)_H$ is a constant factor. The enthalpies of ionization of the various halogen acids determined as above, fully support the variation of their strengths in the order HF < HCl < HBr < HI .

d. Oxidation number of central atom. In oxoacids, the higher the oxidation number of the central atom, the greater would be the strength of the acid. This is as expected. A higher oxidation number of central atom

increases its electron-pulling capacity and thus makes the release of H atom as H^+ ion easier. This is the reason why the strength of various oxoacids of chlorine varies in the order.

$$HClO_4 > HClO_3 > HClO_2 > HClO$$

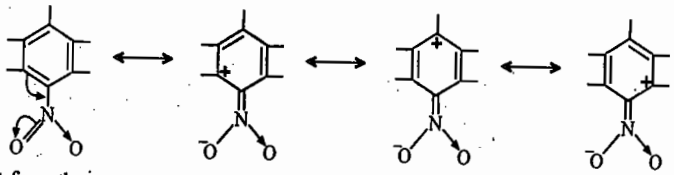
The oxidation number of chlorine in these oxoacids is +7, +5, +3 and +1, respectively.

In oxoacids of similar structures, the acid strength increases with increase in the *electronegativity* of the central atom. Thus, the acid strength of the oxoacids of the three halogens varies in the order

$$HClO_3 > HBrO_3 > HIO_3$$

e. Resonance effect. We shall take aromatic carboxylic acids as a model to explain the effect of resonance. It has been observed that electron-withdrawing groups capable of forming pi bonds with the benzene ring (*e.g.*, NO_2 group) placed at ortho and para positions increase the strength of aromatic carboxylic acids to a greater extent than when such groups are placed at meta position. Further, these groups when placed ortho to the carboxylic group, increase the acid strength to a greater extent than when placed para to the carboxylic group. It may be noted that the increase in acid strength in the above cases is much more than expected from the inductive effect of the NO_2 group *alone. The extra increase in strength is attributed to the resonance effect.*

The various resonance structures of benzene containing the NO_2 group are shown below :



It is evident from these resonance structures that ortho and para positions become **electron-deficient** whereas the meta position retains the original electron density. Therefore, the release of a proton from COOH group attached to an electron-deficient centre, *i.e.*, attached at ortho or para position with respect to the position of the NO_2 group, would be easier. Hence, ortho and para nitrobenzoic acids would be *stronger* than benzoic acid whereas *meta* nitrobenzoic acid would have practically the same strength as benzoic acid.

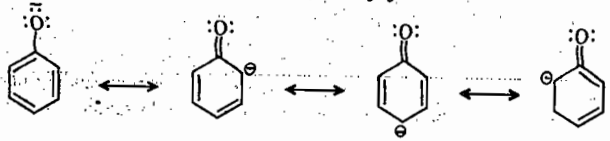
It has been further observed that ortho nitro benzoic acid is relatively stronger than para nitro benzoic acid although the electron deficiency caused by resonance effect is the same at the two positions. A question aries : Why is it so ? The answer is as follows :

In the case of nitrobenzoic acid, both the inductive as well as the resonance effects are operative. Although the resonance effect is the same, yet the inductive effect in ortho and para derivatives is different. This is because the inductive effect of NO_2 group decreases with increase in the number of bonds separating the NO_2 group from the COOH group. Hence, ortho nitrobenzoic acid is stronger than para nitrobenzoic acid.

Electron-donating substituents when placed at ortho and para positions decrease the acid strength of aromatic carboxylic acids to a greater extent than when placed at meta position. This can also be explained easily on the basis of resonance as a result of which the electron density increases at ortho and para positions making the release of proton from the COOH group more difficult.

Another interesting example, showing the effect of resonance, is furnished by the difference in the acidity of the OH group in phenol and ethanol. In phenol, the phenoxide anion formed by deprotonation is stabilised through resonance, thus, favouring the deprotonation reaction.

$$C_6H_5OH \rightleftharpoons C_6H_5O^- + H^+$$



The ethoxide anion $C_2H_5O^-$ formed by deprotonation of ethanol is not stabilised through resonance. It is, therefore, unstable and readily recaptures the proton to form C_2H_5OH which is much more stable than the $C_2H_5O^-$ ion. This explains why phenol exhibits an *acidic character* whereas ethanol is *neutral*.

Measurement of Acid-Base Strength in Gas Phase

As already mentioned, the basic character of a species in gas phase is measured in terms of its proton affinity. The proton affinity is the amount of energy released (ΔH) for the reaction

$$H^+(g) + :B^-(g) \longrightarrow H:B(g)$$

Although the energy released is given a negative sign according to thermodynamic convention, the proton affinity is always taken as positive or zero, as already mentioned. The higher the proton affinity of a species, the higher is the amount of energy released and the greater is the basic character of the species.

Similarly, the acidic character of a species in gas phase is measured in terms of the enthalpy of the reaction.

$$HX(g) \longrightarrow H^+(g) + X^-(g)$$

The more endothermic the above reaction, the weaker is the acidic character of the specie. For example, the enthalpies of dissociation of HF, HCl, HBr, HI (in gas phase) into $H^+(g)$ and $X^-(g)$ are 1550 kJ/mol, 1400 kJ/mol, 1350 kJ/mol and 1300 kJ/mol, respectively. Therefore, the order of their acidities in gas phase is :

$$HF(g) < HCl(g) < HBr(g) < HI(g)$$

The acidities of metal cations in gas phase can be measured from their electron affinities. For example, $K^+(g)$ has lower electron affinity (420 kJ/mol), compared to first electron affinity of $Ca^{2+}(g)$ (1150 kJ/mol). Therefore, the former is a weaker acid compared to the latter in gas phase.

Generalised Acid–Base Concept for Cations and Anions

According to this concept, the positivity of a cation can be measured in terms of its capability to polarise electron charge cloud of an anion and the negativity of an anion can be measured in terms of the capability of its electron charge cloud to get polarised by a cation. The magnitude of positivity of a cation determines its strength as an acid and the magnitude of negativity of an anion determines its strength as a base.

According to the above definition, a 'free' proton, which has highest charge/size ratio and hence highest polarising power, should be the strongest acid. But a proton never occurs freely. Similarly, a 'free' electron which is not bound by any nucleus and has maximum polarizability of its charge cloud by a cation should be the strongest base. Such a 'free' electron in the solvated state exists in solutions of alkali metals in liquid ammonia, THF, etc.

Calculation of Enthalpies of Acid–Base Reactions from Some Empirical Parameters

Drago and coworkers assigned numerical values to a few empirical parameters such as E_A, C_A, E_B, C_B for acidic and basic species from which the enthalpies of reactions between acids and bases can be calculated. The parameters E_A and E_B are a measure of the *susceptibility* of the reacting acidic and basic species, respectively, to undergo *electrostatic interactions* and the parameters C_A and C_B are a measure of the *susceptibility* of the reacting acidic and basic species, respectively, to undergo *covalent interactions*.

According to Drago and coworkers, the enthalpy of an acid–base reaction is given by the empirical relation :

$$-\Delta H = E_A E_B + C_A C_B$$

The enthalpies of reactions calculated by the above equation are found to be quite close to the experimental values for acid–base reactions involving molecular acidic and basic species. However, the calculated values are found to differ considerably from the experimental values for acid–base reactions involving ionic species. Drago *et al* suggested that the difference is due to the transfer of charge from base to acid during the formation of the acid–base adduct. They proposed the following modified equation for such

reactions :

$$-\Delta H = E_A E_B + C_A C_B + R_A T_B$$

where the parameter R_A reflects the receptance of electronic charge of the acid and the parameter T_B reflects the transference of electronic charge of the base. The numerical values assigned to the various parameters in kcal are available in standard books on this subject and are not reproduced here. Nevertheless, we shall illustrate the application of Drago's equation with reference to the reaction :

$$H_2O + H^+ \longrightarrow H_3O^+ ; \qquad \Delta H_{exp} = -166 \text{ kcal mol}^{-1}$$

$$\Delta H_{cal} = -(E_H^+ E_{H_2O} + C_H^+ C_{H_2O} + R_H^+ T_{H_2O})$$

$$= -(45 \times 2{\cdot}3 + 13 \times 0{\cdot}1 + 130 \times 0{\cdot}43) = -160{\cdot}7 \text{ kcal mol}^{-1}$$

As can be seen, ΔH (calculated) is quite close to ΔH (experimental).

It is pertitent to mention here that acids with large E_A form stabler adducts with bases having large E_B compared with those having small E_B. Similarly, acids with large C_A form stable adducts with bases having large C_B.

HARD AND SOFT ACIDS AND BASES. PEARSON CONCEPT

The coordination chemists have known for quite some time that while certain ligands tend to form stable complexes with heavier ions such as Ag^+, Hg^{2+}, Pd^{2+}, Pt^{2+}, etc., some other ligands prefer to form stable complexes with lighter ions such as Li^+, Be^{2+}, Al^{3+}, Sc^{3+}, etc. Based on this preferential tendency to form stable complexes, the ions as well as ligands have been classified into two categories each. While the cations (*i.e.*, Lewis acids) are categorised as **hard and soft acids**, the anions and neutral ligands are categorised as **hard and soft bases.**

A general classification of some common metal cations (*viz.*, Lewis acids) into hard and soft acids is presented in Table 1.

A general classification of some common anions (*viz.*, Lewis bases) into hard and soft bases is presented in Table 2.

A little consideration shows that while hard bases are species which cannot be easily polarised, soft bases are species which can be easily polarised. For example, the I^- ion (a soft base) has a very high polarisability. Ammonia is a hard base. However, the presence of easily polarisable aromatic ring makes both aniline and pyridine to behave as nearly soft bases.

TABLE 1

Classification of Some Common Lewis Acids as Hard and Soft Acids

Hard Acids	Soft Acids
H^+, Li^+, Na^+, K^+	Cu^+, Ag^+, Au^+, Hg^+
Be^{2+}, Mg^{2+}, Ca^{2+}, Sr^{2+}	Pd^{2+}, Cd^{2+}, Pt^{2+}, Hg^{2+}, Tl^{3+}, Pt^{4+}
Al^{3+}, Sc^{3+}, Ga^{3+}, In^{3+}, La^{3+}	I^+, Br^+, HO^+, RO^+
Cr^{3+}, Co^{3+}, Fe^{3+}, As^{3+}, Ce^{3+}	O, Cl, Br, I, N
Si^{4+}, Ti^{4+}, Zr^{4+}, Th^{4+}, Pu^{4+}	M^0 (metal atom)
UO_2^{2+}, VO_2^{2+}, MoO^{3+}	

TABLE 2

Classification of Lewis Bases as Hard and Soft Bases

Hard Bases	Soft Bases
NH_3, RNH_2, N_2H_4	H^-, R^-, C_2H_4, C_6H_6
H_2O, OH^-, O^{2-}, ROH, RO^-	CN^-, RNC, CO
CH_3COO^-, CO_3^{2-}, NO_3^-	$S_2O_3^{2-}$, SCN^-, R_3P
PO_4^{3-}, SO_4^{2-}, ClO_4^-, F^-, Cl^-	R_3As, I^-

R stands for an aryl radical

It may be pointed out that all the species mentioned in any category *are not equally hard or soft*. Thus, Cu^{2+} ion behaves as a harder acid than Mn^{2+} ion because of the smaller size of the former. Similarly, Li^+ ion is a harder acid than Cs^+ ion because of the smaller size of the former. Similarly, bases such as $C_6H_5NH_2$, $(C_6H_5)_2NH$, N_3^-, NH_3, C_6H_5N, all containing nitrogen, are not equally hard. For example, NH_3 is harder than $C_6H_5NH_2$ which, in turn, is harder than $(C_6H_5)_2NH$. In fact, $(C_6H_5)_2NH$ is a soft base.

To sum up :

Hard acids are Lewis acids which are small in size and whose electron charge clouds are not easily polarizable. These are mostly light metal ions generally associated with high positive oxidation states.

Soft acids are Lewis acids which are comparatively larger in size and whose electron charge clouds are easily polarisable. These are mostly heavy metal ions generally associated with low (or even zero) positive oxidation states.

Hard bases are Lewis bases which prefer to coordinate with hard acids. These are anions or neutral molecules which are not easily polarizable.

Soft bases are Lewis bases which prefer to coordinate with soft acids. These are anions or neutral molecules which are easily polarizable.

It is important to note, however, that there is no sharp line of demarcation between soft and hard species and a number of border line cases also exist. For instance, transition metal ions such as Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} behave as border line acids. Metals and non-metals in lower oxidation states behave as soft acids while the same species in higher oxidation states behave as hard acids.

Bonding in Hard–Hard and Soft–Soft Combinations. Since hard acids have generally vacant *d* orbitals, they can accept electrons from hard bases so that the bonding between hard acids and hard bases is predominantly *ionic*. Interaction between soft acids and soft bases occurs mostly through pi bonding so that the bonding between soft acids and soft bases is largely *covalent*.

It must be clearly understood that hardness and softness of acids and bases refer only to hard–hard and soft–soft interactions. It has no relation with their strengths. For instance, both OH^- and F^- ions are hard bases but OH^- ion is several million times more basic than F^- ion. Similarly, SO_3^{2-} ion and Et_3P are both soft bases but Et_3P is 10^7 times more basic than SO_3^{2-}.

HSAB Principle. As already mentioned, in the formation of coordination complexes, *hard acids prefer to combine with hard bases whereas soft acids prefer to combine with soft bases*. This is known as **HSAB principle**. This principle does not state, however, that hard–soft or soft–hard combinations cannot exist. It only states that if there is a choice, a hard–hard or a soft–soft combination would be preferred to a soft–hard or hard–soft combination.

Applications of HSAB Principle. The HSAB principle has several applications, some of which are discussed below.

1. Stability of Complexes. Pearson (1963) explained the relative stability of complexes on the basis of HSAB principle. A complex A : B formed as follows :

$$\underset{\text{Lewis acid}}{A} + \underset{\text{Lewis base}}{:B} \longrightarrow \underset{\text{Complex}}{A:B}$$

would be more stable if A and B are either both hard or both soft.

The complex would be less stable if A is hard and B is soft or vice versa. For example, while AgI_2^- exists as a stable compound, AgF_2^- does not. The reason is as follows :

Ag^+ ion is a *soft acid*. Its interaction with I^- ion, a *soft base*, yields a stable complex AgI_2^- whereas its interaction with F^- ion, a *hard base*, yields an unstable complex, AgF_2^-.

$$\underset{\text{Soft acid}}{Ag^+} + \underset{\text{Soft base}}{2I^-} \longrightarrow \underset{\text{Stable complex}}{AgI_2^-}$$

$$\underset{\text{Soft acid}}{Ag^+} + \underset{\text{Hard base}}{2F^-} \longrightarrow \underset{\text{Unstable complex}}{AgF_2^-}$$

With similar reasoning we can explain why $[CoF_6]^{3-}$ is more stable than $[CoI_6]^{3-}$.

2. Prediction of Coordination in Complexes of Ambidant Ligands. We can predict the formation of various metal ion complexes with *ambidant ligands*. An **ambidant ligand** *is one which, although unidentate, may coordinate to the metal ion through either of its two coordinating atoms*. For example, $[SCN]^-$ is an ambidant ligand ; it coordinates through N atom to form the complex $[Co(NCS)_4]^{2-}$ whereas it coordinates through S atom to form the complex $[Pd(SCN)_4]^{2+}$. The reason for the above is as follows : Pd^{2+} is a *soft acid* so that it prefers to coordinate through the *softer* species S atom to form Pd–SCN linkage. Co^{2+} is a *hard acid* so that it prefers to coordinate through the *harder* species N atom to form the Co–NCS linkage.

3. Predicting Feasibility of a Reaction. The reaction between LiI and CsF to give LiF and CsI is an interesting example of preferential combination of soft – soft and hard – hard species :

$$\underset{\text{hard-soft}}{LiI} + \underset{\text{soft-hard}}{CsF} \longrightarrow \underset{\text{hard-hard}}{LiF} + \underset{\text{soft-soft}}{CsI}; \qquad \Delta H = -138 \text{ kJ}$$

Another example is :

$$\underset{\text{soft-hard}}{HgF_2} + \underset{\text{hard-soft}}{BeI_2} \longrightarrow \underset{\text{hard-hard}}{BeF_2} + \underset{\text{soft-soft}}{HgI_2}; \qquad \Delta H = -397 \text{ kJ}$$

Combination of hard ligands or of soft ligands with a metal ion is more favourable than the combination of a mixture of hard and soft ligands with the metal ion. With this, it is easy to understand why the complexes $[Co(CN)_5I]^{3-}$ and $[Co(NH_3)_5F]^{2+}$ are stable while the complexes $[Co(CN)_5F]^{3-}$ and $[Co(NH_3)_5I]^{2+}$ are unstable. It may be recalled that CN^- and I^- are both soft bases while NH_3 and F^- are both hard bases.

4. Prediction of Hardness and Softness. Consider a base B whose hardness or softness is to be predicted. If the equilibrium :

$$[BH]^+ + \underset{\text{Soft acid}}{[CH_3Mg]^+} \rightleftharpoons [CH_3MgB]^+ + \underset{\text{Hard acid}}{H^+}$$

shifts towards the right, then B is a *soft base* because it shows more affinity for the *soft acid* $[CH_3Mg]^+$ (*soft-soft interaction*). If the equilibrium shifts towards the left, then it is a *hard base* since it exhibits more affinity for the *hard acid* H^+ (*hard-hard interaction*).

Symbiosis. Soft ligands have a tendency to combine with a centre which is already associated with soft ligands and hard ligands have a tendency to combine with a centre which is already associated with hard ligands. This tendency has been termed as **symbiosis**. Thus, F^- ion, a hard ligand, readily combines with BF_3 to form a stable complex BF_4^-. Similarly, H^- ion, a soft ligand, readily combines with BH_3 to form a stable complex BH_4^- :

$$BF_3 + F^- \longrightarrow BF_4^-$$

$$BH_3 + H^- \longrightarrow BH_4^-$$

Mixed substituents are generally not preferred. Thus, compounds such as BF_3H^- and BH_3F^-, having mixed substituents, interact spontaneously to yield BH_4^- and BF_4^-, *i.e.*, compounds with the same substituents :

$$BH_3F^- + BF_3H^- \longrightarrow BH_4^- + BF_4^-$$

Likewise, the following reaction occurs spontaneously :

$$CH_3F + CHF_3 \longrightarrow CH_4 + CF_4$$

Basis for Hard–Hard and Soft–Soft Interactions. Several views have been put forth to explain the basis for hard–hard and soft–soft interactions. However, no single view is completely satisfactory.

According to the most accepted view, the cause of *hard–hard interaction* is an electrostatic interaction.

As already discussed, bonding between hard acids and hard bases is predominantly ionic. The electrostatic energy between a positive and a negative ion pair is inversely proportional to the internuclear distance. Therefore, the smaller the ions, the lesser would be the internuclear distance and the greater would be the electrostatic attraction between the two ions. Consequently, the resulting compound would be highly stable.

Electrostatic interaction cannot explain the *soft–soft interaction* because the sizes of soft species are comparatively very large. Polarisation of the species, however, plays an important role in explaining their interactions. Most of the soft acids have 6 to 10 *d* electrons in their electronic configurations. These electrons get easily polarised favouring covalent bonding between them and the soft bases which are also easily polarisable (recall covalent bonding between Li^+ and I^- ions due to polarisation of I^- ion). Thus, bonding between soft acids and soft bases is assumed to be *largely covalent*.

Considering hard–hard interactions as ionic and soft–soft interactions as covalent, Misons and coworkers (1967) proposed the following relation which can tell whether a given species is hard or soft :

$$pK = -\log K = aX + bY + c$$

where K is the equilibrium constant for the dissociation of the metal–ligand (*i.e.*, acid–base) complex ; X, Y are parameters for the metal ions, *i.e.*, acids ; a, b are parameters for the ligands *i.e.*, bases and c is a constant required to adjust the pK values in such a way that all of them lie on the same scale.

The values of parameter Y for some of the cations are given below :

Hard acids :	Li^+,	Al^{3+},	Mg^{2+},	Na^+,	Ca^{2+},	Fe^{3+},	Co^{2+},	Cs^+,	Co^{2+}
	0·36	0·70	0·87	0·93	1·62	2·37	2·56	2·73	2·96
Soft acids :	Sn^{2+},	Tl^{3+},	Cu^+,	Pb^{2+},	Tl^+,	Hg^{2+},	Au^+		
	3·17	3·2	3·45	3·58	3·78	4·25	5·95		

If the value of Y is less than 2·8 , the acid is hard and if the value is more than 3·2 , the acid is soft.

The value of parameter b for some of the bases are given below :

Hard Bases			Soft Bases		
OH^-	NH_3	Cl^-	Br^-	I^-	$S_2O_3^{2-}$
0·40	1·08	2·49	5·58	7·17	12·4

The value of b, evidently, increases with the softness of the base. If the value is less than 3, the base is hard and if the value is more than 5, the base is soft.

In a similar manner, the values of X and a also give rough information about the hardness and softness of the species.

In **soft–soft interactions**, the contribution of pi bonding is also important. Soft acids are generally metals in low oxidation states and thus have a strong tendency to form pi bonds with soft bases which are also good pi bonding ligands. The polarizability of soft acids and soft bases further favours pi bonding.

To sum up : *While hard–hard interactions are ionic, soft–soft interactions are predominantly covalent involving pi bonding as well.*

QUESTIONS

1. (*a*) How are acids and bases defined in terms of (*i*) Arrhenius concept and (*ii*) Bronsted–Lowry concept ? Give suitable examples.

   (*b*) Comment on the statement, "All Arrhenius acids are also Bronsted acids but all Arrhenius bases are not Bronsted bases."

2. (*a*) What do you understand by conjugate acid–base pairs ? Show that a strong acid has a weak conjugate base and a weak acid has a strong conjugate base.

(*b*) Give examples to show that water can behave both as an acid and a base under suitable conditions.

3. (*a*) Discuss briefly the solvent–system concept of acids and bases. What are the limitations of this concept ?

(*b*) The liquid ammonia solution of phenolphthalein is colourless but becomes red on the addition of $NaNH_2$. Explain.

(c) Define an acid and a base according to Lux–Flood concept.

4. (*a*) What is Lewis concept of acids and bases ?

(*b*) Which of the following can act as Lewis acids :

(*i*) H_2O (*ii*) $CaCl_2$ (*iii*) SO_3 (*iv*) OH^- (*v*) CO_2 (*vi*) Ag^+

5. (*a*) What are Lewis acids ? Arrange the following in the order of increasing acid strength :

(*i*) BCl_3, BI_3, BF_3 (*ii*) $SnCl_2$, $SnCl_4$ (*iii*) BF_3, B_2H_6, BPh_3

(*b*) What are Lewis bases ? Arrange the following in the order of decreasing base strength :

(*i*) NH_3 , PH_3 , AsH_3 (*ii*) NH_3, NCl_3 , NF_3

(*c*) NH_3, $(CH_3)_2NH$, CH_3NH_2, $(CH_2)_3N$

6. Illustrate the effect of substituents on relative strengths of acids and bases.

7. Discuss the effect of solvent on relative strengths of acids and bases.

8. What is meant by levelling effect ? Explain this effect on the basis of solvent-system concept of acids and bases.

9. (*a*) Explain Person's concept of hard and soft acids. Give examples.

(*b*) What are the characteristics of a hard acid, soft acid, hard base and soft base ?

10. Explain HSAB princple. Discuss its applications.

11. (*a*) Explain clearly why hard acids coordinate with hard bases and soft acids coordinate with soft bases.

(*b*) What is symbiosis ? Give examples. What are its applications ?

12. Give reasons for the following :

(*i*) AgI_2^- complex is stable but AgF_2^- is not. (*ii*) $[Co(NH_3)_5F]^{2+}$ complex is stable while $[Co(NH_3)_5I]^{2+}$ complex is unstable. (*iii*) CsF reacts with LiI even though both are ionic. (*iv*) BF_3 readily combines with F^- to form stable complex BF_4^-. (*v*) CH_3F and CHF_3 react to form CH_4 and CF_4.

13. (*a*) "While hard–hard interactions are generally ionic, soft—soft interactions are generally covalent." Why is it so?

(*b*) Discuss the contribution of pi bonding in soft–soft interaction.

9 OXIDATION AND REDUCTION

The concept of oxidation and reduction is very important because oxidation and reduction reactions are frequently encountered in our daily life. Rusting of iron articles, generation of electricity in batteries, extraction and purification of metals, etc., are common examples of such reactions.

According to classical concepts, oxidation is defined as a reaction which involves addition of oxygen (or any other electronegative element) or removal of hydrogen (or any other electropositive element). In a general sense, **oxidation** is defined as a reaction which involves loss of electrons by an atom or a group of atoms and **reduction** is defined as a reaction which involves gain of electrons by an atom or a group of atoms. A substance which can accept one or more electrons is called an **oxidising agent** and a substance which can furnish one or more electrons is called a **reducing agent.** The substance which loses electrons is said to be *oxidised* and a substance which gains electrons is said to be *reduced.*

Oxidation Number (Oxidation State)

The term oxidation number (or oxidation state) is now used instead of valency to describe the combining capacity of an element in a compound. The **oxidation number** (or **oxidation state**) of an element is defined as the charge which an atom of the element appears to have when the electrons on the atom are counted according to the following conventions :

1. Electrons shared between two like atoms are divided equally between the sharing atoms.

2. Electrons shared between two unlike atoms are counted with the more electronegative atom.

In the case of electrovalent compounds, the oxidation number of an element is the same as the charge on its ion. As a general rule, the algebraic sum of oxidation numbers of all the atoms in the formula for any electrovalent compound is zero.

Based on the above conventions, the following **operational rules** have been derived which permit easy calculation of oxidation numbers :

1. The oxidation number of each element in the uncombined state is zero.

2. The oxidation number of an ion is the same as its charge.

3. The sum of the oxidation numbers of all the atoms in the formula for a neutral compound is zero.

4. In all hydrogen compounds (except hydrides of active metals), the oxidation number of hydrogen per atom is +1.

5. In all oxygen compounds (except hydrogen peroxide and other peroxides and superoxides), the oxidation number of oxygen per atom is – 2.

A given species is said to be oxidised if its oxidation number increases and is said to be reduced if its oxidation number decreases.

Galvanic Cells. A galvanic cell is a device in which chemical energy *is converted into electrical energy.* Such a cell, usually, consists of two electrodes immersed in one or more suitable electrolytes. When the electrodes are connected externally through a copper wire and internally through a salt bridge, a chemical reaction occurs in the cell involving *oxidation* at one electrode and *reduction* at the other electrode. According to the latest convention, the electrode at which oxidation occurs is called the **anode** while the electrode at which reduction occurs is called the **cathode.**

Consider, for instance, a copper rod dipping in a solution of copper sulphate and a zinc rod dipping in a solution of zinc sulphate, as in the **Daniell cell.** The two metal rods are connected through an ammeter and the two solutions are connected through a salt bridge, *i.e.*, an inverted U-shaped glass tube filled with a solution of potassium chloride, as shown in Fig. 1.

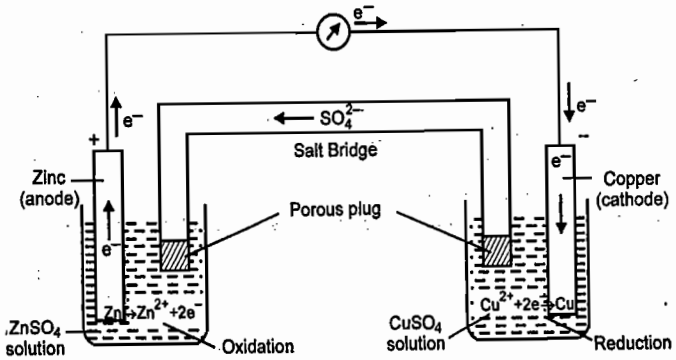


Fig. 1. Production of electricity in a galvanic cell.

As soon as the circuit is closed, current starts flowing which is indicated by deflection in the ammeter. The flow of current is accompanied by the following processes :

The zinc metal passes into the solution as Zn^{2+} ions liberating two electrons ($Zn \longrightarrow Zn^{2+} + 2e^-$). The process involves *oxidation*. The liberated electrons move into the ammeter and then enter the copper rod. Cu^{2+} ions extract two electrons each from the copper rod and are discharged as copper metal on the copper electrode ($Cu^{2+} + 2e^- \longrightarrow Cu$). The process involves *reduction*. The overall chemical reaction taking place in the cell, usually called the **cell reaction**, is, thus,

$$Zn\,(s) + Cu^{2+}\,(aq) \longrightarrow Zn^{2+}\,(aq) + Cu\,(s)$$

Since in this case electrons are generated at the zinc electrode and consumed at the copper electrode, the flow of electrons in the cell is from the zinc electrode to the copper electrode as shown. The SO_4^{2-} ions left unpaired due to the discharge of their partners (*viz.*, the Cu^{2+} ions) as copper, migrate to the other side through the salt bridge as shown in Fig. 1 and become available there for pairing with the Zn^{2+} ions produced by the oxidation of zinc. Thus, while electrons move from the zinc rod to the copper rod in the outside circuit, the SO_4^{2-} ions move through the salt bridge in *opposite* direction as shown. This completes the electric circuit of the cell.

With the passage of time there is more and more depletion of Cu^{2+} ions due to their reduction to Cu and more and more generation of Zn^{2+} ions due to the oxidation of Zn. Both these factors push the cell reaction backwards (Le Chatelier's principle). Ultimately, a state of equilibrium is reached after which the flow of electricity from the cell stops. In order to rejuvinate the cell, we add more of $CuSO_4$ and/or replace $ZnSO_4$ partly by H_2SO_4.

Single Electrode Potential

As is well known, each galvanic cell is made up of two electrodes. At one electrode, oxidation takes place, *i.e., electrons are evolved.* At the other electrode, reduction takes place, *i.e., electrons are taken up.*

The **tendency** *of an electrode to lose or gain electrons when it is in contact with its own ions in solution,* is called **electrode potential.** Since the tendency to gain electrons means also the *tendency to get reduced,* this tendency is called **reduction potential.** Similarly, the *tendency to lose electrons* means *the tendency to get oxidised.* Hence, this tendency is called **oxdiation potential.** Needless to mention that oxidation potential is the reverse of reduction potential. Thus, if the reduction potential of an electrode under given conditions is 1·5 volts, then its oxidation potential is taken as – 1·5 volts and *vice-versa.*

It is not possible to determine experimentally the potential of a single electrode (*i.e.*, of a half-cell). It is only the difference of potentials between the two electrodes that we can measure by combining them to give a complete cell. By arbitrarily fixing potential of one electrode as zero (just as the freezing point of water at atmospheric pressure is arbitrarily fixed as zero on the temperature scale), it is possible to assign numerical values to potentials of the various other electrodes. Conventionally, the potential of a reversible hydrogen electrode in which the gas at one atmospheric pressure is bubbled through a solution of hydrogen ions of unit activity (or, to be approximate, 1 M concentration) has been fixed as zero. This electrode is known as **standard hydrogen electrode** and is represented as

$$Pt\,;\,H_2\,(g)\,(1\text{ atm}),\ H^+\,(aq)\,(c = 1\text{ M})$$

All other single electrode potentials measured with respect to standard hydrogen electrode are referred to as *potentials on the hydrogen scale.*

If it is required to find the electrode potential of, say, zinc electrode dipping in a solution of zinc sulphate (*i.e.*, Zn, Zn^{2+} electrode), all that is needed is to combine it with the standard hydrogen electrode so as to have a complete cell represented as :

$$Zn,\ Zn^{2+}\text{ solution}\,||\,H_2\,(g)\,(1\text{ atm})\,;\,H^+\,(aq)\,(c = 1\text{ M})\,;\,Pt$$

The EMF of the cell, determined potentiometrically, gives the potential of the zinc electrode (on the hydrogen scale) since potential of the standard hydrogen electrode is taken as zero.

Sign of Electrode Potential. According to the latest convention adopted by IUPAC (International Union of Pure and Applied Chemists), the electrode potential is given a *positive sign* if the electrode reaction involves *reduction* when connected to the standard hydrogen electrode and a *negative sign* if the electrode reaction involves *oxidation* when connected to the standard hydrogen electrode whose potential is taken arbitrarily as zero.

Thus, when copper electrode (copper rod dipping in a solution of a copper salt) is connected with a standard hydrogen electrode, *reduction* takes place at the copper electrode. The electrode reactions are as follows :

Copper electrode : $Cu^{2+}(aq) + 2e^- \rightleftharpoons Cu\,(s)$ (Reduction)

Hydrogen electrode : $H_2(g) \rightleftharpoons 2H^+(aq) + 2e^-$ (Oxidation)

Hence, according to the above convention, the potential of copper electrode is taken as *positive.* Thus, $E_{(Cu^{2+},Cu)}$ is positive.

However, if zinc electrode is connected with the standard hydrogen electrode, *oxidation* takes place at the zinc electrode. The electrode reactions are now as follows :

Zinc electrode : $Zn\,(s) \rightleftharpoons Zn^{2+}\,(aq) + 2e^-$ (Oxidation)

Hydrogen electrode : $2H^+(aq) + 2e^- \rightleftharpoons H_2(g)$ (Reduction)

Hence, the potential of the zinc electrode is taken as *negative.* Thus, $E_{(Zn^{2+},Zn)}$ is negative.

Standard Electrode Potentials. The Electrochemical Series

The potential of an electrode, at a given temperature, depends upon the concentration of the ions in the surrounding solution. If the concentration of the ions is unity and the temperature is 25°C, the potential of the electrode is termed as the **standard electrode potential,** E°_{el}). Further, it is assumed that the electrode is working in a thermodynamically reversible manner.

The standard electrode potentials of a number of electrodes are given in Table 1. These values are said to be **on hydrogen scale** since in these determinations the potential of the standard hydrogen electrode, used as the reference electrode, has been taken as zero. The standard reversible electrode potentials arranged in the decreasing order as shown in Table 1 is called the **electrochemical series.**

Adopting the latest convention, the electrode reactions, *i.e.*, the half-cell reactions are written as reduction reactions. The oxidised and reduced species involved in a half-cell reaction (such as Cu^{2+}, Cu ; H^+, H_2, Zn^{2+}, Zn, etc.) are termed as **redox couples.** It may be mentioned, however, that in inorganic chemistry, the discussions are based on oxidation potentials rather than on reduction potentials.

TABLE 1
Electrochemical Series. Standard Electrode Potentials

Electrodes	Electrode Reactions	E°_{el} (volts)
$F_2(g)$, $2F^-$	$F_2 + 2e^- \rightleftharpoons 2F^-$	+2·87
Co^{3+}, Co^{2+} ; Pt	$Co^{3+} + e^- \rightleftharpoons Co^{2+}$	+1·82
Ce^{4+}, Ce^{3+} ; Pt	$Ce^{4+} + e^- \rightleftharpoons Ce^{3+}$	+1·71
Mn^{2+}, MnO_4^- ; Pt	$MnO_4^- + 8H^+ + 5e^- \rightleftharpoons Mn^{2+} + 4H_2O$	+1·51
Au^{3+}, Au	$Au^{3+} + 3e^- \rightleftharpoons Au$	+1·50
$Cl_2(g)$, $2Cl^-$; Pt	Cl_2 (g, 1atm) $+ 2e^- \rightleftharpoons 2Cl^-$	+1·36
Cr^{3+}, $Cr_2O_7^{2-}$	$Cr_2O_7^{2-} + 14H^+ + 6e^- \rightleftharpoons 2Cr^{3+} + 7H_2O$	+1·33
$Br_2(l)$, $2Br^-$: Pt	$Br_2(l) + 2e^- \rightleftharpoons 2Br^-$	+1·06
Hg^{2+}, Hg_2^{2+} : Pt	$2Hg^{2+} + 2e^- \rightleftharpoons Hg_2^{2+}$	+0·92
Ag^+, Ag	$Ag^+ + e^- \rightleftharpoons Ag$	+0·80
Fe^{3+}, Fe^{2+} : Pt	$Fe^{3+} + e^- \rightleftharpoons Fe^{2+}$	+0·77
$Hg_2SO_4(s)$, SO_4^{2-} ; Hg	$Hg_2SO_4(s) + 2e^- \rightleftharpoons 2Hg + SO_4^{2-}$	+0·61
$I_2(s)$, $2I^-$; Pt	$I_2(s) + 2e^- \rightleftharpoons 2I^-$	+0·53
Cu^+, Cu	$Cu^+ + e^- \rightleftharpoons Cu$	+0·52
Cu^{2+}, Cu	$Cu^{2+} + 2e^- \rightleftharpoons Cu$	+0·34
$Hg_2Cl_2(s)$, Cl^-; Hg	$Hg_2Cl_2(s) + 2e^- \rightleftharpoons 2Hg + 2Cl^-$	+0·28
AgCl (s), Cl^-; Ag	$AgCl(s) + e^- \rightleftharpoons Ag(s) + Cl^-$	+0·22
Sn^{4+}, Sn^{2+} ; Pt	$Sn^{4+} + 2e^- \rightleftharpoons Sn^{2+}$	+0·15
Cu^{2+}, Cu^+	$Cu^{2+} + e^- \rightleftharpoons Cu^+$	+0·15
$Hg_2Br_2(s)$, Br^-; Hg	$Hg_2Br_2(s) + 2e^- \rightleftharpoons 2Hg + 2Br^-$	+0·13
AgBr (s), Br^-; Ag	$AgBr(s) + e^- \rightleftharpoons Ag(s) + Br^-$	+0·07
$2H^+$, $H_2(g)$; Pt	$2H^+ + 2e^- \rightleftharpoons H_2$ (g, 1atm)	0·00
Pb^{2+}, Pb	$Pb^{2+} + 2e^- \rightleftharpoons Pb$	−0·13
Sn^{2+}, Sn	$Sn^{2+} + 2e^- \rightleftharpoons Sn$	−0·15
AgI (s), I^-; Ag	$AgI(s) + e^- \rightleftharpoons Ag + I^-$	−0·15
Ni^{2+}, Ni	$Ni^{2+} + 2e^- \rightleftharpoons Ni$	−0·24

(*Continued*)

Electrodes	Electrode Reactions	E°_{el} (volts)
Co^{2+}, Co	$Co^{2+} + 2e^- \rightleftharpoons Co$	−0·27
Cd^{2+}, Cd	$Cd^{2+} + 2e^- \rightleftharpoons Cd$	−0·40
Fe^{2+}, Fe	$Fe^{2+} + 2e^- \rightleftharpoons Fe$	−0·44
Cr^{3+}, Cr	$Cr^{3+} + 3e^- \rightleftharpoons Cr$	−0·74
Zn^{2+}, Zn	$Zn^{2+} + 2e^- \rightleftharpoons Zn$	−0·76
Mn^{2+}, Mn	$Mn^{2+} + 2e^- \rightleftharpoons Mn$	−1·18
Al^{3+}, Al	$Al^{3+} + 3e^- \rightleftharpoons Al$	−1·66
Mg^{2+}, Mg	$Mg^{2+} + 2e^- \rightleftharpoons Mg$	−2·52
Na^+, Na	$Na^+ + e^- \rightleftharpoons Na$	−2·71
Ca^{2+}, Ca	$Ca^{2+} + 2e^- \rightleftharpoons Ca(s)$	−2·87
Ba^{2+}, Ba	$Ba^{2+} + 2e^- \rightleftharpoons Ba$	−2·90
K^+, K	$K^+ + e^- \rightleftharpoons K$	−2·92
Li^+, Li	$Li^+ + e^- \rightleftharpoons Li$	−3·04

Nernst Equation

As mentioned above, the standard electrode potentials given in Table 1 are those when the concentration of the ions in solution is 1 M. The electrode potential would be different if the concentration is different from 1 *M*.

The EMF (*E*) of a reversible cell involving the cell reaction

$$lL + mM \rightleftharpoons xX + yY$$

is given by the relation :

$$E = E^\circ - \frac{RT}{nF} \ln Q \qquad ....(1)$$

where $Q = [X]^x[Y]^y / [L]^l[M]^m$ is called the **reaction quotient** of the concentrations of the reactants and the products at any stage of the cell reaction. E° is the standard EMF of the cell when the concentrations of the species involved are 1 M each.

The electrode potential E_{el} of a metal M in contact with M^{n+} ions involving the electrode reaction :

$$M^{n+} + ne^- \rightleftharpoons M(s)$$

would thus be given by

$$E_{el} = E^\circ_{el} - \frac{RT}{nF} \ln \frac{[M(s)]}{M^{n+}(aq)} \qquad ...(2)$$

$$= E^\circ_{el} - \frac{RT}{nF} \ln \frac{1}{[M^{n+}]} \qquad [(\because [M(s)] \text{ is taken as unity})]$$

$$= E^\circ_{el} + \frac{RT}{nF} \ln [M^{n+}] = E^\circ_{el} + \frac{0{\cdot}0591}{n} \log [M^{n+}] \text{ at } 25°C \qquad ...(3)$$

where E°_{el} is the standard electrode potential of the electrode M^{n+},M and *n* is the number of electrons involved in the redox reaction. The above equation which gives the effect of concentration of M^{n+} ions on the potential of M^{n+},M electrode is known as the **Nernst equation.**

Thus, for the hydrogen electrode for which the half-cell reaction is

$$H^+(aq) + e^- \rightleftharpoons \tfrac{1}{2}H_2(g)$$

the potential of the electrode is given by

$$E_{el} = E^{\circ}_{el} + 0{\cdot}0591 \log [H^+]$$

$$= 0{\cdot}0591 \log [H^+] = -0{\cdot}0591\, pH \text{ at } 25°C \qquad ...(4)$$

because E°_{el} for hydrogen electrode is arbitrarily taken as zero.

Similarly, for silver electrode for which the half-cell reaction is

$$Ag^+ (aq) + e^- \rightleftharpoons Ag (s),$$

the potential of the electrode is given by

$$E_{el} = E^{\circ}_{el} + 0{\cdot}0591 \log [Ag^+]$$

where $E^{\circ}_{el} = 0{\cdot}80$ V (Table 1).

Source of Electrical Energy in a Galvanic Cell

The electrical energy produced by a galvanic cell is given by the product of its electromotive force and the quantity of electricity which passes. If EMF is measured in volts and quantity of electricity in coulombs, the electrical energy is obtained in volt-coulombs or joules (volt-coulomb = joule). Till about the middle of the nineteenth century it was generally believed that electrical energy of a reversible cell originated from the *decrease in the enthalpy* ($-\Delta H$) of the cell reaction. This view received support from the fact that the enthalpy of the reaction :

$$Zn (s) + Cu^{2+} (aq) \rightleftharpoons Zn^{2+} (aq) + Cu (s)$$

taking place in the Daniell cell is about 210000 joules which is quite close to the value 212300 joules obtained by the product of EMF (1·1 volt) and the quantity of electricity passed (2×96500 coulombs). However, it was pointed out by Gibbs, and independently by Helmholtz, that the **electrical energy** in a galvanic cell originates from the *decrease in free energy* of the reaction occurring in the cell.

Suppose, n is the number of electrons involved in a particular cell reaction. Then, evidently, n faradays of electricity will be generated in the complete reaction. If E is the EMF of the cell, then

Electrical energy supplied by the cell = nFE

If $-\Delta G$ is the decrease in the free energy of the cell reaction, then

$$-\Delta G = nFE \qquad ...(5)$$

If $E°$ is the standard EMF of the cell, then the standard decrease in free energy would be given by

$$-\Delta G° = nFE° \qquad ...(6)$$

Application of Electrochemical Series to check Feasibility of Chemical Reactions

1. Suppose we want to know whether zinc and silver would react with dilute sulphuric acid or not. The reaction of zinc with dilute sulphuric acid may be represented as

$$Zn + H_2SO_4 \rightleftharpoons ZnSO_4 + H_2 (g)$$

or

$$Zn (s) + 2H^+ (aq) \rightleftharpoons Zn^{2+} (aq) + H_2 (g)$$

The above reaction may be split into two half-cell reactions, as represented below :

Oxidation half-cell reaction : $Zn (s) \rightleftharpoons Zn^{2+} (aq) + 2e^-$

Reduction half-cell reaction : $2H^+ (aq) + 2e^- \rightleftharpoons H_2 (g)$

Since, as a convention, in a galvanic cell, oxidation occurs at the left hand electrode and reduction at the right hand electrode, the cell involving the above reaction is written as

$$Zn, Zn^{2+} (aq) \parallel H^+ (aq), H_2 (g) ; Pt$$

Therefore, the EMF of the cell would be given by

$$E° = E^{\circ}_R - E^{\circ}_L = 0 - (-0{\cdot}76 \text{ V}) = +0{\cdot}76 \text{ V} \qquad \text{(Table 1)}$$

Since $E°$ is positive, $\Delta G°$ ($= -nFE°$) is *negative*. Hence, the reaction of zinc with sulphuric acid *is feasible, i.e.*, Zn will react with H_2SO_4.

Now let us consider the reaction of silver with dilute sulphuric acid :

$$2Ag + H_2SO_4 \rightleftharpoons Ag_2SO_4 + H_2 (g)$$

or

$$2Ag (s) + 2H^+ (aq) \rightleftharpoons 2Ag^+ (aq) + H_2 (g)$$

Following the same procedure as given above, the cell involving above reaction should be written as

$$Ag, Ag^+ (aq) \parallel H^+ (aq), H_2 (g) ; Pt$$

$$\therefore \quad E° = E^{\circ}_R - E^{\circ}_L = 0 - (+0{\cdot}08 \text{ V}) = -0{\cdot}80 \text{ V} \qquad \text{(Table 1)}$$

Since $E°$ is negative, value of $\Delta G°$ ($= -nFE°$) is *positive*. Hence, the reaction of silver with sulphuric acid is *not feasible, i.e.*, Ag will not react with H_2SO_4.

2. Suppose we want to know whether on mixing H_2O_2 with Fe^{2+} (*aq*), the oxidation of Fe^{2+} (*aq*) to Fe^{3+} (*aq*) will take place or not.

The reaction involving the oxidation of Fe^{2+} (*aq*) to Fe^{3+} (*aq*) with H_2O_2 may be represented as follows :

$$H_2O_2 + 2H^+ (aq) + 2e^- \rightleftharpoons 2H_2O ; \qquad E^{\circ}_{el} = +1{\cdot}77 \text{ V}$$

$$Fe^{2+} (aq) \rightleftharpoons Fe^{3+} (aq) + e^- ; \qquad E^{\circ}_{el} = -0{\cdot}77 \text{ V}$$

Overall reaction would be

$$H_2O_2 + 2H^+ (aq) + 2Fe^{2+} (aq) \rightleftharpoons 2H_2O + 2Fe^{3+} (aq) ; \qquad E° = +1{\cdot}00 \text{ V}$$

Since $E°$ is positive, $\Delta G°$ would be negative. Hence, oxidation of Fe^{2+} (*aq*) to Fe^{3+} (*aq*) will be feasible.

Hydrogen Overvoltage

Consider electrolysis of a solution which is 1 M with respect to H^+ ions. As can be seen from Table 1, the reversible standard potential of hydrogen is zero. Hence, H^+ ions should be discharged at zero potential to liberate hydrogen gas. However, this does not happen. The potential at which H_2 gas is actually evolved using any of the common metals as cathode is considerably higher than the reversible potential of hydrogen electrode. *The difference between the potential of the electrode at which H_2 gas is actually evolved and the theoretical (i.e., reversible) potential of hydrogen electrode is called* ***hydrogen overvoltage.***

Hydrogen overvoltage varies from metal to metal. Thus, hydrogen overvoltage on nickel, lead and mercury is 0·22 V, 0·64 V and 0·80 V, respectively. The origin of this phenomenon is not exactly known.

Problem. A zinc rod is placed in 1M aqueous solution of $ZnSO_4$. Hydrochloric acid is added to this solution. Will there be evolution of H_2 gas if the concentration of H^+ ions in solution is (*A*) 1 M, (*B*) 10^{-4} M at 25°C ?

Solution : The reaction involved in the evolution of H_2 gas is

$$Zn (s) + 2H^+ (aq) \rightleftharpoons Zn^{2+} (aq) + H_2 (g)$$

Case *A* : The two half-cell reactions in this case can be written as

(*i*) $\underset{1\,M}{2H^+ (aq)} + 2e^- \rightleftharpoons H_2 (g) ;$ $\quad E = E° = 0$ (Table 1)

(*ii*) $\underset{1\,M}{Zn^{2+} (aq)} + 2e^- \rightleftharpoons Zn (s) ;$ $\quad E = E° = -0{\cdot}76$ V (Table 1)

Subtracting Eq. (*ii*) from Eq. (*i*) and rearranging, we get

$$2H^+(aq) + Zn(s) \rightleftharpoons Zn^{2+}(aq) + H_2(g); \qquad E = 0 - (-0{\cdot}76) = +0{\cdot}76\ V$$

Since E for the reaction is positive, hence ΔG (= $-nFE$) is negative and, therefore, the reaction is thermodynamically feasible. Since the overvoltage of H_2 on zinc is about 0·70 V, there would be rapid evolution of H_2 gas.

Case *B* : The two half-cell reactions in this case are :

(*i*) $$\underset{(10^{-4}\ M)}{2H^+(aq)} + 2e^- \rightleftharpoons H_2(g); \qquad E = E^\circ + \frac{0{\cdot}0591}{2}\log(10^{-4})^2$$

$$= 0 + \frac{2 \times 0{\cdot}0591}{2} \times (-4) = -0{\cdot}2364\ V$$

(*ii*) $$\underset{1\ M}{Zn^{2+}(aq)} + 2e^- \rightleftharpoons Zn(s); \qquad E = E^\circ = -0{\cdot}76\ V$$

Subtracting Eq. (*ii*) from Eq. (*i*) and rearranging, we get

$$2H^+(aq) + Zn(s) \rightleftharpoons Zn(aq) + H_2(g); \ E = -0{\cdot}2364 - (-0{\cdot}76) = +0{\cdot}5236\ V$$

Although the reaction is thermodynamically feasible (since E is positive and hence ΔG is negative), yet there would be no reaction between Zn(*s*) and H^+ ions, *i.e.*, there would be no evolution of H_2 gas (in spite of the solution being acidic) because the hydrogen discharge potential (0·5236 V) is lower than the hydrogen overvoltage (~ 0·70 V).

Oxygen Overvoltage

The evolution of oxygen on metal anodes also involves overvoltage. The value varies from metal to metal. Thus, oxygen overvoltage on iron, platinum and lead is 0·24, 0·43 and 0·32 V, respectively.

Redox Stability in Water

The stability of an ion or a molecule in a solution depends upon the solvent as also on other solutes including oxygen that may be present in the solution. This is because the ion or the molecule may be destroyed by oxidation or reduction brought about by the solvent or by the other species present in the solution. For instance, metals such as Na, K, Ca, Sc, etc., get oxidised by water or H^+ions liberating hydrogen :

$$M(s) + H_2O(l) \longrightarrow M^+(aq) + \tfrac{1}{2}H_2(g) + OH^-(aq)$$

$$M(s) + H^+(aq) \longrightarrow M^+(aq) + \tfrac{1}{2}H_2(g)$$

and ions such as Co^{3+} get reduced by water liberating oxygen :

$$4\,Co^{3+}(aq) + 2H_2O(l) \longrightarrow 4Co^{2+}(aq) + 4H^+(aq) + O_2(g)$$

It follows from above that water can act as an oxidising agent as well as a reducing agent. In the former case, it is reduced to H_2 and in the latter case it is oxidised to O_2.

The reduction of water, in effect, means reduction of H^+ ions which, in accordance with Nernst equation, may be represented as

$$2H^+(aq) + 2e^- \longrightarrow H_2(g); \qquad E = -(0{\cdot}0591\ V)\,pH \quad \text{(Eq. 4)} \qquad ...(7)$$

Since there is hydrogen overvoltage, E required for the liberation of H_2 would be a little more negative than – 0·6591V at $pH = 1$ and a little more negative than – 0·6 V at $pH = 0$. This means that the species with redox potentials more negative than – 0·6591 V at pH=1 as, for example, Na (E = – 2·71 V), Ca (E = –2·87 V), Li (E = – 3·04V), would get oxidised by water or H^+ ions.

When water acts as a reducing agent, it itself gets oxidised to oxygen ($2H_2O(l) \longrightarrow O_2 + 4H^+ + 4e^-$), as already mentioned. Following the convention of writing all half-cell reactions as reduction reactions, the above reaction may be represented as

$$O_2(g) + 4H^+ + 4e^- \longrightarrow 2H_2O(l); \qquad E = 1{\cdot}23\ V - (0{\cdot}0591\ V)\,pH \qquad ...(8)$$

$$= 1{\cdot}23\ V \text{ at } pH = 0$$

(since E° in this reaction is +1·23 V)

Since there is oxygen overvoltage, the value of E required for the liberation of O_2 would be accordingly higher. This means that species with redox potentials higher than about + 1·5 V at $pH = 0$ [as, for example, the redox couples Co^{3+},Co^{2+} (E = + 1·82 V) and Ce^{4+},Ce^{3+} (E = + 1·71 V)] would get reduced by water.

The variation of reduction potential of H^+ ions to give H_2 and of oxidation potential of H_2O to give O_2 with change in pH of the solution, not taking into consideration hydrogen overvoltage or oxygen voltage, is shown in Fig. 2 by full lines *CD* and *AB*, respectively.

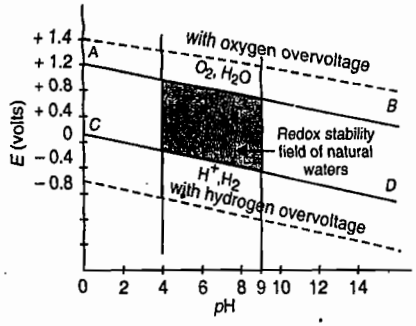

Fig. 2. The redox stability field of natural waters.

It readily follows that redox couples whose redox potentials lie above the upper line *AB* would oxidise water liberating oxygen and redox couples whose redox potentials lie below the line *CD* would reduce water (H^+ ions) liberating hydrogen. Thus, any species having redox potential higher than that given by Eq. 8 would oxidise H_2O to O_2. Similarly, any species having redox potential more negative than that given by Eq. 7, would reduce H^+ ions to H_2. Two vertical lines are drawn at pH 4 and pH 9 which mark the limits on pH values that commonly prevail in water obtained from lakes and rivers (natural waters). The stability field of water shown by shaded area in the figure depicts the range of values of redox potentials and pH values for which water is thermodynamically stable towards both oxidation and reduction. This shows that redox couples whose redox potentials and pH values lie within the stability field of water are stable. They are not destroyed by the oxidising or the reducing action of water.

If hydrogen overvoltage and oxygen overvoltage are also taken into consideration, the stability field of water would get extended on the upper as well as on the lower side, as shown in the figure by broken lines.

Disproportionation

Disproportionation is defined as a reaction in which the oxidation number of an element is raised and lowered simultaneously. In other words, the element undergoing disproportionation acts as its own oxidising and reducing agent. $Cu^+(aq)$, for instance, disproportionates into $Cu^{2+}(aq)$ and Cu(*s*) :

$$Cu^+(aq) \longrightarrow Cu^{2+}(aq) + Cu(s)$$

The above reaction is the difference of the following two reduction half reactions of the cell $Cu^+, Cu^{2+} \| Cu^+, Cu$

$$Cu^+(aq) + e^- \longrightarrow Cu(s); \text{ (at Reduction half cell)} \qquad E^\circ_{cl} = 0{\cdot}52\ V$$

$$Cu^{2+}(aq) + e^- \longrightarrow Cu^+(aq); \text{ (at Oxidation half cell)} \qquad E^\circ_{cl} = 0{\cdot}16\ V$$

Since E° (= 0·52 – 0·16 = 0·36 V) is positive, the disproportionation reaction is spontaneous. This explains why Cu^+ ion is unstable in aqueous solution.

Oxidation by Atmospheric Oxygen

When a solute in solution is exposed to atmosphere, there is need to consider the possibility of reaction between the solute and the dissolved oxygen. Consider, for instance, a solution containing $Fe^{2+}(aq)$ out of contact with air. Since the standard redox potential of Fe^{3+}, Fe^{2+} couple lies within the stability field of water (Fig. 1), it follows that $Fe^{2+}(aq)$ should be stable in water. This is actually the case. The situation, however, becomes different if the solution is exposed to air (O_2) because there is now a possibility that $Fe^{2+}(aq)$ may get oxidised to $Fe^{3+}(aq)$ by atmospheric oxygen. Let us explore this possibility.

The reaction

$$4Fe^{2+}(aq) + O_2(g) + 4H^+(aq) \longrightarrow 4Fe^{3+}(aq) + 2H_2O(l)$$

is the difference of the following two reduction half-reactions of the cell $Fe^{2+}, Fe^{3+} \parallel O_2(g), O^{2-}$:

$$O_2(g) + 4H^+(aq) + 4e^- \longrightarrow 2H_2O(l)\text{; (at reduction half cell)} \quad E_{cl} = 1{\cdot}23\ V - (0{\cdot}0591)\,pH$$

$$Fe^{3+}(aq) + e^- \longrightarrow Fe^{2+}(aq)\text{; (at oxidation half cell)} \quad E_{cl} = +0{\cdot}77\ V$$

Accordingly, E for the complete oxidation reaction given above $= 1{\cdot}23 - 0{\cdot}77 = +0{\cdot}46$ V at $pH = 0$. Since E is positive, the oxidation of $Fe^{2+}(aq)$ by O_2 is spontaneous. Atmospheric oxidation of $Fe^{2+}(aq)$ is feasible even in neutral solution ($pH = 7$) because the potential for the reaction involving oxidation of $Fe^{2+}(aq)$ to $Fe^{3+}(aq)$, although very very small, being $+0{\cdot}05$ V, is still positive. This explains why $Fe^{3+}(aq)$ is the most common form of iron present in the Earth's crust as also in sediments deposited from aqueous environments.

Consider now the atmospheric oxidation of copper in damp environment. The reaction

$$2Cu(s) + O_2(g) + 4H^+(aq) \longrightarrow 2Cu^{2+}(aq) + 2H_2O(l)$$

is the difference of the following two reduction half reactions of the cell $Cu, Cu^{2+} \parallel O_2(g), O^{2-}$:

$$O_2(g) + 4H^+(aq) + 4e^- \longrightarrow 2H_2O(l)\text{; (at reduction half cell)} \quad E_{cl} = 1{\cdot}23\ V - (0{\cdot}0591)\,pH$$

$$Cu^{2+}(aq) + 2e^- \longrightarrow Cu\text{; (at oxidation half cell)} \quad E_{cl} = +0{\cdot}34\ V$$

Evidently, for the complete oxidation reaction given above, $E = 1{\cdot}23 - 0{\cdot}34 = +{\cdot}89$ V at $pH = 0$ and $+0{\cdot}48$ V at $pH = 7$.

Hence, the oxidation of copper to Cu^{2+} is spontaneous in solutions which are neutral ($pH = 7$) or acidic ($pH = 0$). If the atmosphere contains CO_2 and SO_2, Cu^{2+} ions would be converted to $CuCO_3$ and $CuSO_4$, respectively. Thus, the copper roofs get covered by a green layer of a mixture of $CuCO_3$ and $CuSO_4$ in damp environments.

Oxidation of magnesium and aluminium in moist air is also spontaneous. However, these metals can last for years in the presence of air and water. This is due to the formation of impervious layers of oxides on their surface which protect the metals from further attack. In such cases, the metals are said to be **passivated.**

Role of Redox Potentials in the Extraction of Metals. This aspect has been discussed in details with the help of the Ellingham diagram in the next chapter on Metals and Metallurgy.

Diagrammatic Presentation of Potential Data

There are several diagrammatic presentations which give summaries of useful redox potential data depicting relative stabilities of compounds in which one element exists in a series of different oxidation states. Two such diagrammatic presentations are the **Latimer diagrams** and the **Frost diagrams.** These diagrams furnish a good deal of information in a compact form.

Latimer Diagrams

As mentioned above, a Latimer diagram for an element presents redox potential data for a series of compounds of an element in which the element is in different states of oxidation. The most highly oxidised form of the element is placed on the left. In species placed on the right the element has successively lower oxidation states. The **Latimer diagram for chlorine** in acidic solution, for example, is

$$\underset{+7}{ClO_4^-} \xrightarrow{+1{\cdot}20} \underset{+5}{ClO_3^-} \xrightarrow{+1{\cdot}18} \underset{+3}{HClO_2} \xrightarrow{+1{\cdot}65} \underset{+1}{HClO} \xrightarrow{+1{\cdot}67} \underset{0}{Cl_2} \xrightarrow{+1{\cdot}36} \underset{-1}{Cl^-}$$

The redox potentials for the couples involved are written over the arrows and the oxidation numbers are written below the spieces, as shown above. The notation $ClO_4^- \xrightarrow{+1{\cdot}20} ClO_3^-$, for instance, represents the reduction half-cell reaction :

$$ClO_4^-(aq) + 2H^+(aq) + 2e^- \longrightarrow ClO_3^-(aq) + H_2O(l)\text{;} \quad E^\circ = +1{\cdot}20\ V$$

Similarly, the notation $HClO \xrightarrow{+1{\cdot}67} Cl_2$ represents the reduction half-reaction :

$$2HClO(aq) + 2H^+(aq) + 2e^- \longrightarrow Cl_2(g) + 2H_2O(l)\text{;} \quad E^\circ = +1{\cdot}67\ V$$

A Latimer diagram is, thus, converted into a reduction half-cell reaction by including the predominant species present in acidic solution, (*viz.*, H^+ ion and H_2O) and balancing the equation by adding appropriate number of electrons. The solution in the above cases is **acidic** with $pH = 0$.

In **basic solution** corresponding to $pH = 14$ ($pOH = 0$), the Latimer diagram for chlorine is :

$$ClO_4^- \xrightarrow{+0{\cdot}37} ClO_3^- \xrightarrow{+0{\cdot}30} ClO_2^- \xrightarrow{+0{\cdot}68} ClO^- \xrightarrow{+0{\cdot}42} Cl_2 \xrightarrow{+1{\cdot}36} Cl^-$$

The notation $ClO^- \xrightarrow{+0{\cdot}42} Cl_2$ in Latimer diagram represents the reaction :

$$2ClO^-(aq) + 2H_2O(l) + 2e^- \longrightarrow Cl_2(g) + 4OH^-(aq)\text{;} \quad E^\circ = 0{\cdot}42\ V$$

In basic solution, the predominant species are OH^- and H_2O. Hence, these species are included to balance the equation for the half-cell reaction, as shown above.

To illustrate the application of Latimer diagram, we may consider the disproportionation of H_2O_2 into O_2 and H_2O under acid conditions :

$$2H_2O_2(aq) \longrightarrow 2H_2O(l) + O_2(g)$$

The Latimer diagram for O_2 including other species involved in the above reaction is

$$\underset{0}{O_2} \xrightarrow{+0{\cdot}70} \underset{-1}{H_2O_2} \xrightarrow{+1{\cdot}76} \underset{-2}{H_2O}$$

The half-cell reactions for the notations $H_2O_2 \xrightarrow{+1{\cdot}76} H_2O$ and $O_2 \xrightarrow{+0{\cdot}70} H_2O_2$ may be written as

$$H_2O_2(aq) + 2H^+(aq) + 2e^- \longrightarrow 2H_2O(l)\text{; (at reduction half cell)} \quad E^\circ = +1{\cdot}76\ V$$

$$O_2(g) + 2H^+(aq) + 2e^- \longrightarrow H_2O_2(aq)\text{; (at oxidation half cell)} \quad E^\circ = +0{\cdot}70\ V$$

The difference of the two half-cell reactions (of the cell $H_2O_2, O_2 \parallel H_2O_2, H_2O$) gives

$$2H_2O_2(aq) \longrightarrow 2H_2O(l) + O_2(g)\text{;} \quad E^\circ = +1{\cdot}06\ V$$

Since E° is positive, the disproportionation reaction is spontaneous. This explains why an aqueous solution of H_2O_2 in acidic solutions decomposes spontaneously to give H_2O and O_2.

A Latimer diagram can also help in calculating E° for a redox reaction which involves non-adjacent members of the Latimer diagram.

Suppose we want to find out E° for the reaction,

$$\underset{+7}{HClO_4} + 4H^+ + 4e^- \longrightarrow \underset{+3}{HClO_2} + 2H_2O$$

The two half-cell reactions as written above in the Latimer diagram for chlorine can be rewritten along with ΔG° values as follows :

$$\underset{+7}{HClO_4} + 2H^+ + 2e^- \longrightarrow \underset{+5}{HClO_3} + H_2O\text{;} \quad E^\circ = 1{\cdot}20\ V\text{;}\ \Delta G^\circ = -2 \times F \times 1{\cdot}20$$

$$\underset{+5}{HClO_3} + 2H^+ + 2e^- \longrightarrow \underset{+3}{HClO_2} + 2H_2O\text{;} \quad E^\circ = 1{\cdot}18\ V\text{;}\ \Delta G^\circ = -2 \times F \times 1{\cdot}18$$

Adding the two half-cell reactions, we get

$$\underset{+7}{HClO_4} + 4H^+ + 4e^- \longrightarrow \underset{+3}{HClO_2} + 2H_2O\text{;} \quad \Delta G^\circ = (-2{\times}F{\times}1{\cdot}20) + (-2{\times}F{\times}1{\cdot}18)$$

$\Delta G°$ for the overall reaction can also be written as :

$$\Delta G° = -nF(E')° = -4F(E')°$$

where $(E')°$ is the potential for the overall reaction.

$$\therefore \quad -4F(E'°) = (-2 \times F \times 1{\cdot}20) + (-2 \times F \times 1{\cdot}18)$$

$$(E')° = 1{\cdot}19\,V$$

Frost Diagrams

Suppose an element X forms a redox couple, X(n),X(0), in which the element has oxidation number n in oxidised state and zero in reduced state. The **frost diagram** for element X is the plot of $nE°$ for the couple against oxidation number n. Since $-\Delta G° = nFE°$ (Eq. 6), hence $nE° = -\Delta G°/F$. This means that the plot of $nE°$ versus n is the same as a plot of $-\Delta G°$ versus n. Obviously, the most stable oxidation state of an element corresponds to the species which occupies the lowest position in its Frost diagram, as shown in Fig. 3.

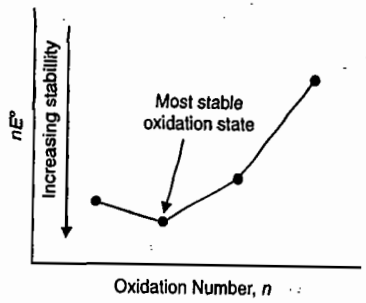

Fig. 3. Plot of $nE°$ vs n showing the most stable oxidation state of an element.

The Frost diagram for nitrogen under standard conditions (pH = 0) is shown in Fig. 4.

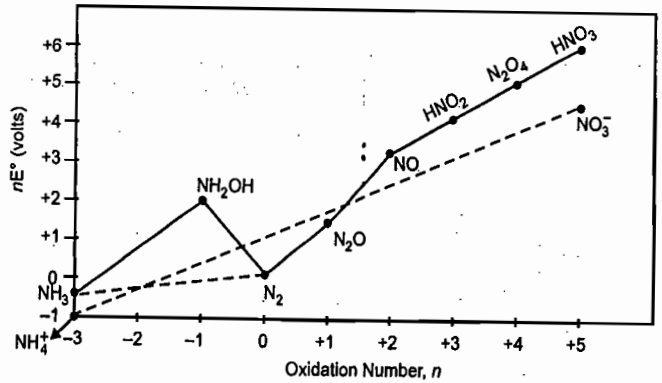

Fig. 4. The Frost diagram for nitrogen.

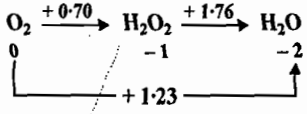
For analysing this diagram, we make use of the fact that if the point for a species lies *above* the line connecting two points which represent two other species, one on each side of the species under consideration, then that species would be thermodynamically *less stable* than the two neighbouring species and if the said point lies *below* the connecting line, then that species would be thermodynamically *more stable* than the two neighbouring species. Since the point for NH_2OH lies above the line connecting points for NH_3 and N_2, hence NH_2OH is thermodynamically less stable than NH_3 and N_2. This explains why NH_2OH decomposes readily into NH_3 and N_2 even at room temperature.

$$3NH_2OH \longrightarrow NH_3 + N_2 + 3H_2O,$$

Likewise, since the point for N_2O lies below the line connecting points for NH_4^+ and NO_3^- ions, hence N_2O is thermodynamically more stable than NH_4^+ and NO_3^- ions. This explains why NH_4NO_3 decomposes on heating into N_2O and H_2O.

If in the Frost diagram, three consecutive points representing three species lie more or less on a straight line, then the three species would be almost equally stable. Thus, NO, HNO_2 and N_2O_4 are almost equally stable.

Problem. Construct a Frost diagram for oxygen from the Latimer diagram given below :



Solution. The oxidation numbers of O in the above diagram are 0, – 1 and – 2 in the three species. For the change of oxidation number from 0 to – 1, *i.e.*, for the change of O_2 to H_2O_2, $E° = 0{\cdot}70$ V and $n = -1$ so that $nE° = -0{\cdot}70$ V. Since the oxidation number of O in H_2O is – 2, $n = -2$ and $E°$ for the formation of H_2O from O is + 1·23 V. Hence $nE° = -2{\cdot}46$ V. These results are plotted in Fig. 5.

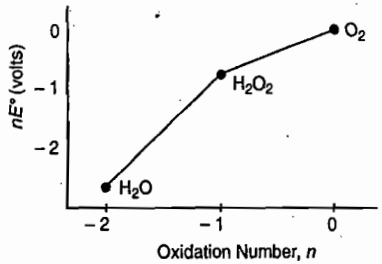


Fig. 5. Frost diagram for oxygen in acidic solution.

It follows from the above discussion that the steeper the line joining the two points in a Frost diagram, the higher is the standard potential of the corresponding couple.

Suppose, the plot of $nE°$ vs n in a particular case is as shown in Fig. 6. The line CD is steeper than the line BC. This shows that the couple corresponding to points C and D would have higher reduction potential than the couple corresponding to points B and C. This indicates that the species represented by the point D would be liable to undergo reduction while the species represented by the point B would be liable to undergo oxidation.

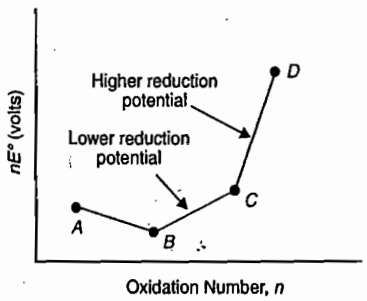

Fig. 6. Frost diagram depicting higher and lower reduction potentials of a species.

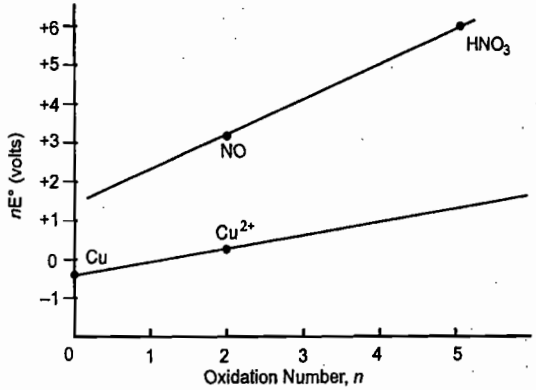

Fig. 7. Plot of $nE°$ vs oxidation number for HNO_3–NO and Cu–Cu^{2+} systems.

We can thus make use of the Frost diagram to predict whether a particular oxidant would oxidise a particualr species or not. The deciding factor which follows from the above discussion is that an oxidant occupying a position in $nE°$ vs n plot with a more positive slope would easily oxidise a species occupying a position in a similar plot with a less positive slope. Thus, as can be seen from Fig. 7, the HNO_3 – NO line has distinctly more positive slope than the Cu – Cu^{2+} line. Hence, HNO_3 would easily oxidise Cu to Cu^{2+} and would itself get reduced to NO ($3Cu + 8HNO_3 \longrightarrow 3Cu(NO_3)_2 + 2NO + 4H_2O$).

Pourbaix Diagrams

A Pourbaix diagram is a map depicting the conditions of potential and *p*H under which a given metal species is thermodynamically stable towards oxidation or reduction. As an illustration, we may consider the Pourbaix diagram for iron species in natural waters (Fig. 8). The various reactions that would be involved in the construction of this diagram would be as follows :

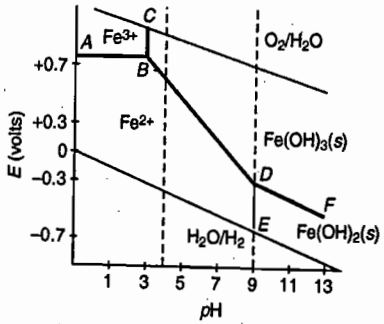

Fig. 8. Pourbaix diagram for iron species in natural waters.

1. The reduction half-cell reaction

$$Fe^{3+}(aq) + e^- \longrightarrow Fe^{2+}(aq); \qquad E^\circ = +0{\cdot}77$$

Since this reaction does not involve H^+ ions, it would be independent of *p*H. This is represented by the horizontal line *AB*. If the solution of the iron species contains a redox couple whose redox potential lies above the line *AB*, the Fe^{3+} ions would retain their identity. There would be no Fe^{2+} ions in solution. The line *AB* thus forms a boundary between the regions in which Fe^{3+} and Fe^{2+} ions dominate.

2. Another reaction which is needed to be considered is :

$$Fe^{3+}(aq) + 3H_2O(l) \longrightarrow Fe(OH)_3(s) + 3H^+(aq)$$

This reaction, evidently, is not a redox reaction as there is no change in the oxidation number of any species during the reaction. Since, however, H^+ ions are liberated in this reaction, it does depend upon *p*H. The formation of $Fe(OH)_3(s)$ is favoured by high *p*H whereas the continuation of $Fe^{3+}(aq)$ in solution is favoured by low *p*H. The vertical line *BC* represents the *p*H at which the Fe^{3+} ions remain dominant. At higher *p*H, $Fe(OH)_3(s)$ is formed :

3. The third reaction which is required to be considered is the reduction half-cell reaction :

$$Fe(OH)_3(s) + 3H^+(aq) + e^- \longrightarrow Fe^{2+}(aq) + 3H_2O(l)$$

Since H^+ ions are involved in this reaction, it is dependent on *p*H. The variation of potential with change in *p*H is given by Nernst equation as

$$E = E^\circ - (0{\cdot}0591)\log[Fe^{2+}] - (3 \times 0{\cdot}0591)\,pH$$

The potential falls linearly with increase in *p*H, as shown by the line *BD*. The regions of potential and *p*H that lie above the line *BD* corrrespond to conditions in which the oxidised species $Fe(OH)_3(s)$ is stable. The regions below the line *BD* correspond to conditions under which the reduced species $Fe(OH)_2(s)$ is stable.

4. Let us consider the reaction

$$Fe^{2+}(aq) + 2H_2O(l) \longrightarrow Fe(OH)_2(s) + 2H^+(aq)$$

which is also involved in the Pourbaix diagram. This is, evidently, not a redox reaction. Since H^+ ions are liberated in this reaction, it depends upon *p*H. While the presence of Fe^{2+} ions is favoured by low *p*H, the formation of $Fe(OH)_2$ is favoured by high *p*H. Thus, the vertical line *ED* at *p*H = 9, divides the regions in which the reactants and the products of the above reaction dominate.

5. We may consider yet another reaction

$$Fe(OH)_3(s) + H^+(aq) + e^- \longrightarrow Fe(OH)_2(s) + H_2O(l)$$

involved in Pourbaix diagram. This reaction is, obviously, dependent on *p*H. The variation of potential with change in *p*H is given by Nernst equation as

$$E = E^\circ - (0{\cdot}0591)\,pH$$

The line *DF* separates the region in which $Fe(OH)_2(s)$ and $Fe(OH)_3(s)$ are stable.

The Pourbaix diagram shows that Fe^{3+} ions can exist in water if the environment is oxidising. Hence, where O_2 is plentiful and the *p*H is low (less than 4), iron will be present as Fe^{3+} ions. Since the *p*H of natural waters varies between 4 and 9, there is very little possibility of the presence of Fe^{3+} ions in natural waters. Iron will be present almost entirely in the form of insoluble $Fe(OH)_3$.

If the conditions of the water are as represented by the regions falling below the sloping line *BD*, the iron present as insoluble Fe_2O_3, gets reduced to FeO which then goes in solution as Fe^{2+} ions. At higher *p*H, Fe_2O_3 would change into Fe^{2+} ions only if strong reducing agents are present. Thus, the formation of Fe^{2+} ions is very unlikely in oxygen–rich water. Organic matter consumes lot amount of oxygen for its bio-degradation which means that organic matter has a strong reducing character. Therefore, in organic matter–rich water logged soils with *p*H around 4·5, the insoluble Fe_2O_3 present gets reduced and dissolves in the form of Fe^{2+} ions. Thus, while oxygen rich–waters contain Fe^{3+} ions, the organic matter–rich water logged soils contain Fe^{2+} ions.

QUESTIONS

1. Define oxidation and reduction in terms of electron transfer and change in oxidation number.
2. Explain the term single electrode potential. How is this quantity measured ? How do we assign a negative or a positive sign to electrode potential ?
3. What is meant by Electrochemical series ? Discuss one important application of this series.
4. State and explain Nernst equation for giving the effect of concentration of an electrolyte on electrode potential.
5. What is a galvanic cell ? What is the source of electrical energy in a galvanic cell ?
6. What is hydrogen overvoltage ? What is its significance ?
7. Explain the term stability field of water. Explain why metals such as Na, K, Ca react with water to liberate hydrogen.
8. Explain why ions such as Ce^{4+} and Co^{3+} are not stable in aqueous solution.
9. How would you account for the disproportionation reaction : $Cu(I) \longrightarrow Cu(II) + Cu$
10. How would you explain the following :
    (*i*) Fe^{3+} is most common form of iron present in Earth's crust.
    (*ii*) Iron present in sediments deposited from aqueous environments is mostly in the form of Fe^{3+}.
    (*iii*) Copper roofs get covered by a green layer of a mixture of $CuSO_4$ and $CuCO_3$ in damp environments.
11. What are Latimer diagrams ? Explain how a Latimer diagram is converted into reduction half-cell reactions in acidic and basic solutions.
12. How would you account for the disproportionation of H_2O_2 with the help of a Latimer diagram ?
13. What are Frost diagrams ? To what use are they put ? Explain giving examples.
14. What are Pourbaix diagrams ? To what use are they put ? Explain giving examples.

10 METALS AND METALLURGY

Elements have been broadly divided into *metals* and *non-metals* on the basis of their physical and chemical properties. Metals have generally low ionisation energies, low electron affinities and low electronegativities which are responsible for their high electrical and thermal conductivities, high malleability and ductility, metallic lustre and hardness. Of the 108 elements known at present, about 70 are metals. In the present chapter, we shall study the occurrence and general methods used for the extraction of metals from their ores.

Occurrence of Metals

Metals occur in nature sometimes free but mostly in the combined state. The earth's crust is the biggest source of metals. Some soluble salts of metals are also found in sea water.

Noble metals which have little or no affinity for oxygen and which resist the attack of water and other chemical reagents, occur in the free, *i.e.*, the **native state.** Thus, metals such as silver, gold and platinum occur in nature in native state along with alluvial impurities such as clay and sand. Sometimes lumps of pure metals are also found. These are called **nuggets.**

The standard electrode potentials (*i.e.*, reduction potentials) of noble metals are always *positive* which means that the ions of such metals have a tendency to accept electrons and get reduced to the corresponding metals. That is why these metals occur in metallic, *i.e.*, native state.

The standard electrode potentials of active metals, on the other hand, are *negative* which means that these metals have a tendency to get oxidised to their ions. In other words, the ions of such metals are reluctant to get reduced to the metallic state. That is why the active metals occur in nature in the form of their compounds, *i.e.*, in the **combined state**. These compounds are known as **minerals.**

The minerals from which metals can be conveniently and economically extracted are referred to as **ores.**

Active metals occur in the form of the following categories of ores :

Sulphide ores. Metals such as iron, mercury, copper, etc., occur as their sulphides, *e.g., iron pyrites* (FeS), *galena* (PbS), *cinnabar* (HgS), *copper pyrites* ($CuFeS_2$), *zinc blende* (ZnS), etc.

Oxide ores. Metals such as iron, aluminium, manganese, tin, zinc, etc., occur as their oxides, *e.g., haematite* (Fe_2O_3), *bauxite* ($Al_2O_3.2H_2O$), *pyrolusite* (MnO_2), *cassiterite* (SnO_2), *zincite* (ZnO), etc.

Carbonate ores. The important carbonate ores are of magnesium, iron, copper, zinc and lead, *e.g., magnesite* ($MgCO_3$), *dolomite* ($CaCO_3,MgCO_3$), *siderite* ($FeCO_3$), *malachite* [$Cu(OH)_2.CuCO_3$], cerussite ($PbCO_3$), calamine ($ZnCO_3$), etc.

Halide ores. Chloride ores are the most common among the halide ores. The chlorides of sodium, potassium and magnesium are found in salt beds on the surface of the earth and in sea water. *Carnallite* ($KCl.MgCl_2.6H_2O$), *rock salt* (NaCl) and *horn silver* (AgCl) are common examples of chloride ores.

Bromides and iodides of potassium and magnesium are present in small amounts in sea water. The fluoride ores include *fluorspar* (CaF_2) and *cryolite* ($AlF_3.3NaF$).

Sulphate ores. Many sulphide ores get converted into sulphates by atmospheric oxidation. The common sulphate ores are *barytes* ($BaSO_4$), *anglesite* ($PbSO_4$), *epsomite* ($MgSO_4.7H_2O$), *anhydrite* ($CaSO_4$), etc.

Metallurgy

The process of extracting metals from their ores is called **metallurgy.** The metallurgical process would necessarily depend upon the nature of the ore which is to be worked out for the extraction of the metal. It is not possible to chalk out a universal scheme for the extraction of all metals since the extraction of each metal involves individual procedure depending upon its nature and properties. However, heavy metals such as copper, iron, zinc, lead, tin, etc., are extracted from their ores by the conventional 'Roasting and Smelting' processes. The active metals such as alkali metals, magnesium, calcium, aluminium, etc., are obtained by the electrolysis of their chlorides, oxides or hydroxides in fused state and the noble metals such as gold and silver are obtained by the amalgamation or the cyanide process.

Various Steps Involved in Metallurgical Processes. The various steps essentially involved in the extraction of pure metals from their respective ores are as follows.

1. Concentration of the Ore

Metallic ores are often found mixed with rocky material, *e.g.*, quartz, felspar, mica and other silicates. These impurities are known as **gangue.** Before the ore is subjected to metallurgical process, it is necessary to remove these unwanted impurities mechanically. This operation is known as concentration of the ore. The common methods of concentration are as follows :

a. Hand picking. Quite often, the ore is separated from the main stock in a sufficient degree of purity by simply picking it by hand and then eliminating the adhering rocky material by breaking with hammer.

b. Gravity separation. The ore can be concentrated by taking advantage of the differences in the specific gravities of metallic ore and the earthy impurities. The ore, after grinding, is washed with a running stream of water. The heavy ore settles down rapidly while the lighter earthy material (gangue) is washed away. The two common techniques of gravity separation are described below.

Hydraulic Classifier. Finely powdered ore is dropped into a conical reservoir, called *hydraulic classifier,* from the top. A powerful stream of water is introduced from the bottom of the reservoir. The gangue, being lighter, is carried away by water and the heavier ore particles accumulate at the apex of the cone. The conical shape of the reservoir helps in reducing the velocity of water and thus prevents the ore particles from being carried away along with the stream of water.

Wilfley Table. Wilfley table is a wooden table having a slanting floor on which long wooden strips called cleats or riffles are fixed. The powdered ore is suspended in a stream of water and delivered at the upper end of the table which is then given a bumping motion. The heavier ore particles are obstructed by the cleats while the lighter impurities pass over and are carried away by the stream of water. The ore particles which collect behind in the cleats move to one side as a result of the motion of the table and are collected.

c. Magnetic separation. Ferromagnetic ores, as of iron, that are affected by a magnet, are separated from the non-magnetic impurities by means of magnetic separators. A magnetic separator consists of a leather belt moving over two rollers, one of which is magnetic. The powdered ore is dropped on the belt at one end. At the other end, the magnetic portion of the ore is attracted by the magnetic roller and falls nearer to the roller while the non-magnetic impurities fall farther off.

d. Electrostatic separation. This method is based on the fact that the particles which are good conductors of electricity become electrically charged as soon as they are brought into an electrostatic field and are consequently repelled by the electrode carrying the like charge. Lead sulphide and zinc sulphide ores which occur together in nature are separated by this technique. The mixed ore, after grinding, is fed upon a roller in a thin layer and subjected to the influence of an electrostatic field. Lead sulphide ore, being a good conductor, gets charged immediately and is thrown away from the roller due to electrical repulsion. The zinc sulphide ore which is a poor conductor is not charged and hence drops vertically from the roller.

e. Froth flotation. This process is based on the principle of *preferential wetting of solids by liquids*. Metallic sulphides, for instance, are wetted by certain oils, like pine oil, but not by water.

The finely divided ore is put in water to which a small quantity of oil (*e.g.*, pine oil) has been added. The water is agitated violently with air (Fig. 1) when froth is formed at the air–water interface. The ore which is preferentially wetted by the oil rises to the surface along with the foam while the stony matter (gangue) which is preferentially wetted by water remains in the water below the foam, as shown on the right of the figure. The foam separates out and, in due course, settles down as shown on the left of the figure. This process is known as **froth flotation process.**

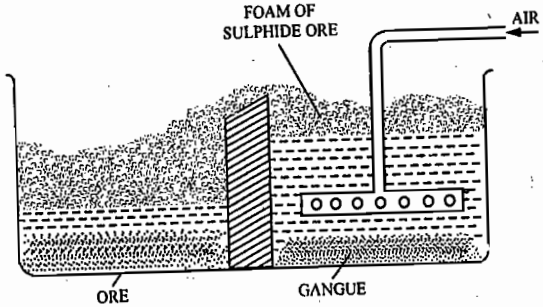

Fig. 1. Froth flotation process.

f. Leaching. This is a chemical method for the concentration of ores. In this method, the powdered ore is treated with some suitable reagent which may dissolve the ore but not the impurities. The impurities are filtered off and the ore is recovered from the solution by suitable chemical methods. For example, during the extraction of aluminium from bauxite ($Al_2O_3.2H_2O$) ore, the finely divided ore is treated with hot sodium hydroxide solution. Alumina present in the ore dissolves forming soluble sodium metaaluminate but impurities are left behind as such and are filtered off.

2. Calcination

Calcination is a process in which the ore is heated in a limited supply of air at a temperature insufficient to melt it. During calcination, organic matter, volatile impurities and moisture present in the ore are expelled and the remaining mass becomes porous. Calcination is also done to remove water from hydrated oxide ores or carbon dioxide from a carbonate ore. For example, when limestone is heated, carbon dioxide is given off and limestone is said to be calcined. When bauxite is calcined, water is removed and anhydrous alumina is left behind. Similarly, iron ores on calcination give anhydrous iron oxide. The various chemical changes are represented below :

$$CaCO_3 \longrightarrow CaO + CO_2$$

$$Al_2O_3.2H_2O \longrightarrow Al_2O_3 + 2H_2O$$

$$2Fe_2O_3.3H_2O \longrightarrow 2Fe_2O_3 + 3H_2O$$

Calcination is generally done in a reverberatory furnace (Fig. 2). It renders the ore porous and easily workable in subsequent stages.

3. Roasting

Roasting is a wider term used to denote the process in which the ores (usually sulphide ores) either

alone or with the addition of other materials, are subjected to the action of heat in the presence of air, at temperatures well below their melting points, in order to bring about their oxidation.

$$2ZnS + 3O_2 \longrightarrow 2ZnO + 2SO_2$$

$$2PbS + 3O_2 \longrightarrow 2PbO + 2SO_2$$

$$2Cu_2S + 3O_2 \longrightarrow 2Cu_2O + 2SO_2$$

Sometimes, during roasting, oxidation of sulphides takes place only upto sulphates. For example,

$$ZnS + 2O_2 \longrightarrow ZnSO_4$$

$$PbS + 2O_2 \longrightarrow PbSO_4$$

During roasting, the non-volatile impurities like sulphur, arsenic, phosphorus, etc., are removed in the form of their volatile oxides which escape as gases through the chimney.

$$S + O_2 \longrightarrow SO_2 \uparrow$$

$$4As + 3O_2 \longrightarrow 2As_2O_3 \uparrow$$

$$P_4 + 5O_2 \longrightarrow 2P_2O_5 \uparrow$$

Roasting is carried out either in a reverberatory furnace or in a blast furnace. In a reverberatory furnace (Fig. 2), the charge is placed on the hearth and heated by the flames deflected from its roof. The reverberatory furnace is used in roasting the ores of copper, tin, lead, etc.

Blast furnace is a long vertical furnace (Fig. 3), made of steel plates, lined inside with fire clay bricks. It is provided with an arrangement for blowing in air near the base, as shown in the figure. It is also provided with a hole for removing the slag and a tapping hole for taking out the metal.

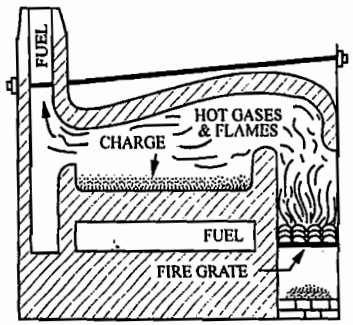

Fig. 2. A reverberatory furnace.

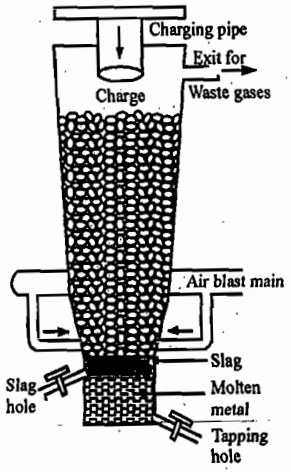

Fig. 3. A blast furnace.

4. Smelting. Reduction of Metal Oxides by Carbon

A large number of metal oxides obtained during roasting can be reduced to metals by heating with carbon at elevated temperatrues (> 1000°C). This process is called **smelting.**

The roasted ore is mixed with a suitable quantity of carbon (coal or coke) and heated to a high temperature above the melting point of the metal. Carbon and carbon monoxide (produced by the

incomplete combustion of carbon) reduce the oxide to the free metal. For example,

$$Fe_2O_3 + 3C \longrightarrow 2Fe + 3CO$$
$$Fe_2O_3 + 3CO \longrightarrow 2Fe + 3CO_2$$
$$PbO + C \longrightarrow Pb + CO$$
$$PbO + CO \longrightarrow Pb + CO_2$$

During reduction, an additional substance, called the *flux*, is added to the ore. It combines with impurities to form easily fusible product known as **slag**.

$$\underset{\text{(Present in the ore)}}{\text{Impurities}} + \text{flux} \longrightarrow \underset{\text{Slag}}{\text{fusible product}}$$

Slag is not soluble in molten metal. Being lighter, it can be easily skimmed off from the surface of the molten metal.

The choice of flux depends upon the impurities present in the ore. For example, if the ore contains acidic impurities such as SiO_2, P_2O_5, then basic fluxes like lime (CaO), magnesite ($MgCO_3$), haematite (Fe_2O_3), etc., are used.

$$\underset{\text{Acidic impurity}}{SiO_2} + \underset{\text{Basic flux}}{CaO} \longrightarrow \underset{\text{(Slag)}}{CaSiO_3}$$

On the other hand, if the ore contains basic impurities such as CaO, FeO, $MgCO_3$, then acidic fluxes like sand and borax are used.

$$\underset{\text{Basic impurity}}{FeO} + \underset{\text{Acidic flux}}{SiO_2} \longrightarrow \underset{\text{(Slag)}}{FeSiO_3}$$

Smelting is generally carried out in a **reverberatory furnace** (Fig. 2) or a **blast furnace** (Fig. 3) in a controlled supply of air.

In the case of metals which are volatile in nature (for example, zinc), smelting cannot be done in an open furnace. In such cases, reduction of the oxide ore is carried out in fire-clay retorts. The vertical retort, which is now in common use, is shown in Fig. 4. Heating is done by producer gas.

It is to be noted that reduction with carbon is practical only if the required temperature is achieved conveniently which may not be so always.

Reduction by controlled heating in air. In the case of less active heavy metals whose oxides are unstable towards heat, only roasting in air is enough for the separation of the metal. For example, roasting of the sulphide ore of mercury (*cinnabar*) gives the metal rather than its oxide.

$$HgS + O_2 \longrightarrow Hg + SO_2$$

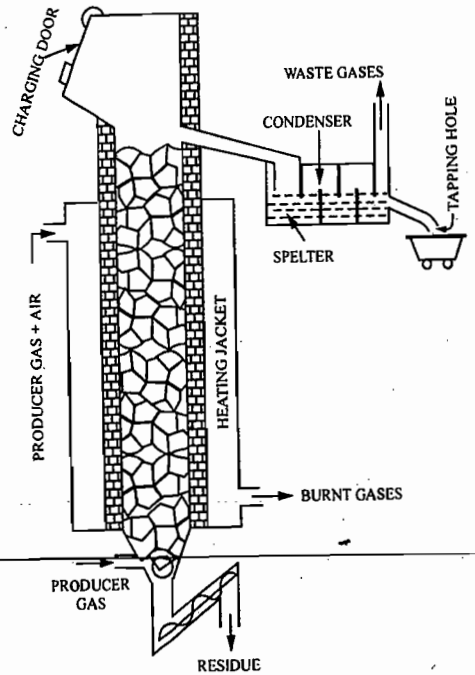

Fig. 4. A vertical retort furnace for the smelting of zinc ore.

Mercury vapours are condensed to the liquid state in the condensing chambers. This process is known as **air reduction** process. The Idrian furnace commonly used for the process is shown in Fig. 5.

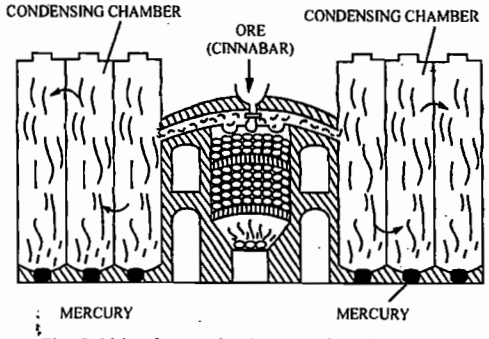

Fig. 5. Idrian furnace for the extraction of mercury.

Sulphide ores of several metals such as Pb, Cu, Sb, may be first roasted in a limited supply of air to partially convert them to oxides. These are further roasted in the absence of air when the sulphides and the oxides formed react to give the metals. For instance,

$$Cu_2S \xrightarrow[\text{in limited supply of air}]{\text{Roasting}} \underbrace{Cu_2S + Cu_2O} \xrightarrow[\text{absence of air}]{\text{Roasting in}} Cu + SO_2$$

This process is known as **self reduction**.

Electrometallurgy. The carbon reduction methods are not applicable for the chemically active metals such as alkali metals, alkaline earth metals, aluminium, etc. The oxides of these metals are very stable and have to be heated very strongly with carbon in order to reduce them to metals. But at high temperatures, these metals combine with carbon to form carbides. Hence, these metals are extracted by the electrolysis of their oxides, hydroxides or chlorides in fused state. The metal is liberated at the cathode.

Other Methods for Reduction of Oxides of Metals. If the temperature required for the reduction of the oxide by carbon is not easily attainable, then reduction is carried out by another metal such as aluminium. This is called **Goldschmidt thermite process.** Examples are :

$$Cr_2O_3 + 2Al \longrightarrow Al_2O_3 + 2Cr$$
$$3Mn_3O_4 + 8Al \longrightarrow 4Al_2O_3 + 9Mn$$

In a few cases, as for example, in the case of Ag_2O, reduction is carried out by thermal decomposition alone. Such cases have been dealt with below on the basis of the **Ellingham diagram.** The thermodynamics of carbon reduction process and the electrolytic process have also been discussed with the help of this diagram.

Thermodynamics of the Oxidation of Metals to Metal Oxides. The Ellingham Diagram

Consider a general oxidation reaction of a metal M in which $2x/y$ moles of the metal react with one mole of oxygen to form the oxide M_xO_y :

$$\underset{\text{solid}}{(2x/y)\,M} + \underset{\text{gas}}{O_2} \longrightarrow \underset{\text{solid}}{2/y\,M_xO_y}$$

Thermodynamically, the oxidation reaction would be feasible and the oxide formed would be stable if the free energy change ΔG of the oxidation reaction is negative. Free energy change of a

reaction is given by the well known thermodynamic relation $\Delta G = \Delta H - T\Delta S$ where ΔH is the enthalpy change and ΔS is the entropy change accompanying the reaction. Since oxygen, being a gas, has higher entropy than the metal and the metal oxide, there would be a decrease in entropy in going from the reactants to the product. In other words, ΔS for the oxidation reaction would be negative. Obviously, the term $T\Delta S$ would become more and more negative and thereby ΔG would become less and less negative with increase in temperature. If the temperature is very high, ΔG may become zero and even positive in which case the oxidation reaction would no longer remain feasible. The variation of ΔG with increase in temperature for the oxidation of some common metals to their oxides (using one mole of oxygen in each case) is represented in Fig. 6. This figure is known as the **Ellingham diagram.** Similar diagrams can be drawn for the conversion of metals to metal sulphides or metal halides using one mole of sulphur or the halogen, as the case may be.

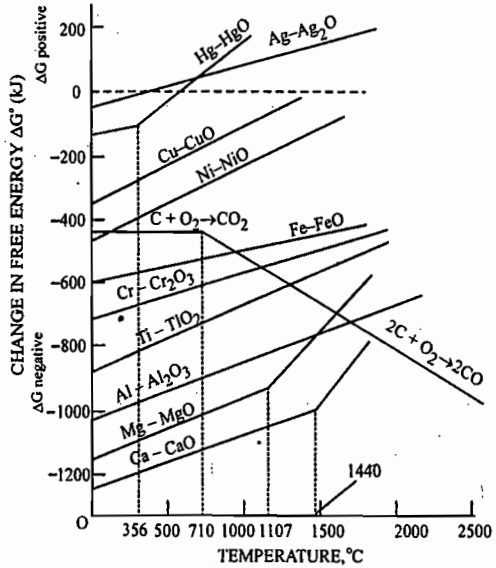

Fig. 6. Ellingham diagram showing the change in free energy ΔG with temperature for metal–metal oxide reactions, based on one mole of oxygen in each case.

Consider the relation,

$$\Delta G = \Delta H - T\Delta S$$

Differentiating with respect to T (assuming that ΔH does not vary with change in temperature), we get

$$d(\Delta G)/dT = -\Delta S$$

Thus, for a reaction with *negative* ΔS, the slope of the line obtained by plotting ΔG vs T will be *positive* while the slope of a similar line for a reaction with *positive* ΔS will be *negative*. Since for the reaction of metals with oxygen to give metal oxides, ΔS is negative, the slope of the lines obtained by plotting ΔG vs T, will be *positive*. Since for a reaction such as $C(s) + O_2(g) \longrightarrow CO_2(g)$, ΔS is zero, the slope of the line will be zero and the plot of ΔG vs T will be parallel to the temperature axis. The slope of the line for the reaction $2C(s) + O_2(g) \longrightarrow 2CO(g)$, for which ΔS is obviously positive, has to be *negative*, as actually observed.

The Ellingham diagram for the oxidation of metals to metal oxides, represented in Fig. 6, has a number of significant features :

1. All the ΔG vs T lines slope upward since ΔG becomes less and less negative with increase in temperature.

2. The ΔG vs T graphs are straight lines upto the temperatures at which the metals remain in solid state. There is a large change in entropy when the metals undergo fusion or vaporisation. This considerably changes the slopes of ΔG vs T lines. Thus, the slopes of Hg – HgO, Mg – MgO and Ca – CaO lines change appreciably at 356°, 1107° and 1440°C which are, respectively, the boiling points of Hg, Mg and Ca.

3. With continuous increase in temperature, a state would be reached when the ΔG vs T graphs cross the $\Delta G = 0$ line. Below these temepratures, ΔG is negative, *i.e.*, the heats of formation of the oxides are negative and hence the oxides formed are stable. Above these temperatures, ΔG would be

positive and the oxides formed would, therefore, be unstable and would decompose to give the metals and oxygen. According to the Ellingham diagram, all oxides should decompose to give the metal and oxygen provided the temperatures are sufficiently high at which ΔG becomes positive. Such temperatures are, in practice, not easily attainable. The Hg – HgO and Ag – Ag_2O lines, however, cross the $\Delta G = 0$ line at temperatures which are easily attainable. These oxides, therefore, decompose easily to give the metals. This is the reason why Hg and Ag are obtained by thermal decomposition of their oxides.

4. Quite frequently, one metal is used to reduce the oxide of another metal. For example, aluminium is used to reduce Cr_2O_3 to Cr. Any metal would reduce the oxides of other metals which lie above it in the Ellingham diagram. This has been illustrated below.

Consider the following reactions taking place at a particular temperature :

$$4/3\ Cr + O_2 \longrightarrow 2/3\ Cr_2O_3\ ; \qquad \Delta G = -x\ kJ \qquad ...(1)$$

$$4/3\ Al + O_2 \longrightarrow 2/3\ Al_2O_3\ ; \qquad \Delta G = -y\ kJ \qquad ...(2)$$

We see from the Ellingham diagram that the ΔG vs T line for Al – Al_2O_3 system lies below the ΔG vs T line for Cr – Cr_2O_3 system so that $|y| > |x|$. Subtracting Eq. 1 from Eq. 2, we get

$$4/3\ Al - 4/3\ Cr \longrightarrow 2/3\ Al_2O_3 - 2/3\ Cr_2O_3\ ; \qquad \Delta G = -y - (-x)\ kJ \qquad ...(3)$$

or

$$4/3\ Al + 2/3\ Cr_2O_3 \longrightarrow 4/3\ Cr + 2/3\ Al_2O_3\ ; \qquad \Delta G = (x - y)\ kJ \qquad ...(4)$$

Since $|y| > |x|$, hence $(x - y)$ is negative, that is, ΔG accompanying reaction (4) is negative. Reaction (4) is, therefore, thermodynamically feasible, *i.e.*, Al would reduce Cr_2O_3 to Cr.

Now subtracting Eq. 2 from Eq. 1, we get

$$4/3\ Cr + 2/3\ Al_2O_3 \longrightarrow 2/3\ Cr_2O_3 + 4/3\ Al\ ; \qquad \Delta G = (y - x)$$

Since $y - x$ and hence ΔG for the above reaction is positive, it would not occur, *i.e.*, Cr would not reduce Al_2O_3 to Al. However, Mg – MgO line lies below the Al – Al_2O_3 line in Ellingham diagram. Hence, Mg would reduce Al_2O_3 to Al.

5. As can be seen from the Ellingham diagram, the ΔG vs T graph for the oxidation of carbon is typical in itself.

Two reactions are possible for the reaction of carbon with oxygen :

$$C + O_2 \longrightarrow CO_2$$

$$2C + O_2 \longrightarrow 2CO$$

In the first reaction, there is pratically no change in entropy because the volume of CO_2 produced is the same as the volume of O_2 used. As a result, the ΔG vs T graph for $C \longrightarrow CO_2$ reaction is practically horizontal, as shown. The second reaction is accompanied by an increase in entropy because one volume of O_2 produces two volumes of CO. Since ΔS is positive, hence ΔG (= $\Delta H - \Delta S$) goes on becoming more and more negative with increase in temperature. As a result, the ΔG vs T graph for the second reaction slopes downward, as shown. The two graphs cross at about 710°C. Below this temperature, carbon reduces metal oxides to metals which lie above the horizontal line in Ellingham diagram, carbon itself being oxidised to CO_2. Above 710°C, reduction of oxides results in the formation of CO. Since the ΔG line for $C \longrightarrow CO$ slopes downwards, it would eventually cross all other metal–metal oxide graphs and would lie below all of them. This implies that, in principle, carbon can be used for reducing any metal oxide to metal provided a sufficiently high temperature is made available for the purpose. But, sometimes it is difficult to attain such high temperatures and, therefore, other techniques are used for the reduction of the metal oxides.

It can thus be concluded from the above discussion that *HgO and Ag_2O can be reduced to their respective metals simply by heating* since the temperatures at which ΔG for the decomposition reactions of these oxides becomes positive are easily attainable. The process in which the metal is obtained simply by heating the oxide ore to an easily attainable temperature is called **pyrometallurgical process.**

The extraction of other metals simply by heating their oxides is difficult since the temperatures at which ΔG for the decomposition reactions of their oxides becomes positive, are not easily attainable. In such cases, the metal oxide is reduced by heating it with coke to temperatures at which C – CO line in the Ellingham diagram lies below the metal–metal oxide line. Thus, iron is obtained from its oxide ore by heating it with C at temperatures around 1000°C at which the C – CO line lies below the Fe – FeO line (Fig. 6).

The reduction of SiO_2 with C is extremely difficult as the temperature at which C can reduce SiO_2 is very high, *viz.*, around *1500°C* (the *Si – SiO_2 line is not shown in the diagram*).

If the temperatures at which the reduction of metal oxides with C can be affected are difficult to achieve, then reduction is carried out electrolytically. In this technique, the process of reduction of the oxide gets coupled with the electrolytic process for which ΔG is sufficently negative so as to make the overall ΔG for the coupled process decidedly *negative*. The process, therefore, becomes feasible. Thus,

$$\Delta G = \Delta G \text{ (reduction process)} + \Delta G \text{ (from external cell)}$$

$$= \Delta G \text{ (reduction process)} - (nFE_{\text{external}})$$

(E_{external} is the potential difference applied across the two electrodes of the electrolytic cell).

In order that ΔG (overall) is negative so that the reduction process becomes feasible, the factor [ΔG (reduction process) – nFE_{ext}] should be negative, *i.e.*, nFE_{ext} should be greater than ΔG (reduction process), Thus, E_{ext} should be greater than ΔG (reduction process)/nF.

A question may arise in reader's mind : Why do we almost invariably convert metal sulphides into metal oxides before reducing them with carbon ? Why can't we directly reduce metal sulphides with carbon ? The answer is that there is no compound CS analogous to CO for which ΔG vs T graphs slope downwards. Therefore, the sulphide ores are first converted into the oxides and then reduced by carbon.

Hydrogen is of limited use as a reducing agent for extracting metals from their oxides. This is because of two reasons. Firstly, the ΔG vs T line for the oxidation of hydrogen ($2H_2O + O_2 \longrightarrow 2H_2O$) runs parallel to most of the metal–metal oxide lines so that only a very few metals, having metal–metal oxide lines above the hydrogen line, can be reduced by hydrogen. The increase in temperature will not be of any use because at elevated temperatures hydrogen reacts with many metals forming hydrides.

The thermodynamic treatment discussed above has two limitations as well. These are :

1. The treatment is based on the assumption that the reactants and products are in a state of equilibrium which is often not true.

2. The treatment only predicts the feasilibty of the reaction. It gives no information about the rate of the reaction.

Specialised Techniques for the Extraction of Metals

Some specialised techniques are also employed for the extraction of metals in specific cases. These techniques include amalgamation, hydrometallurgy, solvent extraction and ion-exchange chromatography.

a. Amalgamation. This process is used for the extraction of gold which occurs native. The finely crushed auriferous quartz is brought into contact with mercury which takes up the metal forming an amalgam. The metal is then recovered by distilling the amalgam.

b. Hydrometallurgy. Hydrometallurgy involves bringing the metal in solution by the action of suitable chemical reagents, *e.g.*, sodium cyanide solution. This is followed by the recovery of the metal by the use of suitable precipitating agents. For example, native silver or poor ores of silver are suspended in dilute solution of sodium cyanide and air is blown through it. The native silver or silver ore goes into

solution as the argentocyanide complex from which the metal is precipitated by adding zinc turnings.

$$4Ag + 8NaCN + O_2\text{ (air)} + 2H_2O \longrightarrow 4Na[Ag(CN)_2] + 4NaOH$$

or

$$AgCl + 2NaCN \longrightarrow Na[Ag(CN)_2] + NaCl$$

$$2Na[Ag(CN)_2] + Zn \longrightarrow Na_2[Zn(CN)_4] + 2Ag \downarrow$$

c. Solvent Extraction. Solvent extraction is a technique in which the solution of a solute in a solvent is brought into contact with a second solvent which is essentially immiscible with the first solvent in order to bring about the transfer of the solute into the second solvent. It can be shown in a smiple manner that with a given volume of the extracting liquid, the extraction is more complete if it is used in a number of instalments than if the whole of it is used in a single operation. The efficiency of the process largely depends upon the partition coefficient which tells how many times the solute is more soluble in the extracting liquid.

The solvent extraction process is successfully employed in the desilverization of lead by zinc (Parke's process). In this process, argentiferous lead is melted and heated to 800°C. Molten zinc is then added. Molten lead and molten zinc behave as two immiscible liquids in contact with each other and silver behaves as a solute which is more soluble in zinc than in lead, the partition coefficient being of the order of 300 at 800°C. Silver, therefore, passes readily from the heavier lead layer into the lighter zinc layer which is separated. By repeating the process three or four times, almost the entire amount of silver passes into the zinc layer from which it can be recovered by distilling off zinc.

d. Ion exchange Chromatography. This technique is effectively employed for the separation of lanthanides. This has been discussed in details in Chapter 25.

5. Refining or Purification

After various metallurgical operations, the metal first obtained is usually impure. The impurities largely consist of

(*i*) other metals produced by the simultaneous reduction of their respective oxides originally present in the ore.

(*ii*) unreduced oxides and sulphides of the metals and

(*iii*) substances such as residual slag, flux, etc.

The impure metal is, therefore, subjected to certain purifying processes which depend upon the metal under treatment and the nature of the impurities to be removed. The usual refining processes are :

a. Liquation process. This process is employed when the impurity is less fusible than the metal itself. The impure metal is placed on the sloping hearth of a furnace and gently heated. The metal melts and drains away leaving behind the infusible material on the hearth.

b. Distillation process. This process is employed for purification of volatile metals like mercury, zinc and cadmium. The impure metal is heated in a retort and its vapours are condensed in a receiver. While the pure metal distils over, the non-volatile impurities are left behind in the retort.

c. Oxidation processes. Oxidation processes are employed for refining when impurities consisting of other metals get oxidized more readily than the metal itself. The impure metal is exposed in a molten state to the oxidizing influence of air in a suitable furnace. The oxides of other metals which are formed are removed from the surface by skimming. Sometimes, the oxide of the metal itself is added which provides the oxygen to the impurities. Thus, copper oxide is added to impure molten copper to provide oxygen required for the oxidation of impurities.

d. Thermal decomposition of suitable compounds. In this method, the impure metal is converted into some volatile compound which decomposes easily to yield the pure metal. Two examples are given below.

(*i*) *Mond Process.* Impure nickel is treated with CO at 50°C when $Ni(CO)_4$ gas is produced which

when heated to 250°C in a closed vessel decomposes to give CO and pure nickel. CO is recycled to react with more of the impure nickel. This process is known as Mond process.

(*ii*) *Van Arkel-de-Boer Process*. This method is used for ultrapurification of Zr and Ti. The impure metal is heated with iodine to give volatile MI_4 (M = Ti, Zr). The iodide is then heated electrically in a closed container when MI_4 decomposes to give the metal which deposits on the tungsten filament of the electric heater. The iodine liberated is recycled to react with further quantity of the impure metal. The tungsten filament is then drilled out leaving behind the hollow bar of pure titanium or zirconium, as the case may be.

e. Electrorefining. A large number of metals are refined electrolytically. The impure metal in the form of blocks is made the anode of an electrolytic cell while the cathode is a thin plate of the pure metal. A solution of a suitable salt of the metal is used as the electrolyte. On passing the electric current, the pure metal dissolves from the anode and is deposited on the cathode. The soluble impurities go into solution while the insoluble matter settles down at the bottom and is called the *anode mud*.

f. Zone refining. This technique is employed for preparing extremely pure metals. This is based on the principle that when the melt of an impure metal is allowed to cool, the pure metal crystallizes out while the impurities remain in the melt. In this technique, the impure metal is converted into a bar which is heated *at one end* with a moving circular heater. The impure metal melts at this end and forms a molten zone. As the heater is moved slowly along the length of the rod, the pure metal cystallizes out of the earlier molten zone while the impurities pass into the adjacent newly created molten zone. This process is carried out throughout the length of the rod. As a result, the impurities are completely driven to one end of the rod which is cut off and discarded. The process is carried out in an inert atmosphere to prevent oxidation of the metal.

QUESTIONS

1. How do metals occur in nature ? Describe the general procedure of extracting a metal from its ores.
2. What is meant by the term metallurgy ? Describe the various steps involved in getting a pure metal from its sulphide ore.
3. Explain the terms : Mineral, Ore, Gangue, Flux and Slag. Give examples.
4. Write short notes on :
   (1) Dressing of the ore (2) Electrometallurgy
   (3) Hydrometallurgy (4) Electrorefining (5) Zone refining
5. What is meant by the term concentration of the ore ? Describe the various methods used for the purpose.
6. Describe the various methods employed for the refining of crude metals.
7. Differentiate between
   (*i*) mineral and ore
   (*ii*) calcination and roasting
   (*iii*) gangue and flux
8. Discuss briefly the various methods used for the reduction of the roasted ores to the metallic state.
9. Give a brief description of specialised techniques for the extraction of metals.
10. What is an Ellingham diagram. Discuss briefly the applications of this diagram.
11. Explain how with the help of an Ellingham diagram, we can fix the criterion for each of the following reactions :
    (*i*) Reduction of a metal oxide by carbon at a given temperature.
    (*ii*) Reduction of an oxide X_2O_3 by a metal Y.
    (*iii*) Reduction of a metal oxide by hydrogen.

11 HYDROGEN

Position of Hydrogen in the Periodic Table. Hydrogen is the first element in the periodic table. Its atomic number is 1 and atomic mass 1·008 a.m.u. The nucleus of the hydrogen atom contains one proton but no neutron. There is only one planetary electron arranged in the *s* orbital of the *K* shell. The hydrogen atom has a tendency to lose this electron and change into H^+ ion. Hydrogen, therefore, has an electropositive character like alkali metals. The hydrogen atom has also a tendency to gain an electron to complete the 1*s* subshell and thus has an electronegative character like the halogens. Thus, in some respects it resembles alkali metals (Group 1) while in some other respects it resembles the halogens (Group 17). The points of resemblance and the points of difference of hydrogen with alkali metals on one hand and the halogens on the other hand are discussed below.

Resemblance with Alkali Metals. 1. Like alkali metals (*i.e.*, elements of Group 1), hydrogen has only one electron in its outer shell.

2. The atoms of alkali metals have a strong tendency to lose the solitary electron from their outer shell and change into positive ions (*i.e.*, Li^+, Na^+, K^+, Rb^+, Cs^+). Hydrogen also has a tendency, though not as strong as the alkali metals, to lose the solitary electron to change into H^+ ion.

3. The normal valency of hydrogen as well as of alkali metals is 1.

4. Hydrogen forms a stable oxide, H_2O. Alkali metals also form stable oxides, *e.g.*, Na_2O, K_2O. Hydrogen forms a peroxide, H_2O_2. Alkali metals also form peroxides, *e.g.*, Na_2O_2.

5. Alkali metals are good reducing agents and so is hydrogen.

Although hydrogen resembles alkali metals in many respects, yet it has some **differences** also. For example, the ionization energy of hydrogen is very high in comparison with alkali metals. This is because the 1*s* electron of hydrogen atom is tightly held by the nucleus because of its small size.

The size of H^+ ion is extremely small in comparison with the sizes of alkali metal ions.

Resemblance with the Halogens. 1. Hydrogen has also a tendency to gain one electron more so as to complete its outer *K* shell and acquire helium configuration and thus change into negative ion, H^-. The halogens (the elements of Group 17) have seven (ns^2p^5) electrons in their outer shells, hence their atoms also have a strong tendency to gain one electron more so as to acquire stable noble gas configurations and thus form negative ions.

2. The ionization energy of hydrogen (1312 kJ mol^{-1}) is of the same order as that of the halogens, as shown below :

Halogens	F	Cl	Br	I
Ionization energy (kJ mol^{-1})	1680·8	1255·5	1140·1	1008·8

3. Hydrogen molecule is diatomic and so are the molecules of the halogens.

4. Hydrogen forms hydrides with carbon (*e.g.*, CH_4, C_2H_2). Halogens also form well known halides with carbon (*e.g.*, CCl_4, $CHCl_3$).

5. Hydrogen in organic compounds can be substituted by halogens by suitable means :

$$C_6H_6 + Cl_2 \xrightarrow[FeCl_3]{\text{Catalyst}} C_6H_5Cl + HCl$$

However, there are some **points of difference** also. Hydrogen differs from the halogens in the fact that it has a much smaller tendency to form the anion H^-. Its electron affinity (72·8 kJ mol^{-1}) is smaller than those of the halogens which are greater than 295 kJ mol^{-1}. It forms stable hydrides only with strongly electropositive metals like sodium and calcium yielding NaH and CaH_2.

In view of the anomalous behaviour of hydrogen, it is difficult to assign any definite position to it in the periodic table. It is customary to include it in Group 1 as well as in Group 17, although it would be preferable to place it in a group of its own. It differs from the alkali metals in being much less electropositive and from the halogens in being much less electronegative. The position of hydrogen in the periodic table thus remains enigmatic.

HYDROGEN

Hydrogen occurs most commonly in the combined state in the form of water, hydrocarbons and carbohydrates. All organic matter contains hydrogen in combination with carbon, nitrogen and oxygen.

Preparation. On a small scale, the gas is prepared by the action of metals such as Na, K, Ca on cold water ; Mg on hot water ; Fe, Zn on superheated steam, Al, Sn, Zn on caustic alkalies and Fe, Zn, Al on dilute acids.

On a commercial scale, the gas is prepared by (*i*) electrolysis of acidulated water (*ii*) reduction of steam with carbon or iron and (*iii*) partial catalytic oxidation of crude naphtha and natural gas (methane).

Properties. Hydrogen forms covalent compounds with a number of non-metallic elements such as oxygen, nitrogen, fluorine, chlorine, bromine, etc. But at ordinary temperatures hydrogen exists in molecular state and in molecular hydrogen, the atoms have the stable helium structure (H : H), *i.e.*, both the H atoms acquire stable $1s^2$ configuration of He. It combines with oxygen, sulphur, nitrogen, bromine, iodine, etc., only when energy is supplied in the form of heat. With oxygen, for example, the reaction $2H_2 + O_2 \longrightarrow 2H_2O$, is not perceptible even at 300°C. The reaction is extremely slow even at 500°C. It is only at 700°C that the reaction becomes almost instantaneous. At higher temperatures it becomes explosive. It is believed that when energy is supplied to the gaseous mixture in the form of heat, some of the H_2 molecules get dissociated into atoms which combine more readily. Further, as the reaction is exothermic, the heat produced dissociates more molecules into atoms and a cumulative effect is thus produced. This explains the instantaneous and explosive nature of the reaction.

The combination with sulphur resulting in the formation of H_2S also takes place at high temperatures, though not so vigorously.

The combination with nitrogen requires a high temperature (450–500°C) besides a high pressure (200 atm) and the presence of a catalyst (finely divided iron with molybdenum as promoter). The product is ammonia.

Hydrogen combines with strongly electropositive metals such as Li, Na, K, Ca, etc., when heated, to form hydrides which are electrovalent compounds (hydrogen forming an anion) which have high melting points and conduct electricity when fused. The metal hydrides find many industrial applications. Calcium and lithium hydrides, for example, are used in **portable hydrogen generators** since they evolve large amount of hydrogen when added to water. The hydrides are also good reducing agents.

Hydrogen gas acts as a reducing agent. The oxides of the less electropositive metals, such as those of Cu, Zn, Pb, Fe, etc., are reduced when they are heated and hydrogen is passed over them. The oxides

of strongly electropositive metals, such as those of alkali metals and alkaline earths, are not reduced by hydrogen. Certain chlorides also get reduced by hydrogen.

Uses of Hydrogen. From the above discussion of physical and chemical properties it is easy to follow the important uses to which hydrogen has been put at various times.

1. *Hydrogen Generators.* The metallic hydrides, such as NaH and LiH, are used in portable hydrogen generators since, when put in water, they release large amounts of hydrogen. Tin and silicon hydrides have high heats of combustion. They are being examined as rocket fuels. The complex borohydrides, such as sodium borohydride, $NaBH_4$, on account of their solubility in organic solvents, are used as reducing agents in a number of organic reactions.

2. *Hydrogenation Processes.* Hydrogen gas is largely used in hydrogenation processes, that is, *processes in which hydrogen gas is added as such to compounds in the presence of a catalyst.* A few examples are given below.

(*i*) Vegetable oils, such as coconut oil, groundnut oil, cotton seed oil, which are liquid at ordinary temperatures, are treated with hydrogen at 170°C in the presence of finely divided nickel. They take up hydrogen and change into semi-solid fats which are used as a cooking medium in several countries.

(*ii*) Carbon monoxide takes up hydrogen under pressure in the presence of a catalyst consisting of a mixture of zinc oxide and finely divided copper, to give methyl alcohol.

$$CO + 2H_2 \xrightarrow{\text{Catalyst}} CH_3OH$$

(*iii*) Hydrogen is used in the production of synthetic petroleum. In the Bergius process, for example, the hydrogenation of coke is carried out at moderately high temperatures and extremely high pressures when several compounds of carbon and hydrogen which constitute different petroleum products, such as gasoline, kerosene and lubricating oils, are produced.

3. *Oxy-Hydrogen Flame and Atomic Hydrogen Flame.* When hydrogen is burnt in oxygen, a very hot flame known as oxy-hydrogen flame with a temperature of about 2000°–2500°C is produced. This temperature is sufficient to melt platinum and to cause a stick of lime to glow with a dazzling light, known as lime light. It is used in welding and other allied processes. The apparatus in which this flame is produced is known as *oxy-hydrogen torch.*

Langmuir, in 1927, devised another torch known as *atomic hydrogen torch* which gives a flame with temperature twice as high as that of oxy-hydrogen torch. It makes use of the heat liberated by the change of atomic hydrogen into molecular hydrogen. The molecular hydrogen is made to pass through an electric arc of tungsten when it absorbs energy and gets heated to a very high temperature between 3500 – 4000°C. As a result of this, the hydrogen molecules break down into atoms. $\Delta H_D = 458{\cdot}1$ kJ/mol. As soon as these atoms come out of the arc, they immediately reunite to form molecules. A large amount of heat equal to 458·1 kJ per mole of hydrogen is liberated in this process. The development of a very high temperature is not only due to the cumulative effect of the union of hydrogen atoms to form molecules but also due to the burning of hydrogen in oxygen.

Recently, a flame giving as high a temperature as 4000°C has been produced by burning fluorine in hydrogen.

4. *Reducing Agent.* Hydrogen is used in the reduction of metallic oxides in metallurgical processes. Molybdenum and tungsten, for instance, are prepared by the reduction of their oxides by hydrogen.

5. *Production of Ammonia.* Appreciable quantities of hydrogen are used in the production of ammonia by direct combination with nitrogen under pressure by Haber process. Ammonia is used as a refrigerant and as a source of fertilizers and explosives. At present, more hydrogen is being used in the manufacture of ammonia than for any other purpose.

NASCENT HYDROGEN

Hydrogen gas cannot reduce acidified solutions containing ferric, permanganate, dichromate or chlorate ions. But, if a small zinc piece is added to such solutions, these ions are reduced to ferrous,

manganous, chromic and chloride ions, respectively, by the hydrogen produced by the action of zinc on the acid present. Thus, hydrogen at the moment of its formation is more active than the ordinary hydrogen gas. *The hydrogen produced in contact with the substance to be reduced is known as* **nascent hydrogen.**

Theories of Nascent Hydrogen. A number of theories have been proposed to explain the superior activity of nascent hydrogen. Some of these are briefly discussed below.

a. Atomic hydrogen theory. Initially it was considered that at the moment of its liberation, hydrogen exists as atoms which are ready to react. In ordinary hydrogen, the atoms have already combined into molecules (H_2) which require extra energy to separate into atoms prior to chemical combination. Hence, nascent hydrogen is more active than ordinary (molecular) hydrogen. The theory, however, fails to explain why nascent hydrogen obtained from different sources is not equally reactive. Thus, chlorates are not reduced by nascent hydrogen generated by the action of sodium amalgam and water although they are easily reduced by nascent hydrogen produced by the action of zinc and dilute sulphuric acid. Again, hydrogen liberated during electrolysis at a lead cathode is more reactive than that set free at a silver cathode.

b. Energy association theory. According to this theory, it is believed that a part of the energy set free in a given reaction producing hydrogen, becomes associated with the liberated hydrogen and thus makes it hyperactive. Since the energy changes involved in different chemical reactions producing nascent hydrogen are different, the difference in the chemical reactivity of nascent hydrogen from different sources is understandable.

This theory also explains the difference in the reducing powers of hydrogen produced by electrolysis using cathodes of different metals. It has been, in general, observed that the higher the voltage required by the metallic cathode to liberate hydrogen, the greater is the reactivity of the nascent hydrogen formed. Here again some of the extra energy supplied becomes associated with the hydrogen and enhances its chemical activity.

c. Pressure theory. It has been shown by Ipatiev that the activity of ordinary hydrogen can be increased by applying a high pressure on it. The hydrogen gas at the moment of its liberation is in the form of very minute bubbles having a very high internal pressure. In the light of Ipatiev's work, this high internal pressure of gas bubbles may be responsible for the high chemical activity of the nascent hydrogen.

It may, however, be pointed out that none of the theories described so far is entirely satisfactory to explain the behaviour of nascent hydrogen.

ACTIVE HYDROGEN

When a stream of hydrogen gas at ordinary temperatures is subjected to silent electric discharge at the voltage of about 30,000 volts, an active variety of hydrogen is obtained. It is marked by its great chemical activity. For example, it combines directly at ordinary temperatures with lead and sulphur forming their hydrides. It also reduces copper oxide at ordinary temperatures.

The half-life period of this active hydrogen is only one-third of a second though some believe that it can be extended upto 10 seconds. It has been suggested that this active hydrogen exists either in the form of atoms or as H_3 molecules like ozone (O_3). But neither of these views has been finally accepted.

ATOMIC HYDROGEN

Atomic hydrogen can be prepared by exposing ordinary hydrogen at a low pressure to a high-tension electric discharge. The apparatus used is shown in Fig. 1. It consists of an S-shaped discharge tube fitted with water-cooled aluminium electrodes *A* and *B*. The discharge tube is about one and a half metre long and about 2 cm in diameter. Hydrogen is admitted into the tube at a low pressure (1 mm or less) while a high-tension discharge is passed by means of the electrodes *A* and *B*. Some of the hydrogen molecules get dissociated into atoms.

The action of atomic hydrogen on various substances can be studied by placing them in the gas current at *C*.

Atomic hydrogen can also be obtained by passing molecular hydrogen through an electric arc set up between tungsten rods. The temperature of the arc is maintained at 3500°–4000°C. In order to get maximum formation of atomic hydrogen, the pressure of the hydrogen gas led into the arc should be close to the atmospheric pressure.

In another more recent method, hydrogen containing mercury vapour is subjected to radiations emitted from a mercury vapour arc in a discharge tube. The radiation energy is first absorbed by the mercury vapour and then transferred from the mercury vapour to the hydrogen molecules which get dissociated into atoms.

$$Hg + h\nu \longrightarrow \underset{\text{Excited atom}}{Hg^*}$$

$$H_2 + Hg^* \longrightarrow 2H + Hg$$

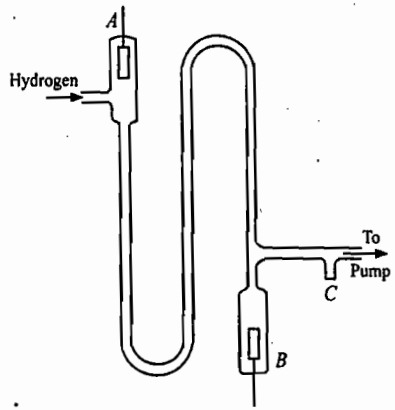

Fig. 1. Production of atomic hydrogen.

Properties of Atomic Hydrogen. 1. Unstable character and reactivity. Atomic hydrogen is highly unstable. Its half-life period is only 0·3 second. The atoms combine readily to form hydrogen molecules liberating a large amount of heat ($\Delta H_f = -458{\cdot}1$ kJ mol^{-1}).

The combination of hydrogen atoms takes place still more readily in the presence of metals like platinum, tungsten and molybdenum.

The half-life period of hydrogen increases considerably at very low pressures. This is due to the fact that at very low pressures, the atoms of hydrogen remain at considerable distances and take lot more time to come in contact with one another to form H_2 molecules. In other words, the atoms retain their identity for a longer period.

2. Combination with non-metals. Atomic hydrogen combines readily at ordinary temperatures with sulphur, phosphorus, arsenic, antimony and bismuth to form their hydrides. However, it does not combine with nitrogen. It also combines with halogens in cold and dark and reduces them to their hydracids. It combines readily with oxygen even at a very low temperature forming hydrogen peroxide.

3. Combination with metals. It combines with metals such as lithium, sodium, calcium at ordinary temperatures, producing their hydrides. It combines with silver and mercury at –180°C to form their hydrides, AgH and HgH_2.

4. Reducing action. Atomic hydrogen is an energetic reducing agent. The various reduction reactions of atomic hydrogen are described below.

It reduces the oxides, chlorides and sulphides of certain metals (*e.g.*, Cu, Ag, Hg and Bi) to free metals at ordinary temperatures. It also reduces barium sulphate to barium sulphide.

However, the more stable oxides like those of aluminium, magnesium, chromium and zinc, remain unaffected.

It reduces carbon dioxide to formic acid and carbon monoxide to formaldehyde.

$$CO_2 + 2H \longrightarrow HCOOH$$

$$CO + 2H \longrightarrow HCHO$$

It reduces phosphorus pentoxide to phosphine.

$$P_2O_5 + 16H \longrightarrow 2PH_3 + 5H_2O$$

Alkali metal salts, such as nitrates, amides and cyanides, are reduced to the free metals. Thus,

$$NaX + H \longrightarrow Na + HX; \quad X = NO_3^-, NH_2^-, CN^-$$

However, the sulphates and halides of these metals are unaffected.

Atomic hydrogen reduces benzene to cyclohexadiene and reduces olefins and acetylenes to the corresponding saturated hydrocarbons.

5. Hydrogenation. Atomic hydrogen immediately hydrogenates unsaturated fatty acids to saturated ones.

Uses of Atomic Hydrogen. It is used as a strong reducing agent. It is used in the preparation of certain metallic hydrides such as AgH and HgH_2. It is also used in the hydrogenation of certain unsaturated organic compounds.

ORTHO AND PARA HYDROGEN

It is now fully established that each particle in the nucleus of an atom is spinning either in clockwise or anticlockwise direction. This phenomenon is similar to the spinning of extra-nuclear electrons. The aggregate of all the spins of particles present in the nucleus gives a net spin to the nucleus called **nuclear spin**. It is represented by I. Each nuclear particle (proton or neutron) has a spin $\frac{1}{2}$. Since the nucleus of hydrogen atom contains only one particle, *i.e.*, a proton, its nuclear spin would be $\frac{1}{2}$. Thus, the nucleus of each of the two atoms of hydrogen in a H_2 molecule would have a nuclear spin $= \frac{1}{2}$.

The spins of the two nuclei may be parallel or antiparallel.

1. If the spins of the two nuclei in hydrogen molecule are *parallel, i.e.*, in the same direction, the total spin I of the nuclei would be $\frac{1}{2} + \frac{1}{2} = 1$. This type of hydrogen molecule in which *the total nuclear spin* is 1, is called **ortho hydrogen** (Fig. 2 *a*).

2. If the spins of the two nuclei in hydrogen molecule are *antiparallel, i.e.*, in opposite direction, total spin I of the nuclei would be $\frac{1}{2} - \frac{1}{2} = 0$. This type of hydrogen molecule in which *the total nuclear spin is zero*, is called **para hydrogen** (Fig. 2 *b*).

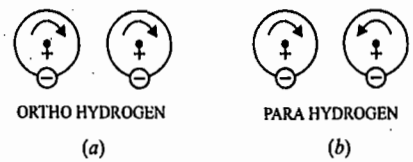

Fig. 2. Ortho and para hydrogen.

The Ratio of Ortho to Para Hydrogen. Ordinary hydrogen gas is an equilibrium mixture of ortho and para hydrogen :

$$\text{Ortho hydrogen} \rightleftharpoons \text{Para hydrogen}$$

The ratio of ortho to para hydrogen varies with temperature, as shown in Fig. 3. Evidently, this ratio increases with rise in temperature upto a temperature of about 300 K (*i.e.*, 27°C) and remains almost constant thereafter.

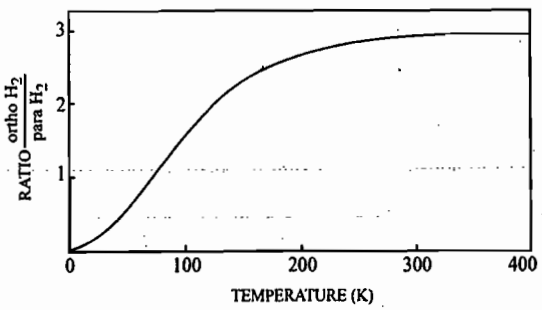

Fig. 3. Variation of the ratio of ortho to para hydrogen with temperature.

The ratio of ortho to para hydrogen at 300 K and above is 3 : 1. This means

that it is not possible to get pure ortho hydrogen at ordinary temperatures or above. The equilibrium

$$\text{Ortho hydrogen} \rightleftharpoons \text{Para hydrogen}$$

shifts toward the right on lowering the temperature, *i.e.*, the proportion of ortho hydrogen decreases and of para hydrogen increases on lowering the temperature. Thus, it has been possible to get pure para hydrogen by cooling ordinary hydrogen gas to a very low temperature close to about 20 K. This evidently means that while we *can get pure para hydrogen* by lowering the temperature, we *cannot get pure ortho hydrogen* at any temperature.

The occurrence of ortho and para hydrogen in the ratio of 3:1 at room temperature and above may be explained as follows :

Any spinning nucleus or nuclei with nuclear spin $I > 0$, would generate spin angular momentun which is a vector quantity of the magnitude $\sqrt{(I(I+1)}\ h/2\pi$. The angular momentun vector is quantized in space, *i.e.*, it is allowed $(2I + 1)$ orientations in space with respect to any direction. *Each of these orientations corresponds to a particular energy state for the nucleus.* As mentioned above, the total nuclear spin I for *ortho hydrogen* is 1. Hence, the spin angular momentum vector has $(2\times1 + 1) = 3$ orientations with respect to, say, the Z-direction with $I_z = M_I \doteq +1, 0, -1$ which would generate three nuclear energy states, as shown in Fig. 4.

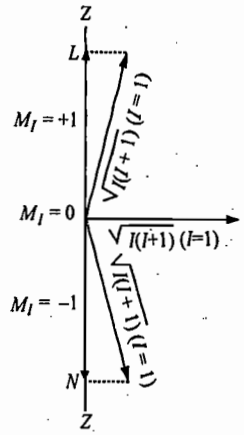

Fig. 4. The orientations of spin angular momentum vector $I = 1$. $I_z (= M_I)$ has the value +1, 0 or −1, according as the vector is parallel, perpendicular or antiparallel to the Z-axis. I_z is the z-component of the angular momentum vector for any of its orientations.

In the absence of an external magnetic field, all the three nuclear energy states are *degenerate, i.e.*, of equal energy. *The population of the molecules of ortho hydrogen would thus be the same in all the three energy states.*

The total nuclear spin I for *para hydrogen*, as mentioned above, is zero, *i.e.*, $I = 0$. Therefore, the spin angular momentum vector would have only one orientation $(2\times0 + 1) = 1$ with $I_z = M_I = 0$ with respect to the Z-direction. This would generate only one nuclear energy state. Hence, *all the molecules of para hydrogen would be populated in this lone energy state.*

Because of the differences in the nuclear spin interactions encountered in ortho and para hydrogen, the nuclear energy state of para hydrogen would have *lower energy* and the three degenerate nuclear energy states of ortho hydrogen would have *higher energy*, as shown in Fig. 5, although, ΔE, the energy difference between states I and II is quite small.

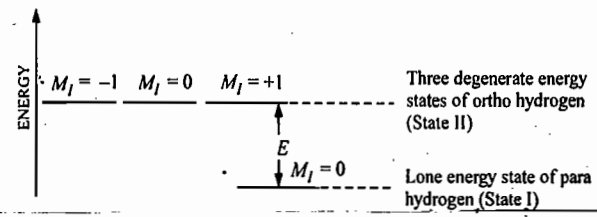

Fig. 5. The energy states of ortho and para hydrogen.

Hydrogen molecules at very low temperatures would mostly occupy state I of lower energy in the form of para hydrogen. The equilibrium

$$\text{Para hydrogen} \rightleftharpoons \text{Ortho hydrogen}$$

remains almost entirely towards the left. As the temperature is gradually increased, more and more of the molecules would get excited from the lower energy para hydrogen state to yield ortho hydrogen which would occupy state II of higher energy. Since state II comprises of three energy states of equal energy, molecules of ortho hydrogen get distributed equally in all the three states. With further increase in temperature, the equilibrium shifts more and more towards the right yielding more and more of ortho hydrogen. Ultimately, at room temperature the amount of ortho hydrogen produced is such that its population in each of the three degenerate energy states II becomes equal to that of para hydrogen in lower energy state I. In other words, *all the four energy states are now occupied by hydrogen to almost the same extent.* Of these four energy states, there are three energy states for the occupancy of ortho hydrogen and only one energy state for the occupancy of para hydrogen. Hence the ratio of ortho to para hydrogen becomes 3 : 1. The ratio would remain the same irrespective of any further increase in temperature because the occupancy of all the four states would now be equally affected by the increase of temperature.

Preparation of Para Hydrogen. 1. The best method of obtaining para hydrogen in almost pure state consists in adsorbing hydrogen gas on activated charcoal contained in a quartz vessel and gradually lowering the temperature of the vessel to 20 K. After the lapse of some time interval the gas is pumped off and is found to consist of 99·8% of para hydrogen.

2. Para hydrogen can also be prepared by keeping ordinary hydrogen under high pressure at liquid air temperature for several days.

Preparation of Ortho Hydrogen. Preparation of ortho hydrogen in pure form is very difficult as, at room and higher temperatures, it is always mixed with the para form and at lower temperatures, the equilibrium, para $\rightleftharpoons$ ortho, shifts towards para form. However, when molecular hydrogen is brought in contact with materials containing unpaired electrons, like Fe, Ni, O_2, NO, etc., reasonably pure ortho form is obtained.

Properties of Ortho and Para Hydrogen. The two forms resemble each other in their chemical properties. However, the parallel and antiparallel nuclear spins lead to different internal energies of the two forms. This results in differences in some of their physical properties like boiling point, specific heat and thermal conductivity. These differences have been used in measuring the proportion of ortho and para forms in a sample of ordinary hydrogen.

Ionised Forms of Hydrogen. The known ionised forms of hydrogen are H^+, H_2^+, H_3^+ and H^-. We are too familiar with H^+ to discuss it here. However, it is pertinent to add that it is a very very strong acid so much so that it combines in gaseous state even with helium atom to form HeH^+. The species H_2^+ is highly unstable with H – H bond distance of 1·06 Å. The species H_3^+ was first detected by J. J. Thomson when a high voltage electric discharge was passed through hydrogen gas and has a bent structure formed by a $3c-2e$ bond resulting from the angular overlap of three $1s$ orbitals of H atoms. H_3^+ is also a shortlived species. The species H^-, however, exists in a number of hydrides. The chemistry of hydrides is discussed below in some details.

HYDRIDES

Hydrogen combines with a number of other elements including metals and non-metals to form compounds called *hydrides*. Based on their physical and chemical properties, the hydrides have been classified into three main categories :

1. *Ionic or Salt-like Hydrides*
2. *Molecular or Covalent Hydrides* and
3. *Interstitial Hydrides.*

Another category, named as *Indermediate Hydrides*, is also known.

1. Ionic Hydrides. These are formed by metals which are more electropositive than hydrogen. Such metals are located towards the left of the periodic table. The examples are alkali metals and alkaline earth metals except Be and Mg. These are formed by transfer of electrons from metals to hydrogen atoms and contain hydrogen as H^- ion, *e.g.*, lithium hydride (Li^+H^-) and calcium hydride ($Ca^{2+}2H^-$). These are white crystalline solids, have ionic lattices and behave like salts. They have high melting and boiling points and conduct electricity in fused state liberating hydrogen at the anode. The reaction

$$\tfrac{1}{2}H_2(g) + e^- \longrightarrow H^-(g); \qquad \Delta H = +146{\cdot}4 \text{ kJ mol}^{-1}$$

is evidently *endothermic*. Therefore, unless the element with which hydrogen combines is highly electropositive (*i.e.*, has a high tendency to lose electrons), the ionic hydride formed would be unstable. This is the reason why only alkali and alkaline earth metals, which can readily lose electrons to yield cations, form stable ionic hydrides.

Ionic hydrides are prepared by direct combination of the metals with hydrogen at high temperatures, usually close to 700°C. They are strong reducing agents, as shown below.

$$2CO + NaH \longrightarrow HCOONa + C$$
$$SiCl_4 + 4NaH \longrightarrow SiH_4 + 4NaCl$$
$$PbSO_4 + 2CaH_2 \longrightarrow PbS + 2Ca(OH)_2$$

They burn spontaneously in air on heating on account of their decomposition into hydrogen (*e.g.*, $CaH_2 \longrightarrow Ca + H_2$) which is inflammable.

They are strong bases. When dissolved in water they form hydroxides and evolve hydrogen.

$$NaH + H_2O \longrightarrow NaOH + H_2$$

They form complexes, *e.g.*, lithium aluminium hydride, $Li[AlH_4]$ and sodium borohydride, $Na[BH_4]$.

$$LiH + AlH_3 \longrightarrow Li[AlH_4]$$
$$NaH + BH_3 \longrightarrow Na[BH_4]$$

The complexes are also good reducing agents.

The thermal stabilities of alkali metal hydrides decrease and their chemical reactivities increase from LiH to CsH. The alkaline earth metal hydrides behave similarly.

Uses. The ionic hydrides and their complexes are used as reducing agents. Since they evolve hydrogen when heated and, therefore, ignite spontaneously, they are used as solid fuels.

2. Molecular or Covalent Hydrides. Beryllium and magnesium of Group 2 form hydrides which have considerable covalent character in their M–H bonds. The hydride MgH_2 has a *rutile* structure. It has lower enthalpy of formation and is thermally less stable than the true saline hydrides. In fact, MgH_2 represents a state of transition between pure ionic hydrides and pure covalent hydrides. Bonding in BeH_2, on the other hand, is predominantly covalent. It has a polymeric structure with hydrogen atoms forming bridges between the Be atoms as in boranes. Both BeH_2 and MgH_2 are prepared by direct action of the metal with hydrogen at elevated temperatures.

The hydrides formed by elements of Groups 13 to 17 are predominantly covalent although in some cases, as, for example, in HF, the bonds are partly ionic.

The hydrides of Group 13 elements (*i.e.*, BH_3 and AlH_3) are electron-deficient compounds and exist in polymerised forms [*e.g.*, B_2H_6, B_4H_{10} and $(AlH_3)_n$]. Hydrides of B and Al are employed as efficient reducing agents.

Carbon of Group 14 forms polynuclear hydrides in which two or more atoms of the element are directly bonded to each other as well as to hydrogen thus giving numerous hydrocarbons. Silicon and some other non-metal elements of Group 14 also show this property but to a very limited extent. Silicon, for example, gives hydrides such as Si_2H_6, Si_3H_8, Si_4H_{10}, etc. Sn and Pb also form hydrides which are rather unstable.

The covalent hydrides of As, Sb, Bi are also known.

The hydrides of elements after Group 13 become increasingly acidic in character on moving from left to right along a given row in the periodic table. Thus, while NH_3 is a weak base, H_2O is neutral and HF is acidic. Similarly, in the next row, while PH_3 is a weak base, H_2S is a weak acid and HCl is highly acidic.

In covalent hydrides, the H–X bond energies generally *decrease* with increase in atomic number (and hence atomic size) of the element within a group. The lesser the bond energy, the lesser is the stability of the H–X bond. This readily accounts for the *instability* of the hydrides of heavier elements of Groups 14 and 15. In fact, PbH_4 and BiH_5 are so unstable that these can be prepared only in traces.

Within a group, the boiling points of covalent hydrides (barring the hydride of the first element) *increase regularly with increase in atomic number of the element and the molar mass of the hydride.* Thus, boiling points of hydrides of elements of Group 15, 16 and 17 (with the exception of top elements) increase as we move down the groups, as shown in Table 1.

TABLE 1

Boiling Points of Hydrides of Elements of Groups 15, 16 and 17

Group 15		Group 16		Group 17	
Hydride	b.p. (°C)	Hydride	b.p. (°C)	Hydride	b.p. (°C)
NH_3	– 33·0	H_2O	+ 100	HF	+ 19·4
PH_3	– 84·6	H_2S	– 59·6	HCl	– 85·0
AsH_3	– 55·1	H_2Se	– 42·0	HBr	– 67·1
SbH_3	– 17·0	H_2Te	– 1·8	HI	– 35·5

The boiling points of the hydrides of top elements, *viz.*, NH_3, H_2O and HF are abnormally high. This is because of the association of these molecules through hydrogen bonding. These molecules, thus, have long polymeric structures.

The electronegativity difference in carbon (the first element of Group 14) and hydrogen is very small. There is thus no association of CH_4 molecules through hydrogen bonding. It has, therefore, the lowest boiling point amongst the hydrides of Group 14 elements. As expected, the boiling points of these hydrides vary in the order :

$$CH_4 < SiH_4 < GeH_4 < SnH_4$$

3. Transition and Inner Transition Metal Hydrides. Interstitial Hydrides. The transition metal hydrides are almost invariably non-stoichiometric compounds with varying composition. Ti, Zr and Hf, for instance, form hydrides with compositions $TiH_{1\cdot7}$, $ZrH_{1\cdot9}$ and $HfH_{1\cdot8}$, respectively. The M–H distances in all these non-stoichiometric compounds are different. Cr and Cu form hydrides approximating to CuH and CrH. The transition metals V, Nb and Ta form hydrides which are also non-stoichiometric. These hydrides are unstable and have *extensive range of composition.*

The transition metal hydrides are strong reducing agents and are used as such in metallurgical processes.

There is lot of ambiguity in the nature of bonding in non-stoichiometric transition metal hydrides. The arrangements of metal atoms in transition metal hydrides remain the same as in the corresponding metals although the densities of the hydrides are less than the densities of the corresponding metals. This suggests that *hydrogen occupies interstitial sites in the metallic lattices.* These hydrides are, therefore, sometimes called **interstitial hydrides.** Some research workers consider these hydrides as mere *solid solutions.* There is, however, strong evidence to suggest that there is some sort of association between the metal and the interstitial hydrogen in these hydrides.

The **inner transition metal hydrides** are of varying composition which falls between the limiting formulae MH_2 and MH_3. These hydrides are formed when the inner transition metals react with hydrogen slightly above the room temperature at atmospheric pressure. Lanthanides Yb and Eu give hydrides of stoichiometry approximating to YbH_2 and EuH_2. These two lanthanides do not form hydrides approximating to MH_3. There is evidence to suggest that the bonding in YbH_2 and EuH_2 is *predominantly ionic* and the two hydrides contain Yb^{2+} ($4f^{14}$) and Eu^{2+} ($4f^7$) ions. YbH_2 is known to absorb more hydrogen to give a non-stoichiometric hydride approximating to $YbH_{2\cdot5}$ in which probably both Yb^{2+} and Yb^{3+} ions are present.

Other lanthanides also form hydrides approximating to the formula MH_2. The bonding in these hydrides is also *predominantly ionic* in which the lanthanide ion is present as M^{3+} and not as M^{2+}. The third valence electron of the metal in such hydrides is located in a metallic conduction band so that these hydrides have considerable conductivity. For instance, LaH_2 is a dark coloured material with a conductivity of about 10 ohm^{-1} per centimetre in which the 5*d* electron enters the La metallic conduction band. With further uptake of hydrogen, the stoichiometry approaches LaH_3 in which all the three valence electrons (*i.e.*, $5d^1s^2$) are used up in bonding and there is thus no valence electron to be contributed to the La metallic conduction band. As a result, there is 100-fold decrease in the conductivity of LaH_3 compared to that of LaH_2.

A number of actinides form stoichiometric and non-stoichiometric hydrides out of which UH_3 is the most studied. It can be prepared by reacting uranium directly with hydrogen. It exists in two crystalline forms α and β. Both the forms are highly reactive and are thus used for the preparation of other compounds of uranium.

Occlusion of Hydrogen by Palladium and Palladium Alloys. If red hot palladium is cooled in the atmosphere of hydrogen, it absorbs or occludes about 1000 times its own volume of hydrogen. As the gas is absorbed, the metallic conductivity falls till the material becomes a semiconductor at a composition approximating $PdH_{0\cdot5}$. Palladium does not lose its ductility unless the amounts of hydrogen absorbed are very large.

In the process of occlusion, hydrogen is first chemisorbed at the surface of Pd and at increased pressures it enters the metal lattice. The precise nature of the metal–hydrogen interaction is not clear although there is some evidence to suggest that a disordered, non-stoichiometric palladium hydride approaching the composition PdH is formed. The occluded hydrogen has high mobility inside the metal lattice and diffuses rapidly through the metal.

Alloys of palladium such as Pd-Ag and Pd-Au occlude greater amount of hydrogen than the palladium metal.

ISOTOPES OF HYDROGEN

Hydrogen has three isotopes with mass numbers 1, 2 and 3. These are described below.

1. Protium or Ordinary Hydrogen. This isotope is the most common and constitutes 99·984 per cent of total hydrogen available in nature. The molecule of ordinary hydrogen is diatomic. The nucleus of the hydrogen atom ^1_1H which consists of a solitary proton (mass number = 1) has no neutron at all. There is a solitary electron outside the nucleus (atomic number = 1).

2. Deuterium or Heavy Hydrogen. Deuterium constitutes only about 0·016 per cent of total hydrogen occurring in nature. In other words, in nature there are roughly 6000 atoms of hydrogen for every 1 atom of deuterium. The molecule of deuterium or heavy hydrogen is diatomic. The nucleus of the heavy hydrogen atom ^2_1H or ^2_1D contains a proton and a neutron (mass number = 2). There is, however, a solitary electron outside the nucleus as expected (atomic number = 1).

3. Tritium. Tritium is formed in the upper atmosphere by certain nuclear reactions which are induced by cosmic rays. It constitutes only 10^{-15} per cent of total natural hydrogen. The molecule of tritium is diatomic. The nucleus of tritium atom ^3_1H or ^3_1T consists of one proton and two neutrons

(mass number = 3). There is a solitary electron outside the nucleus as expected (atomic number = 1). It is radioactive in character.

All the three isotopes have similar chemical properties. However, they differ from one another in the rates of their reactions. Their physical properties differ appreciably from one another on account of differences in their mass numbers.

HEAVY HYDROGEN OR DEUTERIUM

History of Discovery. The discovery of heavy hydrogen or deuterium was the result of the discrepancy observed between the very exact physical and chemical atomic masses of hydrogen. Aston was the first to show this discrepancy and the difference between the two values led Birge and Menzel, in 1931, to predict the existence of a heavier hydrogen isotope. In the same year, Urey, Brickwedde and Murphy obtained, by fractional evaporation of liquid hydrogen, a heavy residue which was examined spectroscopically and was found to contain an isotope of mass number 2. They called it deuterium and gave it the symbol D. Urey was awarded Chemistry Nobel Prize in 1934.

Methods of Preparation

1. Separation from Ordinary Hydrogen. There are several methods by which deuterium can be separated from ordinary hydrogen. Some of these are described below.

a. By diffusion process. Deuterium can be isolated from ordinary hydrogen by taking advantage of different rates of diffusion of the two isotopes. Protium (^1_1H), which is lighter, diffuses more readily than deuterium. This method, though slow and tedious, has been found to give spectroscopically pure deuterium. The diffusion is carried out under reduced pressure. The lower the pressure, the greater is the efficiency of the process.

b. By fractional distillation of liquid hydrogen. Deuterium can be separated from ordinary hydrogen by careful fractional distillation of liquid hydrogen. Heavy hydrogen boils at – 249·5°C while protium boils at a lower temperature of –252·8°C. Hence, fractional distillation of liquid hydrogen can result in enrichment of the last fraction in deuterium. This fraction, very much enriched in deuterium, can be used for recovery of deuterium by the diffusion process described above.

c. By adsorption on charcoal. Protium is adsorbed more readily and more strongly on solid surfaces in general and on charcoal surface in particular. Thus, when a mixture of the two isotopes is led over charcoal kept at liquid air temperature, most of the protium gets adsorbed while most of the deuterium passes out unchanged.

d. By chemical methods. The lighter isotope (protium) is more reactive than the heavier isotope (deuterium). Thus, when ordinary hydrogen is passed over red hot copper oxide, the lighter component is consumed more than the heavier one in the reaction involving the reduction of CuO. In this way enrichment of ordinary hydrogen in deuterium is possible. Deuterium is then isolated by the process of diffusion, discussed above.

2. From Heavy Water. a. By electrolysis of heavy water, D_2O. The first step in this method is to get higher concentration of D_2O (heavy water) in ordinary water. It may be noted that ordinary water contains a very small proportion (about 1 part in 5000) of the oxide of heavy hydrogen, *i.e.*, D_2O. Although the boiling point of D_2O (101·42°C) is only slightly higher than that of H_2O (100°C), yet it has been found that a partial separation of the heavy water can be affected by fractional distillation of water. This method of getting a higher concentration of heavy water was used, originally, by Urey, Brickwedde and Murphy.

The concentration of heavy water can also be increased by fractional freezing of water. Heavy water freezes at 3·8 °C while ordinary water freezes at 0°C at 1 atm pressure.

The residual water left after prolonged electrolysis of water is also richer in D_2O.

In the **second step,** heavy water along with ordinary water is electrolysed to give a mixture of deuterium and ordinary hydrogen (protium). The deuterium content in the mixture is very much higher than that in ordinary hydrogen. Deuterium can be obtained from this mixture by the *diffusion process* already discussed.

b. By chemical methods. Deuterium is obtained from heavy water by the action of sodium metal.

$$2D_2O + 2Na \longrightarrow 2NaOD + D_2$$

However, in this method a part of heavy water changes into sodium deuteroxide and, therefore, complete recovery is not possible.

Deuterium can also be obtained by passing vapour of heavy water over heated metals such as zinc or tungsten (the metals are converted into their oxides in the process).

Physical Properties. Deuterium, like hydrogen, is a colourless, odourless and tasteless gas. It is insoluble in water and is a bad conductor of heat and electricity. Some of the physical constants of deuterium are presented in Table 2 in which, for comparison, the corresponding figures for ordinary hydrogen have also been given.

TABLE 2

Some Physical Constants of Hydrogen and Heavy Hydrogen

Property	Ordinary hydrogen, H_2 (Protium)	Heavy hydrogen, D_2 (Deuterium)
Boiling point	– 252·8°C	– 249·5°C
Melting point (or Triple point)	– 259·2°C	– 254·3°C
Heat of vaporisation	904 J mol^{-1}	1226 J mol^{-1}
Heat of fusion	117 J mol^{-1}	219 J mol^{-1}
Vapour pressure (at triple point)	5·4 mm Hg	5·8 mm Hg
Molar volume of solid	26·14 cm^2	23·17 cm^2
Dissociation energy	435·1 kJ mol^{-1}	438 kJ mol^{-1}

Chemical Properties 1. Burning in oxygen. Like hydrogen, deuterium is combustible and burns in air or oxygen forming deuterium oxide, D_2O.

2. Action with halogens. It combines with halogens under suitable conditions forming their *deuterides* which are analogous to the halogen hydracids. For example, D_2 reacts with F_2 in dark to produce D_2F_2. However, it reacts with Cl_2 in the presence of light to produce DCl.

3. Combination with nitrogen. Deuterium combines with nitrogen in the presence of a catalyst and forms nitrogen deuteride (ND_3) which is similar to ammonia. ND_3 is also known as deutero ammonia.

4. Combination with metals. Like hydrogen, deuterium combines with alkali metals at high temperature (363°C) forming deuterides which closely resemble metallic hydrides in their chemical properties as well as crystalline structures.

5. Addition reactions with unsaturated hydrocarbons. Deuterium, like hydrogen, gives addition reactions with unsaturated hydrocarbons. Thus, when a mixture of deuterium and ethylene is passed over heated nickel, ethylene deuteride, $C_2H_4D_2$, is formed which is a saturated hydrocarbon like ethane.

6. Exchange reactions. The deuterium and hydrogen atoms undergo ready exchange. Thus, detuerium reacts with H_2, NH_3, H_2O and CH_4, at high temperatures and exchanges its hydrogen partially or completely to give products such as HD, ND_3, D_2O, CD_4, etc. The exchange reactions, in general, are catalysed by finely divided nickel or chromium.

Uses of Deuterium. 1. Accelerated deuterons (nuclei of deuterium atoms) are employed for bombarding atoms in nuclear transformations and artificial radioactivity.

2. Since the replacement of an ordinary hydrogen atom in a compound by a deuterium atom causes an increase in the density of the compound, deuterium has been found useful as a *tracer element* in chemical and biological research and in understanding mechanisms of various reactions.

TRITIUM

Tritium occurs very very rarely in nature and constitutes only a negligibly small fraction (10^{-15} per cent) of the total hydrogen. Its atom is denoted by the symbol $^{3}_{1}T$. The molecule of tritium is diatomic. T_2O is present in water in extremely minute traces and, therefore, its recovery from water is of no practical interest.

Production of Tritium. Tritium has been obtained in small quantities by nuclear reactions, as shown below.

1. By bombardment of beryllium with deuterium.

$$^{9}_{4}Be + ^{2}_{1}D \longrightarrow \underset{\text{Isotope of beryllium}}{^{8}_{4}Be} + \underset{\text{Tritium}}{^{3}_{1}T}$$

2. By bombardment of boron, nitrogen or lithium by slow moving neutrons.

$$\underset{\text{Boron}}{^{10}_{5}B} + \underset{\text{neutron}}{^{1}_{0}n} \longrightarrow \underset{\text{Isotope of boron}}{^{11}_{5}B} \longrightarrow \underset{\text{Tritium}}{^{3}_{1}T} + \underset{\alpha\text{ particles}}{2\,^{4}_{2}He}$$

$$\underset{\text{Nitrogen}}{^{14}_{7}N} + \underset{\text{neutron}}{^{1}_{0}n} \longrightarrow \underset{\text{Isotope of nitrogen}}{^{15}_{7}N} \longrightarrow \underset{\text{Tritium}}{^{3}_{1}T} + \underset{\alpha\text{ particles}}{3\,^{4}_{2}He}$$

$$\underset{\text{Lithium}}{^{6}_{3}Li} + \underset{\text{neutron}}{^{1}_{0}n} \longrightarrow \underset{\text{Tritium}}{^{3}_{1}T} + \underset{\alpha\text{ particle}}{^{4}_{2}He}$$

Properties of Tritium. Tritium is a radioactive isotope of hydrogen. The half-life period of tritium atom is 12·4 years. It undergoes β transformation yielding an isotope of helium of mass number 3.

$$^{3}_{1}T \longrightarrow \underset{\text{Isotope of helium}}{^{3}_{2}He} + \underset{\beta\text{ particle}}{^{0}_{-1}n}$$

The molecule of tritium is diatomic and is written as T_2

Some of the physical constants of tritium are : Boiling point = – 248·1°C ; Melting point = –252·4°C ; Vapour pressure at the triple point = 162·0 mm, Heat of vaporisation at the boiling point = 139·3 kJ mol^{-1}

Being an isotope of hydrogen, it shows the same reactions as hydrogen and deuterium. For example, when burnt in oxygen, it forms tritium oxide, T_2O. Tritium hydride is obtained by treating lithium hydride with tritium.

$$LiH + T_2 \longrightarrow LiT + TH$$

However, the rate at which it reacts is very slow.

Uses. 1. It is used in several tracer experiments. 2. Tritium hydride is used in preparing a large number of organic compounds containing this radioactive isotope.

HEAVY WATER

The oxide of heavy hydrogen is called **heavy water.** It was discovered by Urey (1932). He showed that ordinary water contains small proportion (about 1 part in 5000) of the oxide of heavy hydrogen, *i.e.*, D_2O.

Preparation of Heavy Water

Heavy water is finding increasing applications in scientific research and as a moderator for slowing down neutrons in nuclear reactions. It is, therefore, being prepared in large amounts. The main source of heavy water is ordinary water from which it is isolated either by prolonged electrolysis or by fractional distillation.

1. By Prolonged Electrolysis of Water. The apparatus designed by Brown, Dagget and Urey for electrolysis of water consists of a steel cell about 45 cm long and 10 cm in diameter (Fig. 6). The cell itself serves as the cathode while the anode consists of a cylindrical sheet of nickel with a number of holes punched in it. A large number of such cells are used for electrolysis of water in several stages. The gases obtained from each stage are separately burnt and the water thus formed is returned to the previous stage. The heavy water gradually concentrates in the residue left behind. The process usually consists of five stages, as described below.

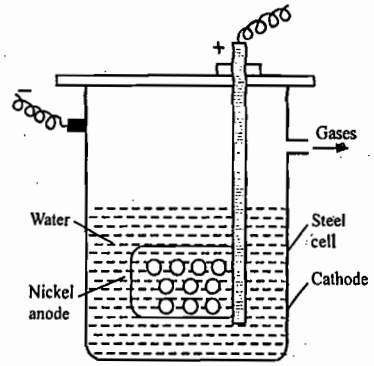

Fig. 6. Electrolytic cell for the preparation of heavy water.

First stage. Thirty electrolytic cells, described above, are used in the first stage. Each cell is charged with three litres of a 3 per cent solution of sodium hydroxide in ordinary water. An electric current at 110 volts is used for electrolysis. The evolved gases containing light hydrogen ($^{1}_{1}H$) and oxygen are discarded. When the electrolysis has been going on for about 72 hours, the total charge gets reduced to 1/6th of its volume and contains about 2·5% heavy water.

Second stage. In the second stage, the residue from the first stage is electrolysed using 6 cells till the content of heavy water increases to about 12%. The gases evolved evolved are burnt and the water formed is returned to the first stage cells.

Third stage. The residue from the second stage is further electrolysed and the content of heavy water is raised to nearly 60%. The gases evolved are burnt and the water formed is returned to the second stage cells.

Fourth stage. The residue from evolved the third stage is further subjected to electrolysis and nearly 99·5% heavy water is obtained. The gases evolved are burnt, as usual and sent to the third stage cells.

Fifth stage. The nearly 99·5% heavy water obtained from the fourth stage is freed from alkali and other impurities by distillation and the distillate is then electrolysed. The hydrogen evolved is pure deuterium. This, when burnt in oxygen, yields 100% pure D_2O.

2. By Fractional Distillation of Water. A partial separation of heavy water from ordinary water can be affected by fractional distillation. Advantage is taken of small difference in boiling points of protium oxide and deuterium oxide (Table 3).

TABLE 3

Physical Properties of Water and Heavy Water

Property	H_2O	D_2O
Density at 20°C (g cm^{-3})	0·988	1·017
Freezing point (°C)	0	3·82
Boiling point (°C)	100	101·42
Temperature of maximum density (°C)	4	11·6
Maximum density	1·000 (4°C)	1·1073 (11·6°C)
Heat of fusion (kJ mol^{-1})	6·01	5·68
Heat of vaporisation (kJ mol^{-1})	40·5	41·9
Surface tension (dyn cm^{-1}) at 20°C	72·8	67·8
Refractive index at 20°C	1·3330	1·3284
Dielectric constant	82·0	80·5
Viscosity (millipoises) at 20°C	10·09	12·6
Solubility of NaCl (g per litre)	350	805
Dissociation constant at 25°C	$1·0\times10^{-14}$	$0·3\times10^{-14}$
Ionic mobilities ($cm^2\,s^{-1}\,V^{-1}$) at 18°C :		
of K^+ ions	64·2	54·4
of Cl^- ions	65·5	55·3

Since the boiling points do not differ much, it is necessary to use a very long column and to repeat the process several times.

Properties of Heavy Water. Physical Properties. Heavy water, like ordinary water, is a colourless, odourless and tasteless mobile liquid. However, there is a marked difference between physical properties of ordinary water and heavy water, as shown in Table 3.

Higher viscosity of heavy water is responsible for lower solubility of ionic solids like NaCl and smaller mobilities of ions. Density of heavy water is expected to be higher on account of higher molar mass of this compound.

Chemical Properties. Heavy water differs only slightly from ordinary water in its chemical properties. However, the reactions of D_2O are slower than those of H_2O. Some of the important chemical reactions of heavy water are given below. All these reactions are given by ordinary water with a much greater vigour.

1. Action with metals. D_2O reacts slowly with alkali and alkaline earth metals producing deuteroxides and liberating heavy hydrogen.

2. Action with metallic oxides. Basic oxides of metals like sodium and calcium dissolve in D_2O and form heavy alkalies such as NaOD and $Ca(OD)_2$.

3. Action with acid anhydrides. D_2O dissolves acid anhydrides or acidic oxides of non-metals like P_2O_5, SO_3, etc., to form the corresponding acids containing heavy hydrogen, *e.g.*, D_2SO_4, D_3PO_4, etc.

4. Action with metallic carbides. Like H_2O, heavy water reacts with metallic carbides and forms deutero-hydrocarbons.

$$Al_4C_3 + 12D_2O \longrightarrow 4Al(OD)_3 + 3CD_4$$

$$CaC_2 + 2D_2O \longrightarrow Ca(OD)_2 + C_2D_2$$

5. Action with metallic nitrides, phosphides and arsenides. Heavy water decomposes metallic nitrides, phosphides, etc., forming deutero ammonia, deutero phosphine, etc.

$$Mg_3N_2 + 6D_2O \longrightarrow 3Mg(OD)_2 + 2ND_3$$

$$Ca_3P_2 + 6D_2O \longrightarrow 3Ca(OD)_2 + 2PD_3$$

$$Na_3As + 3D_2O \longrightarrow 3NaOD + AsD_3$$

The melting and boiling points of deutero-compounds are higher than those of the corresponding compounds of hydrogen. Thus, the melting and boiling points of ND_3 are higher than those of NH_3.

6. Electroysis. Heavy water containing dissolved P_2O_5 (to make it a good conductor) on electroysis decomposes into deuterium and oxygen which are liberated at the cathode and anode, respectively.

7. Formation of deuterates. Like ordinary water, D_2O may be associated with salts and other compounds as water of crystallization. The hydrates so formed are termed **deuterates** *e.g.*, $CuSO_4.5D_2O$, $Na_2SO_4.10D_2O$, $NiCl_2.6D_2O$, etc.

8. Exchange reactions. When compounds containing hydrogen are treated with D_2O, hydrogen undergoes an exchange for deuterium. If the compounds contain ionically bound hydrogen, the exchange reactions take place almost instantaneously, *e.g.*,

$$NaOH + D_2O \longrightarrow NaOD + HOD$$

$$HCl\,(aq) + D_2O \longrightarrow DCl + HOD$$

$$NH_4Cl + 4D_2O \longrightarrow ND_4Cl + 4HOD$$

In the case of compounds containing non-ionic hydrogen, the exchange reactions take place slowly and require the presence of a catalyst.

9. Biological properties. The biological properties of heavy water are still in dispute although it is established that heavy water retards the growth of living organisms, plants and animals. Lewis had shown that tobacco seeds do not grow in heavy water. Also, pure heavy water kills small fish, tadpoles and mice when fed upon it. Certain moulds have, however, been found to develop better in heavy water.

Uses of Heavy Water. 1. Heavy water is used for slowing down the fast moving neutrons. Neutrons are used for bringing about fission of uranium atoms. But, for this purpose their speed should be slowed down. This is done by passing them through heavy water.

2. Heavy water is commonly employed as a *tracer compound* for studying the mechanisms of many chemical reactions for confirming the structures of compounds. For example, when hypophosphorous acid, H_3PO_2, is treated with D_2O, only one ionic hydrogen of the acid is found to exchange for deuterium. Since deuterium is known to exchange only with ionic hydrogen, it can be safely inferred that H_3PO_2 contains only one ionizable hydrogen and, therefore, it is a monobasic acid.

3. Heavy water is used as one of the *references* in nuclear magnetic resonance spectroscopy.

OTHER COMPOUNDS OF DEUTERIUM

A brief description of some other deuterium compounds is given below.

1. Deuterium peroxide, D_2O_2. This compound is prepared by treating barium peroxide with dilute deutero sulphuric acid (D_2SO_4) dissolved in D_2O.

2. Deutero ammonia, ND_3. This is prepared by the action of heavy water on magnesium nitride, as already shown.

$$Mg_3N_2 + 6D_2O \longrightarrow 3Mg(OD)_2 + 2ND_3$$

ND_3 boils at 242 K whereas NH_3 boils at 238·5 K.

3. Deuterium chloride, DCl. It is prepared by a number of methods, for instance, by reducing silver chloride with deuterium, by treating NaCl with D_2SO_4 or by the action of D_2O on thionyl chloride.

$$2AgCl + D_2 \longrightarrow 2Ag + 2DCl$$

$$2NaCl + D_2SO_4 \longrightarrow Na_2SO_4 + 2DCl$$

$$SOCl_2 + 2D_2O \longrightarrow D_2SO_3 + 2DCl$$

4. Deutero methane, CD_4. It is most conveniently prepared by the action of D_2O on aluminium carbide.

$$Al_4C_3 + 12D_2O \longrightarrow 4Al(OD)_3 + 3CD_4$$

5. Deutero acetylene, C_2D_2. It can be prepared by treating calcium carbide with heavy water.

$$CaC_2 + 2D_2O \longrightarrow Ca(OD)_2 + C_2D_2$$

QUESTIONS

1. Discuss the position of hydrogen in the periodic table. Describe its important properties and uses.
2. Describe the preparation of nascent hydrogen. Discuss the theories of nascent hydrogen.
3. How is atomic hydrogen prepared ? Why is atomic hydrogen more reactive than molecular hydrogen?
4. What do you understand by ortho and para hydrogen ? How and why does the ratio of ortho to para hydrogen vary with temperature ? How can para hydrogen be obtained ?

5. Differentiate carefully between ortho and para hydrogen. Explain clearly why the ratio of ortho to para hydrogen at room temperature and above is 3 : 1.
6. Describe the methods for the preparation of ortho and para hydrogen. Give important properties of these two forms of hydrogen.
7. What are hydrides ? How are they classified ? Discuss briefly the ionic hydrides, covalent hydrides and interstitial hydrides.
8. Name the three isotopes of hydrogen. Give their electronic structures.
9. Describe the methods of preparation, properties and uses of deuterium and tritium.
10. (*a*) What is meant by heavy hydrogen ? How is it separated from ordinary hydrogen ? Discuss the important chemical properties of heavy hydrogen.

    (*b*) Write a note on spin isomerism of hydrogen.
11. What is meant by heavy water ? How is it obtained on a large scale ? Compare its properties with those of ordinary water.
12. What is heavy water ? How does it differ from ordinary water ? Give at least four chemical reactions of heavy water.

12 THE MAIN GROUP ELEMENTS. GENERAL CHARACTERISTICS

The *s* **and** *p* **block elements** taken together are known as the **main group elements** and as such they include the elements belonging to Groups 1, 2, 13 to 18. The elements belonging to Groups 1 and 2 which have one or two electrons in their outermost s orbitals preceded by noble gas configurations are known as *s* **block elements** while the elements belonging to Groups 13 to 18 which have one, two, three, four, five and six electrons, respectively, in the outermost *p* orbitals constitute the *p* **block elements.** In all these elements, the inner orbitals are completely filled. Thus, while the general outer electronic configuration of *s* block elements is $\mathbf{n}\,s^{1-2}$, that of *p* block element is $\mathbf{n}\,s^2p^{1-6}$.

GENERAL CHARACTERISTICS OF THE MAIN GROUP ELEMENTS

Atomic radii, ionic radii, ionization energies, electron affinities and **electronegativities** of the main group elements have already been discussed in details in Chapter 2. Other characteristics of these elements are discussed below.

Metallic Character

Metals have a tendency to lose electrons yielding positive ions : $M \longrightarrow M^{z+} + ze^-$. This tendency gives rise to what is known as the **metallic character** of an element. The greater the tendency to lose electrons, the greater is the metallic character of the element.

The tendency of an element to lose electrons is closely connected with the ionisation energy of the element. The smaller the ionisation energy of an element, the greater will be its tendency to lose electrons, *i.e.*, the greater will be its metallic character. Further, since it is easier to remove an electron from a larger atom than from a smaller atom, it follows that *metallic character increases as we move down from top to bottom in a given* **group** *of the periodic table.* For example, in Group 13, the metallic character increases as we move down from boron towards thallium. The effect is more striking in Groups 14 and 15. For example, in Group 14 , while carbon, the element at the top, is a non-metal, silicon and germanium, the next two elements, show some metallic character while tin and lead, the last two elements, have distinctly metallic character. In Group 15, nitrogen, the top element, is non-metallic while bismuth, the last element, has distinctly metallic character.

Further, since the ionisation energy increases on moving across a period from left to right on account of decrease in atomic radius, as already discussed in Chapter 2, *metallic character decreases on moving from left to right in a given* **period.** Consequently, the main group elements with strong metallic character are located mostly in the left or lower left portion while those with strong non-metallic character are found in the right or top right portion of the periodic table. Somewhere in between these two extremes, lie a number of other elements which show characteristics of both metals and non-metals. These are called **metalloids** or **semi-metals.** The division of elements into the three categories is

represented in Table 1.

TABLE 1
Division of Elements into Metals, Non-metals and Metalloids

s Block Elements		*p* Block Elements					
1	2	13	14	15	16	17	18
				NON-METALS			
H						H	He
Li	Be		C	N	O	F	Ne
Na	Mg			P	S	Cl	Ar
K	Ca	Ga			Se	Br	Kr
Rb	Sr	In	Sn			I	Xe
Cs	Ba	Tl	Pb	Bi		At	Rn
Fr	Ra						
	Metals				Metalloids		

It may be pointed out, however, that since the electrical properties are generally a function of the crystal structure of the element concerned, the classification of elements into metals, non-metals and metalloids (or semi-metals) becomes somewhat enigmatic because of the existence of some of the elements in more than one allotropic forms having different electrical properties. For example, white tin (or β tin) is metallic in character and is rightly placed in Table 1. However, grey tin (or α tin) having a diamond-like structure resembling that of Si and Ge, shows semi-metallic properties and, therefore, should find a different place in this table. Similarly, one allotropic form of Se consists of eight-membered rings, Se_8 and is non-metallic like S_8 whereas the other allotrope of Se, having a chain structure, has electrical properties of a semi-metal. Likewise, white phosphorus (having P_4 units) and red phosphorus do not conduct electricity and are thus non-metallic whereas black phosphorus having a sheet-like structure conducts electricity to a limited extent and thus behaves as a semi-metal or metalloid. It follows, therefore, that unless we know the crystal structure, it is difficult to unequivocally classify elements into metals, non-metals or semi-metals.

Metallic elements have a crystal structure with high coordination number of 12 (in close-packed lattice) or 8 (in body centred cubic lattice) whereas non-metals exist generally as volatile molecular solids. The semi-metals, generally, have either a three-dimensional network or a layer or a long chain structure. The coordination number in crystals of semi-metals is small compared to metallic crystals.

Polarizing Power and Polarisability

The distortion of the electron charge cloud of an anion by a cation is termed as **polarization.** The distortion of the electron charge cloud occurs due to the *attraction* between the positive charge of cation and the electrons of the anion and the *repulsion* between the electrons and between the positively charged nuclei. *The extent to which a cation can distort the electron charge cloud of an anion is known as the* **polarizing power of the cation** and *the ease with which the electron charge cloud of an anion gets distorted by a cation is known as the* **polarizability of the anion.**

Fajan suggested the following rules to estimate the extent to which a cation can polarize an anion. These are commonly known as **Fajan's rules.**

1. *The cations with high charge and small size have high polarizing power, i.e.*, they can distort the electron charge cloud of an anion highly effectively. In other words, the polarizing power of a cation is directly proportional to its charge and inversely proportional to its size. The polarising power of a cation is generally expressed in terms of a parameter called **ionic potential** which is the *ratio of the effective nuclear charge of the cation and its size.* The higher the ionic potential of a cation, the greater would be its polarizing power.

2. *The anions possessing high negative charge and large size are easily polarizable.* Both these factors would decrease the hold of the nucleus of the anion on its electron charge cloud which, therefore, can be easily distorted by a cation. Thus, anions such as I^- and Se^{2-} are easily polarizable because of their large size. Similarly, anions such as As^{3-} and P^{3-} sare easily polarizable because of their high charge.

3. As we know, the *d* electrons shield the nucleus poorly as compared to *s* and *p* electrons (Chapter 1). If we have two cations of the same size and charge, the cation having a configuration with *d* electrons

would have more effective nuclear charge due to poorer screening of the nucleus by the *d* electrons and would have more ionic potential or polarizing power than the cation having a configuration with no *d* electrons in the *penultimate shell.* For example, Hg^{2+} and Ca^{2+} ions have the same charge and nearly the same size (the ionic radii being 1·16 Å and 1·14 Å, respectively), yet Hg^{2+} ion with $[Xe]4f^{14}5d^{10}6s^0$ configuration has more polarizing power than Ca^{2+} ion with $[Ar]4s^0$ configuration.

It may be noted that these are not only the anions which get polarized; the cations also get polarised though the polarisation is much less due to their smaller size.

Consequences of Polarisation. ***1. Diagonal relationship.*** The ionic potentials of some simple cations are given below.

Cation	Ionic Potential	Cation	Ionic Potential	Cation	Ionic Potential
Li^+	17	Be^{2+}	64	B^{3+}	150
Na^+	10	Mg^{2+}	31	Al^{3+}	60
K^+	8	Ca^{2+}	20	Ga^{3+}	48

The above data clearly show that ionic potential or polarizing power of cations generally *increases* as we move from left to right within a period and *decreases* as we move from top to bottom within a group (cations with charge higher than + 3 generally do not exist).

It is well known that the *first* element in any given group of the periodic table resembles the *second* element of the *next group.* Thus, Li forms organometallic compounds like Mg. None of the other elements of Group 1 forms such compounds. Similarly, the chemistry of Be is similar to that of Al despite the difference in their oxidation states. *This type of relationship of the first element of a group with the second element of the next group is known as* **diagonal relationship.** The cause of similarity in the pairs of such elements can be understood by considering a few examples.

If we move from Be^{2+} to B^{3+}, the charge increases and the size slightly decreases. The polarising power or ionic potential of B^{3+} is thus more than that of Be^{2+}. If, now, we move down from B^{3+} to Al^{3+}, the size increases and, therefore, the polarizing power of Al^{3+} is less than that of B^{3+}. If we make both the moves together, it would amount to moving *diagonally* from Be^{2+} to Al^{3+}. The overall change in charge and size in the above movement is such that they give rise to almost the same ionic potential of Be^{2+} and Al^{3+}, *viz.*, 64 and 60, respectively. Thus, Be^{2+} and Al^{3+} ions have similar polarizing powers and, therefore, have similar properties. Likewise, Li^+ and Mg^{2+} ions have similar polarizing powers and, therefore, have similar properties. Thus, the phenomenon of polarization satisfactorily explains the cause of diagonal relationship in elements of the first three groups of the periodic table. In subsequent groups, the diagonal relationship can be explained on the basis of electronegativities of elements. This aspect would be discussed at an appropriate place in this chapter.

2. Melting points of halides. Let us consider the melting points of $BeCl_2$ (405°C) and $CaCl_2$ (772°C). The anion Cl^- is common in both the compounds. Both the cations belong to Group 2 of the periodic table and carry two units of positive charge each. Because of its small size, Be^{2+} ion has greater polarizing power than the Ca^{2+} ion. As a result, the electron charge cloud of Cl^- ion is pulled towards Be^{2+} and there is considerable overlap of electron charge clouds of Cl^- and Be^{2+} ions. Consequently, the bond formed between Be and Cl atoms is *polar covalent* rather than ionic. In $CaCl_2$, the extent of distortion of electron charge cloud of Cl^- by Ca^{2+} is less. The extent of overlap of electron charge clouds of Ca^{2+} and Cl^- ions is negligible so that the bond formed between Ca and Cl atoms is *mainly ionic* and only negligibly covalent. This explains the lower melting point of $BeCl_2$ which has a polar covalent bond between Be and Cl and higher melting point of $CaCl_2$ in which the bonding is predominantly ionic.

Let us now consider compounds with cations of different charges but of nearly the same size, as, for example, NaBr (m.p. 755°C), $MgBr_2$ (m.p. 700°C) and $AlBr_3$ (m.p. 498°C). The polarizing power of Al^{3+} ion is greater than that of Mg^{2+} ion which, in turn, is greater than that of Na^+ ion. Therefore, NaBr has the least covalent character and highest melting point whereas $AlBr_3$ has maximum covalent character and lowest melting point of the three compounds.

Finally, let us consider anions of different sizes forming compounds with the same cation, *viz.*, LiF (m.p. 870°C), LiCl (m.p. 613°C), LiBr (m.p. 547°C) and LiI (m.p. 466°C). Because of differences of sizes, the polarizability of the anions is in the order : $I^- > Br^- > Cl^- > F^-$. Hence, LiI has the maximum and LiF has the minimum covalent character. As a result, LiI has the lowest and LiF has the highest melting point of all the compounds.

3. Solubilities of silver halides. AgF is soluble in water whereas AgCl is not. This is because the Cl^- ion, due to its large size, is polarised by Ag^+ ion to a greater extent than the F^- ion. As a result, the bonding in AgCl is predominantly covalent whereas in AgF it is mainly ionic. Therefore, AgF being an ionic compound, is soluble in water whereas AgCl, being a covalent compound, is insoluble in water.

4. Decomposition of carbonates. The temperatures at which the various metal carbonates decompose to give metal oxides and CO_2 gas, according to the reaction $MCO_3 \longrightarrow MO + CO_2$, are given below :

Metal Carbonate	Decomposition Temperature (°C)	Metal Carbonate	Decomposition Temperature (°C)
$BeCO_3$	100	$BaCO_3$	1360
$MgCO_3$	400	$CdCO_3$	~ 350
$CaCO_3$	900	$PbCO_3$	~ 350
$SrCO_3$	1290		

From the data on the decomposition of alkaline earth carbonates, it is clear that the greater the size of the cation, the higher is the decomposition temperature of the carbonate. The cations with large size will not be able to polarise the electron charge cloud of the carbonate ion so effectively, with the result that bonding in carbonates with larger cations would be mainly *ionic*. On the other hand, the cations with smaller size would distort the electron charge cloud on the oxygens of the carbonate ion very effectively so that the carbonate ion would get split into CO_2 and O^{2-} ion to form the metal oxides more easily, *i.e.*, at a lower temperature.

It may be observed, however, that although Cd^{2+}, Pb^{2+} and Ca^{2+} ions have nearly the same size, yet the carbonates of Cd^{2+} and Pb^{2+} decompose at a much lower temperature (~ 350°C) than $CaCO_3$ (decomposition temperature 900°C). This is explained as follows : The outer electronic configurations of Cd^{2+}, Pb^{2+} and Ca^{2+} are, respectively, $4s^2p^6d^{10}$, $4f^{14}\,5s^2p^6d^{10}\,6s^2$ and $3s^2p^6$. Thus, while Cd^{2+} and Pb^{2+} ions have *d* electrons in the penultimate shells, Ca^{2+} ion does not have any *d* electron in its electronic configuration. Since *d* electrons have a poorer screening effect than *s* and *p* electrons, therefore, the *effective nuclear charge* in case of Cd^{2+} and Pb^{2+} ions would be more than in Ca^{2+} ions. Consequently, Cd^{2+} and Pb^{2+} ions would have greater polarising power than Ca^{2+} ions. The electron charge cloud on the oxygens of CO_3^{2-} ion would get distorted more in the case of Pb^{2+} and Cd^{2+} ions than in the case of Ca^{2+} ion. The CO_3^{2-} ion would , therefore, get split *more easily* to give CO_2 and O^{2-} ion in the case of $CdCO_3$ and $PbCO_3$ than in the case of $CaCO_3$.

Melting Points and Boiling Points

The metallic character of elements also affects their melting as well as boiling points. As the metallic character *increases*, the melting and boiling points generally *decrease*. This is illustrated in the case of elements of Group 14, the melting and boiling points of which are given in Table 2.

TABLE 2

Melting and Boiling Points of Elements of Group 14

Elements	C	Si	Ge	Sn	Pb
Melting Points (°C)	3727	1410	937·5	231·8	327·4
Boiling Points (°C)	4830	2680	2830	2270	1725

We know, for example, that the metallic character *increases* on moving from carbon to lead in the same group. Hence, the melting and boiling points generally *decrease* in the same order. The melting point of tin is exceptionally low.

The metallic character *decreases* as we move from lithium to carbon in the same period. The melting and boiling points, therefore, *increase* in the same order. The boiling point of boron, however, is comparatively low (Table 3). The remaining four elements (namely, N, O, F and Ne) of this period are gases at ordinary temperatures.

TABLE 3

Melting and Boiling Points of the First Four Elements of the Second Period

Elements	Li	Be	B	C
Melting Points (°C)	181	1277	2030	3727
Boiling Points (°C)	1330	2770	2550	4830

Oxidising and Reducing Properties

It may be recalled that an **oxidising agent** is a substance which is in a position to *gain electrons* and a **reducing agent** is a substance which is in a position to *lose electrons*. Since elements with low ionization energies can easily undergo loss of electrons, they are good reducing agents.

Since ionization energies decrease on moving down a group, it is evident that *reducing character* of elements in a given group increases with increase in atomic number. Conversely, the *oxidising character* of elements in a group decreases with increase in atomic number. Thus, amongst the elements of Group 1, while the first element, lithium, is a *moderate* reducing agent, the last element, cesium, is a *strong* reducing agent. Similarly, in case of Group 14 elements, while the first element, carbon, is a *weak* reducing agent, the last element, lead, is a *strong* reducing agent.

Further, since ionisation energy increases on moving across a period from left to right, it follows that reducing character decreases while oxidising character increases with increase in atomic number in a given period. For example, while the first element of the third period, sodium, is *a reducing agent*, the last element of the same period, chlorine, is an *oxidising agent*.

Electrode Potentials. Electropositive Character

Electrode potential is defined *as the potential developed on a metal when it is immersed in a solution of its own ions*. If the concentration of the ions is *one molar*, the potential developed is called **standard electrode potential**. Standard electrode potentials of some of the main group elements are given in Table 4.

According to the latest convention, the electrode reactions are written in the form of reduction, *i.e.*,

TABLE 4

Standard Electrode Potentials (in volts) of Redox Couples involving Some Important Main Group Elements (on Hydrogen Scale)

H^+, H 0						
Li^+, Li − 3·04	Be^{2+}, Be − 1·85	Be^{3+}, B − 0·87			O_2, OH^- + 0·44	1/2 F_2, F^- + 2·87
Na^+, Na − 2·71	Mg^+, Mg − 2·52	Al^{3+}, Al − 1·66			S, S^{2-} + 0·49	1/2 Cl_2, Cl^- + 1·36
K^+, K − 2·92	Ca^{2+}, Ca − 2·87	Ga^{3+}, Ga − 0·52		As^{3+}, As + 0·25		1/2 Br_2, Br^- + 1·06
Rb^+, Rb − 2·99	Sr^{2+}, Sr − 2·89	In^{3+}, In − 0·34	Sn^{2+}, Sn − 0·15	Sb^3, Sb + 0·21		1/2 I_2, I^- + 0·53
Cs^+, Cs − 3·02	Ba^{2+}, Ba − 2·90	Tl^+, Tl − 0·34	Pb^{2+}, Pb − 0·13	Bi^{3+}, Bi + 0·23		

consumption of electrons. Accordingly, the half-cell reaction for Li^+, Li electrode is written as

$$Li^+ + e^- \longrightarrow Li\,(s)\ ; \qquad E^\circ_{el} = -3{\cdot}04\ V$$

Since negative reduction potential implies positive oxidation potential, we may write the above reaction as

$$Li\,(s) \longrightarrow Li^+ + e^-\ ; \qquad E^\circ_{oxid} = +3{\cdot}04\ V$$

Since a reducing agent is a substance which is capable of *losing* electrons, it is evident that elements with **positive oxidation potentials** (*viz.*, negative standard electrode potentials) are capable of acting as **reducing agents** in aqueous solution. Conversely, the elements with negative oxidation potentials (*viz.*, positive standard electrode potentials), are capable of acting as **oxidising agents**. Accordingly, the elements in Groups 1, 2 and 13 are reducing agents while those in Groups 15, 16 and 17 are oxidising agents.

In general, the reducing character tends to decrease and oxidising character tends to increase as we move across a period from left to right in the periodic table. Lithium is, thus, the strongest reducing agent while fluorine is the strongest oxidising agent.

Elements having *negative reduction potentials* or *positive oxidation potentials* are said to be **electropositive** since they have a greater tendency than hudrogen to chang into **positive ions** ($M \longrightarrow M^+ + e^-$). The greater the positive oxidation potential (or negative standard electrode potential), the greater is the electropositive character of the element. Lithium, evidently, is the *strongest electropositive elements* and fluorine is, accordingly, the *strongest electronegative element.*

The electropositive character is seen to decrease on moving across a period from left to right. The trends on moving down a group, though not so definite, indicate, in general, an increase in electropositive character. In the case of the first group, the values are fairly close. In the case of the second group, the electropositive character shows gradual increase on moving down the group. In the third group, electropositive character increases from boron to aluminium but decreases on moving to the next higher elements, namely, gallium, indium and thallium. The reason is that while boron and aluminium follow the *s* block elements, gallium, indium and thallium follow the *d* block elements. The *d* electrons provide much less shielding of the nucleus and, therefore, the orbital electrons are held more firmly by the nucleus and are thus difficult to be knocked out. These elements, therefore, are less electropositive.

Oxidation States

The oxidation states which various elements can have in forming compounds are closely connected with the number of valency electrons. Since this number changes periodically, it is expected that *the oxidation states of elements will also change periodically.* This is illustrated in Table 5 in which the maximum positive and negative oxidation states of the first 18 elements have been listed.

TABLE 5
Periodicity of Oxidation States

	Group 1	Group 2	Group 13	Group 14	Group 15	Group 16	Group 17	Group 18
Element	H							He
Electrons in shells	1							2
Highest oxidation states	−1 +1							0
Element	Li	Be	B	C	N	O	F	Ne
Electrons in shells	2, 1	2, 2	2, 3	2, 4	2, 5	2, 6	2, 7	2, 8
Highest oxidation states	+1	+2	+3	+4 −4	+5 −3	−2	−1	0
Element	*Na*	*Mg*	*Al*	*Si*	*P*	*S*	*Cl*	*Ar*
Electrons in shells	2, 8, 1	2, 8, 2	2, 8, 3	2, 8, 4	2, 8, 5	2, 8, 6	2, 8, 7	2, 8, 8
Highest oxidation states	+1	+2	+3	+4 −4	+5 −3	+6 −2	+7 −1	0

It is evident that with each unit increase in atomic number, the oxidation state changes by one unit, the change, of course, proceeds in cycles. The noble gases, having zero oxidation state, are followed by elements having + 1 oxidation state (alkali metals) and these, in turn, are followed by elements having + 2 oxidation state (alkaline earth metals), and so on. Negative oxidation states are usually exhibited by elements in Groups 14 to 17.

It is also seen that while positive oxidation state increases, negative oxidation state decreases with increasing atomic number on moving across the period from left to right.

In a group, the *s* block elements show only one stable oxidation state (+1 for alkali metals and +2 for alkaline earth metals). However, *p* block elements generally show more than one stable oxidation state. The maximum oxidation state shown by a *p* block element is equal to the total number of *s* and *p* electrons in the valence shell. In addition to this, some of the *p* block elements show oxidation states which differ from the group oxidation state by steps of two. For example, the elements of Group 14 exhibit two oxidation states of + 4 and + 2. The + 4 state is more important in the first two elements carbon and silicon. The + 2 state becomes more and more stable as we go down the group. Thus, the compounds in which the last two elements tin and lead are in + 2 state, are more stable than those in which these elements are in + 4 state.

Similarly, the elements of Group 13 show + 3 and + 1 oxidation states. As we go down the group, the + 1 oxidation state becomes more and more stable. Thus in the case of heavier elements In and Tl, + 1 oxidation state is more stable than the + 3 oxidation state.

It is evident from the above description that if the elements in a group show variable oxidation state, *the heavier elements of that group* (*e.g.*, elements Sn and Pb of Group 14 and elements In and Tl of Group 13) *show reluctance to exist in higher oxidation state and prefer to stay in lower oxidation state.* The outer electronic configurations of 13th and 14th group elements are ns^2p^1 and ns^2p^2, respectively. Since the valence *p* electrons have lesser probability of being nearer to the nucleus than the valence *s* electrons, the former are easier to be removed or excited to higher orbitals than the latter. Because of this, the two *s* electrons were thought to be inert, *i.e.*, they remained paired and did not take part in bonding especially in heavier elements. This concept was given the name **inert pair effect.** As a result of this effect, the stable oxidation states of such elements were two units less than the total number of valence electrons. Thus, Sn ($5s^2p^2$) and Pb ($6s^2p^2$) have more stable oxidation state of $4 - 2 = 2$ while In ($5s^2p^1$) and Tl ($6s^2p^1$) have more stable oxidation state of $3 - 2 = +1$. However, *the concept of inert pair effect has several lacunae* which we shall discuss a little later in this chapter.

An alternative explanation for the stability of lower oxidation states in heavier elements is as follows : Since the atomic sizes of heavier elements are comparatively large, a sideways overlap to form pi bonds is not favoured. Thus, only sigma covalent bonds are formed in the case of heavier elements. In contrast, the lighter elements, because of their smaller size, are capable of forming both sigma and pi bonds. In other words, comparatively *fewer* valence electrons are involved in bond formation in the case of heavier elements. This accounts for the stability of *lower* oxidation states in these elements.

Diagonal Relationship

As we move diagonally across the periodic table, the elements, although belonging to different (adjacent) groups, show certain similarities. These similarities, though weaker than those within a group, are, nevertheless, quite well prononuced particularly in the following pairs of the main group elements :

Group 1	Group 2	Group 13	Group 14
Li	Be	B	C
Na	Mg	Al	Si

The reason for this diagonal similarity, as already discussed, is as follows : On moving from left to right across a period, the ionic charge increases while the ionic size decreases, thus causing an increase in its polarising power (Fajan's rule). On the other hand, on moving down a group, the ionic charge

remains the same while the ionic size increases and, therefore, the polarising power decreases. When we move diagonally, these two effects partly balance each other and, therefore, there is no marked change in their properties.

Diagonal relationship is also exhibited by elements of Groups 15, 16 and 17. Thus, C shows diagonal relationship with P ; N with S and O with Cl. The diagonal effect in the case of non-metals (C, P, N, S, O, Cl) cannot be explained on the basis of the ionic charge. This is because these elements have no metallic character and, therefore, the explanation of *similarity in their properties on the basis of their polarising power, generally expressed in terms of ionic potential, viz.*, cationic charge/cationic size ratio, has no meaning.

However, the diagonal effect in non-metals can be explained on the basis of similarity in electronegativities of diagonal elements. Consider the electronegativities of elements, as shown :

C	N	O	F
(2·5)	(3·0)	(3·5)	(4·0)
Si	P	S	Cl
(1·8)	(2·1)	(2·5)	(3·1)

As can be seen, the electronegativities *decrease* on moving down a group and *increase* on moving across a period. These two effects balance each other on moving diagonally so that the diagonal elements have similar electronegativities and hence similar chemical properties. Thus, the pairs of elements C, P ; N, S and O, Cl have similar electronegativities and, therefore, have similar chemical properties. It may, however, be emphasised that the similarities in electronegativities of the diagonal non-metal elements are not as close as the similarities in the polarizing powers (ionic potentials) of the diagonal metal elements.

COMPOUNDS OF MAIN GROUP ELEMENTS

OXIDES

Almost all the main group elements form oxides which can be classified into ***three categories*** : 1. *Basic oxides* which react with acids 2. *Acidic oxides* which react with bases and 3. *Amphoteric oxides* which react with both acids and bases. The products in all cases are termed as *salts*.

Periodic Trends in Acid-Base Character of Oxides. Generally speaking, on moving across a period, *the acid-base character of the oxides gradually changes from basic to amphoteric and finally to acidic*. Thus, on moving across the third period, it is observed that while Na_2O is strongly basic, MgO is less basic, Al_2O_3 is amphoteric, SiO_2 is weakly acidic, P_2O_5 is acidic, SO_3 is strongly acidic and Cl_2O_7 is even more strongly acidic. On moving down a group, it is observed that the oxides exhibit gradually *increasing basic character* or *decreasing acidic character*. This may be illustrated by considering oxides of Group 13 elements. Thus, while B_2O_3 is weakly acidic, Al_2O_3 and Ga_2O_3 are amphoteric whereas In_2O_3 and Tl_2O_3 show increasing basic character.

Type of Bonding in Oxides. The type of bonding in oxides depends considerably on the difference in the electronegativities of the element and oxygen. If this difference is large, the oxide generally has ionic structure. For example, the oxides of alkali metals have an ionic antifluorite structure in which each metal ion is surrounded by four oxide ions and each oxide ion is surrounded by eight metal ions. Alkaline earth metal oxides with the general formula MO have an ionic NaCl type structure (Chapter 6).

If the electronegativity differences are small, the bonds formed are predominantly *covalent*. Thus, oxides of non-metals whose electronegativity is close to that of oxygen, exist as discrete molecules and not as ions. Examples are NO, F_2O, etc.

The oxides of *heavier* non-metals and semi-metals have *complex* crystal structures in solid state. Thus, while CO_2 exists as a discrete molecule, SiO_2 has an infinite three-dimensional network in which each Si atom is *covalently bonded* with four oxygen atoms. GeO_2 and SnO_2 also have complex three-

dimensional structures containing Ge–O and Sn–O covalent bonds. Oxides of N, P and As have simple molecular structures whereas oxides of Sb and Bi have complex three-dimensional net work containing Sb–O and Bi–O covalent bonds. In Group 16, oxides of sulphur have simple molecular structures whereas SeO_2 and TeO_2 have infinitely long-chain structures.

Stability of Oxides. Almost every main group element (with the exception of halogens, nitrogen and noble gases) forms *at least one oxide which has a negative free energy of formation and is thus stable*. The stabilities of M–O bonds are represented by the magnitude of their molar enthalpies of formation or better by their equivalent enthalpies of formation. The equivalent enthalpy of formation of an oxide M_xO_y is obtained by dividing the molar enthalpy of formation by $2y$. The equivalent enthalpies of formation of various oxides when plotted as a function of the positions of the elements in the periodic table, give a curve as shown in Fig. 1.

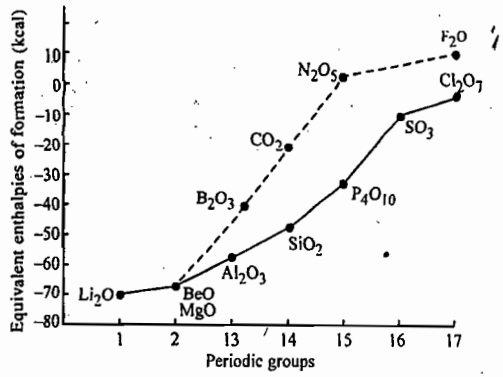

Fig. 1. Equivalent enthalpies of formation of various oxides (in kcal) as a function of the positions of the elements in the periodic table.

It is apparent from this figure that oxygen forms compounds of greater stability with elements that are farther off from it in the periodic table. Thus, while Li_2O, with a high negative enthalpy of formation, is the most stable, F_2O with a positive enthalpy of formation, is the least stable oxide.

According to Fig. 1, the order of stability of oxides of elements from Mg to Cl is as follows :

$$MgO > Al_2O_3 > SiO_2 > P_4O_{10} > SO_3 > Cl_2O_7$$

HYDRIDES

Hydrogen combines with a number of other elements including metals and non-metals to form compounds called *hydrides*. Based on their physical and chemical properties, the hydrides have been classified into three main categories, *viz.*, *1. Ionic or Salt-like Hydrides 2. Molecular or Covalent Hydrides* and *3. Interstitial Hydrides*. The preparation, properties and uses of these hydrides have already been discussed in details in the last chapter on 'Hydrogen.'

HALIDES

The main group elements form halides which can be classified as *1. Ionic or Salt-like Halides 2. Covalent or Acid Halides 3. Complex Halides*. However, due to a wide difference of electronegativities amongst the halogens, the classification is just arbitrary. The line of demarcation between ionic and covalent halides is not very sharp. Therefore, the discussion based on this classification is in no way comprehensive and complete.

1. Ionic or Salt-like Halides. These halides exist as ionic or semi-ionic crystals in solid state. They are generally characterised by (*i*) their comparatively high melting and boiling points (*ii*) their solubility in polar solvents and (*iii*) their high conductivity in fused state or in solutions. The magnitude of these properties, however, varies considerably because of factors such as charge and size of the metal ion, electropositive character of the metal and electronegative character of the halogen involved. True ionic character is, however, limited to the halides of alkali and alkaline earth metals. The anhydrous halides of other elements are more covalent than ionic in solid state although they dissolve in polar solvents to give ionic solutions.

The increase in oxidation number and decrease in size of cation increases the polarising power of a cation and promotes covalent character in halides (see Fajan's rules discussed earlier in this chapter). For example, in the fourth period, ionic character goes on decreasing and covalent character goes on

increasing as we move from $KCl \longrightarrow CaCl_2 \longrightarrow ScCl_3 \longrightarrow TiCl_4$. The last halide, $TiCl_4$, is essentially covalent in character.

The covalent character in halides of a particular element increases with increase in size and decrease in electronegativity of the halogen. Thus, there is a distinct decrease in ionic character as we move from $LiF \longrightarrow LiCl \longrightarrow LiBr \longrightarrow LiI$. Similarly, amongst the halides of aluminium, AlF_3 is essentially ionic, $AlCl_3$ has an intermediate character while $AlBr_3$ and AlI_3 exist as covalent dimers. The fluorides of metallic elements are essentially ionic whereas the other halides may or may not be so.

In the case of a metal showing more than one oxidation state, the ionic character of the metal halides decreases with increase in the oxidation state. For example, while $PbCl_2$ is largely ionic, $PbCl_4$ is largely covalent.

Salt-like halides vary widely in their solubility in water. Although many fluorides are soluble, the fluorides of lithium and alkaline earths are insoluble owing to their large lattice energies. Chlorides, bromides and iodides are generally soluble and the solubility increases with increase in the size of the halide ion. The reverse is true of halides in which covalent bonding is appreciable.

The halide ions are oxidisable to free halogens, the ease of oxidation increasing with increase in the size of the halide ion. Thus, out of all halides, the iodides are most easily oxidisable. They undergo oxidation even by aerial oxygen in acidic solutions.

2. Covalent or Acid Halides. These halides generally exist as discrete molecules and are derived from either non-metals, or metals with high charge/size ratios. As a convention, the non-metal halogen compounds containing oxygen, sulphur or nitrogen as a third element (as, for example, $POCl_3$) are also included in this class. The covalent halides have low boiling points, *i.e.*, they are volatile. They are soluble in non-polar solvents and are liable to undergo solvolytic reactions when brought in contact with polar solvents. In the series of halides derived from a particular non-metal, melting points generally increase with increase in their molar masses as is generally the case with characteristic covalent compounds.

The hydrogen halides deserve a special mention here. All of them dissolve in water owing to the following reaction :

$$HX + H_2O \rightleftharpoons H_3O^+ + X^-$$

These halides, therefore, act as acids in water.

Hydrogen fluoride undergoes association because of hydrogen bonding, as already mentioned. In solid state, it exists as an infinite linear zig-zag chain of molecules. The association of HF molecules occurs in liquid and vapour phase as well. Other hydrogen halides show very little hydrogen bonding and very little association of their molecules.

3. Complex Halides. Entry of halide ions into the coordination sphere of a metal ion is a common phenomenon. Fluoride ion forms stable complexes with *smaller cations* such as Ba^{2+}, Al^{3+}, Si^{4+} because of strong electrostatic attraction and high energies of the resulting bonds.

In contrast, the fluoride ion does not form stable complexes with *larger cations*. The stability of halide complexes formed with larger cations increases in the order : Iodide > Bromide > Chloride. These complexes are easily polarisable. Some common halogen complexes of main group elements are : $[BeX_4]^{2-}$, $[BX_4]^-$, $[AlX_6]^{3-}$, $[GaX_6]^{3-}$, $[InX_6]^{3-}$, $[TlX_6]^{3-}$, $[AsX_6]^{3-}$, $[GeX_6]^{2-}$, $[SnX_6]^{2-}$, $[SbX_6]^-$, $[AsX_6]^-$, $[PX_6]^-$.

SOME SPECIAL CHARACTERISTICS OF *p* BLOCK ELEMENTS

The *p* block elements differ from *s* block elements in several respects and exhibit some special characteristics which are a consequence of their size, effective nuclear charge, polarising power and polarisability, the extent of involvement of *p* orbitals in pi bonding and of *d* orbitals in sigma and pi bonding. It may be noted that there are some distinct features which make conspicuous distinction not only between *s* and *p* block elements but also between the lighter and the heavier *p* block elements

themselves. While the differences between *s* and *p* block elements are largely due to differences in their electronic configurations, the differences between lighter and heavier *p* block elements are largely due to differences in their sizes. We know that the atomic size goes on *decreasing* as we move across a period. Also the effective nuclear charge goes on *increasing* with increase in atomic number. Because of these factors, ionization energies, electron affinities, electronegativities and polarising powers of the lighter *p* block elements become considerably different from those of the heavier *p* block elements.

Some **typical properties of *p* block elements** are discussed below.

1. Ionization Energies. As discussed in Chapter 2, ionization energies *decrease regularly* as we move down the groups of *s* block elements. But, *this is not the case in p block elements*. For instance, the ionization energies of Group 13 elements change in an oscillating manner, the values for B, Al, Ga, In and Tl, being 800·1, 577·4, 579·0, 558·2 and 589·2 kJ mol^{-1}, respectively. Evidently, ionization energy *decreases* from B to Al, *increases* from Al to Ga, again *decreases* from Ga to In and again *increases* from In to Tl. Irregularities in the trends of ionization energies are also shown by Group 14 elements. For instance, ionization energies *decrease* as we move from C to Sn (the values being 1086·2, 786·4, 760·4 and 708·5 kJ mol^{-1} for C, Si, Ge and Sn, respectively) but it *increases* as we move from Sn to Pb, the value for Pb being 715· 6 kJ mol^{-1}. The irregularities in ionization energies of elements of Groups 13 and 14 may be attributed to differences in their atomic sizes and electronic configurations, as illustrated below.

The ionisation energy of boron is the highest in the group since its atomic size is the smallest and the shielding effect is the lowest. The sharp decrease from B to Al is due to an appreciable increase in atomic size and the effective shielding of the nuclear charge by the intervening *s* and *p* electrons. In the case of Ga, there are ten *d* electrons in its inner electronic configuration. Since *d* electrons shield the nuclear charge less effectively than the *s* and *p* electrons (Chapter 1), the outer electron is held fairly strongly by the nucleus. As a result, the ionisation energy remains practically the same in spite of an increase in atomic size as we move from Al to Ga. In the case of In, the number of *d* electrons and hence their screening effect remains the same as in Ga. However, since there is an increase in atomic size as we move from Ga to In, there is a noticeable decrease in ionisation energy. The last element, Tl, has fourteen *f* electrons in its inner electronic configuration. Since the shielding effect of *f* electrons is much smaller than that of *d* electrons and also since there is only a marginal increase in atomic size (from 1·44 Å to 1·48 Å) as we move from In to Tl, the outer electron in Tl is held quite firmly and hence there is considerable increase in its ionisation energy.

As for the elements of Group 14, the ionization energy of carbon, the first element, is quite high. This is understandable in view of the small size of the carbon atom. There is a sharp decrease in ionization energy as we move from carbon to the next element silicon. This is due to an appreciable increase in the size of the Si atom. There is, however, a very small decrease in ionization energy as we move from Si to Ge to Sn. This is because the *d* electrons which are now present in the inner configurations of Ge and Sn, shield the nuclear charge less effectively than is done by the *s* and *p* electrons. The outer electrons are, therefore, held strongly by the nucleus and hence, in spite of a sizeable increase in atomic radius, there is only a small decrease in ionization energy as we move from Si to Sn. In the last element, Pb, there are fourteen *f* electrons in its inner configuration which shield the nuclear charge less effectively than even the *d* electrons. Also there is only a marginal increase (of 0·03 Å) in the atomic radius as we move from Sn to Pb. Because of these two factors, the ionization energy of Pb, instead of decreasing, shows a marginal increase.

2. Electron Affinities. Electron affinities of *s* block elements decrease regularly as we move down the groups. *This is, however, not true in the case of p block elements.* There is distinct irregularities in trends as we move down the groups of *p* block elements and also when we move along the periods (Table 10, Chapter 2). These irregularities have already been explained in details in Chapter 2.

Heavier *p* block elements differ from their lighter cogeners also in showing reluctance to exhibit maximum oxidation state, reluctance to involve *p* orbitals for pi bonding but allowing full participation of *d* orbitals in sigma and pi bonding. All these aspects have been discussed below in some details.

3. Reluctance of Heavier *p* Block Elements to Show Maximum Oxidation States. As discussed earlier, the *s* block elements and the lighter *p* block elements show only one oxidation state which is equal to the number of valence *s* electrons in the case of *s* block elements and to the total number of valence *s* and *p* electrons in the case of lighter *p* block elements of Groups 13 and 14. The lighter *p* block elements of Groups 15, 16 and 17 show oxidation states which are equal to 8 minus the sum of *s* and *p* electrons in the valence shells. The situation in the case of heavier *p* block elements of Groups 13, 14 and 15 is, however, different. These elements are reluctant to show the maximum oxidation state. For example, Tl (Group 13) and Bi (Group 15) prefer to exist in their lowest oxidation states of +1 and +3, respectively. Similarly, Sn and Pb (Group 14) are far more stable in their lower oxidation state of +2 instead of +4. It was previously thought that the valence *s* electrons of heavier elements do not take part in bonding, *i.e.*, they remain paired and inert because of greater difficulty in their removal or their excitation **(inner pair effect)**. The heavier elements, therefore, prefer to exist in an oxidation state 2 units lower than their maximum oxidation state.

There is, however, concrete evidence to show that inert pair effect is *not the exact cause* of stabilisation of lower oxidation states in the case of heavier *p* block elements. The following points pertinently support this contention :

1. The oxidation state of Sn in $SnCl_2$ is undoubtedly + 2. But, this molecule has a bent structure with Cl–Sn–Cl angle of about 120° indicating sp^2 hybridisation for Sn. If *s* electrons had been inert and only *p* electrons had taken part in chemical bonding, the Cl–Sn–Cl angle would have been close to 90° and not 120°. This shows clearly that the valence *s* electrons are certainly involved in bonding contrary to the idea of their being inert.

2. The summations of second and third ionisation energies in the case of Group 13 elements and those of third and fourth ionization energies in the case of Group 14 elements are given below :

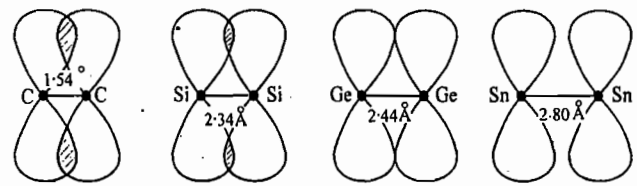
Elements of Group 13	$(IE)_2 + (IE)_3$ (kJ mol^{-1})	Elements of Group 14	$(IE)_3 + (IE)_4$ (kJ mol^{-1})
B ($2s^2 2p^1$)	6090	C ($2s^2 2p^2$)	10820
Al ($3s^2 3p^1$)	4550	Si ($3s^2 3p^2$)	7580
Ga ($4s^2 4p^1$)	4940	Ge ($4s^2 4p^2$)	7710
In ($5s^2 5p^1$)	4520	Sn ($5s^2 5p^2$)	6870
Tl ($6s^2 6p^1$)	4840	Pb ($6s^2 6p^2$)	7160

Evidently, $(IE)_2 + (IE)_3$ is the sum of ionization energies for the removal of both the *s* electrons of Group 13 elements while $(IE)_3 + (IE)_4$ is the summation for the removal of both the *s* electrons of Group 14 elements. According to the data given above, the energy required for the elimination of the pair of valency *s* electrons in heavier elements is *in no way higher* than that required in lighter elements in each group. This implies that the ease with which the *s* electrons can take part in chemical bonding is more or less the *same* in all the elements of a particular group. If at all any element is to show reluctance for bonding, it is the lightest first element in each group and not the heavier elements. This is because the ionization energy summation is the highest in the case of the first element in each group. The ionization energy data thus *negate the contention* that the reluctance of heavier elements to show maximum oxidation states is due to the inert pair effect. A *plausible explanation* for the reluctance of heavier elements to show maximum oxidation state is that the heavier *p* block elements have considerable covalent bond character in their compounds. Since the atomic size of heavier elements is large, a sideways overlap of *p* orbitals is not favoured. These elements, therefore, form only sigma bonds and no pi bonds. This is in contrast to the behaviour of the lighter members of the groups which form both sigma and pi bonds with equal ease. Thus, *fewer valence electrons are involved in bonding in the case of heavier elements. This accounts for the lower oxidation state of these elements.*

4. Reluctance of Heavier *p* Block Elements to Involve *p* Orbitals for pi Bonding. The lighter non-metals, especially of the second period of the *p* block elements, frequently form doubly or triply bonded structures involving *p* orbitals, such as C = C, N ≡ N, O = O, etc. Such structures are very rare

for heavier *p* block elements. For example, while nitrogen exists as N ≡ N, phosphorus exists as P_4 in which all the phosphorus atoms are singly bonded. Similarly, while oxygen exists as O=O, sulphur exists as S_8 in which all the sulphur atoms are singly bonded. Pi bonding through *p* orbitals is quite common in the chemistry of boron but it is not so in the chemistry of aluminium. Thus, while pi bonding through *p* orbitals is quite common in lighter *p* block elements such as B, C, N and O, it is quite rare in heavier *p* block elements although recently some compounds of silicon with Si=Si structure involving $p\pi$–$p\pi$ bonding have been prepared. Because of the reluctance of heavier *p* block elements to form $p\pi$–$p\pi$ bonds, the analogous compounds of lighter and heavier elements in a group tend to have different structures. Thus, while CO_2 has a double bond structure, *viz.*, O=C=O, involving $p\pi$–$p\pi$ bond and is a monomer, SiO_2 is a three-dimensional single-bonded polymer consisting of a large number of Si atoms in which each Si atom is tetrahedrally bonded to four oxygen atoms.

A probable reason for the non-existence or instability of doubly-bonded structures involving $p\pi$–$p\pi$ bonding in heavier elements is that the bigger length of the sigma bond in a heavier element reduces or even excludes the sideways overlapping of *p* orbitals. This is illustrated in Fig. 2 by depicting the effect of the length of C–C, Si–Si, Ge–Ge and Sn–Sn sigma bonds on the sideways overlapping of *p* orbitals of these elements.



Considerable overlapping of orbitals | Very small overlapping of orbitals | No overlapping of orbitals

Fig. 2. Effect of the length of sigma bond on the sideways overlapping of *p* orbitals

A very small overlap implies a very weak $p\pi$–$p\pi$ bond and if no overlap is possible, there is no formation of $p\pi$–$p\pi$ bond at all.

We mentioned above that in SiO_2, each Si atom is attached to four oxygen atoms through sigma bonds. Millikan, however, postulated that all the Si–X bonds (where X stands for O, N, halogens, etc.) have small double bond character as well. This occurs through back bonding involving fully filled $p\pi$ orbitals of X and vacant *d* orbitals of silicon. Thus, each Si–X bond has a partial double bond character. This bond would evidently be stronger than a single sigma bond and more than half as strong as the hypothetical double bond involving $p\pi$–$p\pi$ bonding. A similar situation would exist in compounds of other heavier elements.

5. Participation of *d* Orbitals in Sigma Bonding. The *p* block elements of the second period have only *s* and *p* orbitals whereas the elements of third and higher periods have *d* orbitals also in their valence shells. The elements of the second period, therefore, show a maximum covalency of 4 corresponding to sp^3 hybridisation of their valence shell orbitals. In contrast, the elements of third and higher periods (*e.g.*, Si, P, S, etc.) show a covalency higher than 4 due to the involvement of valence *d* orbitals also in hybridisation. Thus, while the covalency of C in CCl_4, CF_4, etc., involving sp^3 hybridisation is 4, that of Si in $[SiF_6]^{2-}$ involving sp^3d^2 hybridisation is 6. Similarly, while the covalency of N in NF_3 is 3, that of P in PF_5 involving sp^3d hybridisation is 5.

The exhibition of higher covalency by elements in higher periods is fully justified by their atomic sizes. Since the elements in higher periods are bigger in size, they have more space to accommodate substituents around themselves. As a result, a larger number of substituents can be connected with the central element through sigma bonds which implies a higher covalency of the element.

The hydrolysis of tetrahalides of silicon and pentahalides of phosphorus can be explained only on the basis of the involvement of *d* orbitals in sigma bonding. Water acts as a nucleophile in the hydrolytic

reaction. The lone pair of electrons of H_2O is easily accommodated in the vacant *d* orbitals of Si or P thereby facilitating the hydrolysis, Thus,

$$SiCl_4 + 4H_2O \longrightarrow Si(OH)_4 + 4HCl$$

$$PCl_5 + H_2O \xrightarrow{-2HCl} POCl_3 \xrightarrow{+3H_2O} OP(OH)_3 + 3HCl$$

Since carbon has no *d* orbitals, CCl_4 does not undergo hydrolysis at all.

6. Participation of *d* Orbitals in Pi Bonding. a. It is a common experience that trialkyl and triaryl phosphine oxides, *viz.*, (RR′R″)PO, are much more stable than the corresponding amine oxides. The bond dissociation energy of P→O bond is in the range of 500 – 600 kJ mol^{-1} compared to that of N→O bond which is in the range of 200–300 kJ mol^{-1}. This shows that P and O are linked together through more than one bond.

If the bonding between P and O is represented merely as P→O, then, the greater the combined electronegativity (electron attracting power) of (RR′R″), the lesser would be the strength of P→O bond and the greater would be the length of P→O bond. The actual situation is just the reverse, *i.e.*, the greater the combined electronegativity of (RR′R″), the greater is the strength of P→O bond and the shorter is the length of P→O bond. The above facts can be explained only if we assume pi back bonding from fully filled $p\pi$ orbitals of oxygen to vacant $d\pi$ orbitals of phosphorus in phosphine oxide. Accordingly, the structure of the oxide would be as shown in Fig. 3.

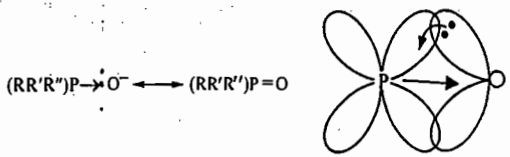


Fig. 3. $p\pi$–$d\pi$ bonding in trialkyl phosphine oxides.

Since nitrogen does not have any *d* orbitals, there would be no $p\pi$–$d\pi$ bonding between N and O in the amine oxides. These compounds would, therefore, have a simple structure, *viz.*, RR′R″N→O. The pi back bonding in phosphine oxides thus readily accounts for their greater dissociation energy and, therefore, greater stability as compared to amine oxides.

It can be easily visualised that the greater the combined electronegativity of (RR′R″), the greater would be the partial positive charge created on P and hence the greater would be the flow of $p\pi$ electronic charge from O to P. This would impart a greater double bond character to the bond between P and O resulting in the shortening of the PO bond and thereby increasing the stability of the phosphine oxide.

b. The electronegativity difference between P and O is more than that in N and O. On the basis of this difference *alone* (*i.e.*, in the absence of any pi back bonding), amine oxides should have been less polar than the corresponding phosphine oxides. But, actually the situation is just the reverse. Phosphine oxides are less polar than the analogous amine oxides. For instance, the dipole moment of $(CH_3)_3PO$ is 4·4 debye whereas the dipole moment of $(CH_3)_3NO$ is 5·0 debye. The pi back bonding, *i.e.*, $p\pi - d\pi$ bonding in the PO bond shifts back some of the charge to P and thus decreases the dipole moment of phosphine oxide. The PO bond should thus be represented as P⇐O and not merely as P→O (the NO bond would be represented merely as N→O). The dipole moment is the product of the amount of charges separated and the distance between the separated charges. On account of $p\pi$–$d\pi$ back bonding, the distance between P and O and also the separated charges on P and O, decrease. As a result there is a decrease in the dipole moment of phosphine oxide.

c. Trimethyl amine, $(CH_3)_3N$, is known to have a distorted tetrahedral structure with C–N–C angle of 107·9° whereas $(SiH_3)_3N$ is a planar molecule with Si–N–Si angle of 120°. Such a large difference in bond angles can be explained only on the basis of pi back bonding between N and Si. The N atom

in $(CH_3)_3N$ molecule involves sp^3 hybridisation of valence shell orbitals of N whereas in $(SiH_3)_3N$ molecule, it involves sp^2 hybridisation. In the latter molecule, the third *p* orbital of N containing a lone pair of electrons is of proper symmetry to overlap with the vacant *d* orbital of Si to form a $p\pi$–$d\pi$ bond. Thus, while in $(CH_3)_3N$ molecule, there are only sigma bonds between N and C atoms, in case of $(SiH_3)_3N$ molecule, there is a sigma and a $p\pi$–$d\pi$ bond between Si and N atoms. The structure of this molecule may thus be represented as shown in Fig. 4.

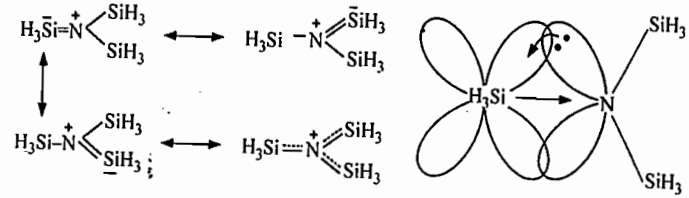

Fig. 4. The structure of trisilylamine molecule.

As discussed earlier, the electropositive character increases and electronegative character decreases as we move down a group. Hence, Si should be more electropositive than carbon. Accordingly, because of the inductive effect, $(SiH_3)_3N$ should be more basic than $(CH_3)_3N$. But, actually it is just the reverse. This can be explained on the basis of $p\pi$–$d\pi$ bonding between N and Si. Since in $p\pi - d\pi$ bonding, N donates its electronic charge to the vacant *d* orbitals of Si, the tendency of N atom in $(SiH_3)_3N$ molecule to lose electrons to an acid solvent becomes less, implying thereby that $(SiH_3)_3N$ is less basic than $(CH_3)_3N$..

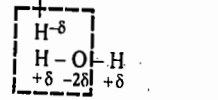
7. Electronegativities. As can be seen from Table 11, Chapter 2, electronegativities of *s* block elements decrease **regularly** as we go down a group. Electronegativities of *p* block elements, however, show **irregular trends.** This is particularly so in the case of elements of Groups 13 and 14. These irregular values, however, are fully supported by the chemical behaviour of some typical compounds of these elements. This is illustrated below.

(*i*) The energy of Ge–X bond is found to be smaller than that of Si–X bond where X stands for a halogen. Because of this, it is more difficult to dissociate a Si–X bond compared to a Ge–X bond. This is evidenced by the fact that while the Ge–X undergoes reduction with Zn and HCl to give Ge–H (Ge – + 2H ⟶ Ge–H + HX), Si–X does not. The Si–X bond would be stronger if it is more polar than Ge–X bond so that the former has higher ionic–covalent resonance energy than the latter and this, in turn, would be possible only if the electronegativity difference between Si and X is more than that between Ge and X or if Si has lower electronegativity than Ge, as is actually the case.

(*ii*) Silane (SiH_4) readily undergoes hydrolysis in the presence of catalytic amounts of OH^- ions whereas germane and stannane do not do so even in the presence of large amounts of OH^- ions. This can be explained only on the assumption that electronegativities of Ge and Sn are higher than that of Si as is actually the case. Since the electronegativities of Ge and Sn are closer to that of H (2·1), the bonds Ge–H and Sn–H would be almost non-polar. But there is considerable electronegativity difference between Si and H so that Si–H bond is *polar* with partial positive charge on Si. It is because of this partial positive charge on Si that silane undergoes hydrolysis readily in the presence of OH^- ions in the following manner :

$$SiH_4 + 2OH^- \longrightarrow [SiH_4(OH)_2]^{2-}$$

$$[H_3\overset{+\delta}{Si}(OH)_2]^{2-} \longrightarrow [H_3Si(OH)_3]^{2-} + H_2$$



$$[H_3Si(OH)_3]^{2-} \xrightarrow{3H_2O} Si(OH)_4 + 2OH^- + 3H_2$$

Further hydrolysis

(Ultimate product)

Since Ge – H and Sn – H bonds are non-polar because of small electronegativity difference between H and the metal, germane, GeH_4 and stannane, SnH_4 do not undergo hydrolysis.

However, R.S. Drago maintains that electronegativity of each of Si, Ge, Sn and Pb is the same, *i.e.*, ~1·8, the conventionally accepted value for Sn and Pb (Table 11, Chapter 2). Therefore, all the four elements should exhibit similar chemical behaviour. But, actually, it is not so. He explained the difference in the chemical behaviour of Si on the basis of its *d* orbital participation in both sigma and pi bonding. According to Drago, the 3*d* orbitals of Si are energetically better suited for bonding than 4*d*, 5*d* and 6*d* orbitals of Ge, Sn and Pb. As a result, the chemistry of Si shows dissimilarities with the chemistry of Ge, Sn and Pb having *d* orbitals with unfavourable energies for participation in bonding.

QUESTIONS

1. What are the main group elements ? Discuss briefly their general characteristics.
2. Explain what is meant by polarising power of a cation and polarizability of an anion. State and explain Fajan rules for estimating the extent to which a cation can polarise an anion.
3. Explain the term polarisation of an anion. Illustrate how the concept of polarisation can account for the diagonal relationship in the main group elements.
4. Illustrate the effect of polarisation on the following :
   (*i*) Melting points of halides of main group elements.
   (*ii*) Solubilities of halides of silver.
   (*iii*) Decomposition of metal carbonates.
5. Discuss the variation of the following properties as we move (*a*) down a group (*b*) along a period amongst the main group elements :
   (*i*) Oxidising and reducing properties.
   (*ii*) Redox potentials. Electropositive character.
   (*iii*) Oxidation states.
6. What is meant by diagonal relationship ? How would you account for this relationship amongst the metallic and non-metallic elements of *s* and *p* block elements ?
7. (*a*) What is meant by oxidation and reduction ? "The oxidising character of elements increases and reducing character decreases as we move from left to right in a period." How would you explain this behaviour ?
   (*b*) "The oxidising character decreases and reducing character increases as we move down a group." How would you explain this trend ?
8. (*a*) How would you account for the diagonal relationship in elements arranged in the periodic table ?
   (*b*) Discuss the variation of oxidation states of elements as we move from left to right in a period.
9. What do you understand by the term redox potential ? How does this quantity change as we move across a period from left to right and down a group and why ?
10. Discuss the trend in the following aspects of the chemistry of *p* block elements in a group and in a period :
    (*a*) Acidic and basic character of oxides.
    (*b*) Ionic and covalent character of halides.
    (*c*) Oxidising and reducing properties of elements.
11. What are acidic, basic and amphoteric oxides ? Discuss the type of bonding which occurs in the various oxides. On what factors does the stability of oxides depend ?
12. "There are some distinctive features not only between *s* and *p* block elements but also between lighter and heavier *p* block elements." How would you justify this statement ?
13. While the ionization energies of *s* block elements decrease regularly as we move down a group, it is not the case in *p* block elements. Why is it so ?
14. Ionization energies in kJ mol^{-1} of elements of Group 13 and Group 14 are as follows :

B	Al	Ga	In	Tl	C	Si	Ge	Sn	Pb
800	577	579	558	589	1086	786	760	708	716

How would you account for these irregular values ?

15. The heavier *p* block elements are reluctant to show maximum oxidation states. How would you account for it ? Explain clearly that this reluctance is not because of inert pair effect.
16. The heavier *p* block elements are reluctant to involve *p* orbitals for pi bonding. Why is it so ?
17. There is a distinct participation of *d* orbitals in sigma bonding in heavier *p* block elements. Illustrate this statement.
18. How would you account for the following :
    (*i*) The elements of the second period can show a maximum covalency of 4 while elements of the third and higher periods can show a maximum covalency higher than 4.
    (*ii*) CCl_4 does not undergo hydrolysis whereas $SiCl_4$ and PCl_5 are easily hydrolysed.
    (*iii*) CO_2 is a monomer while SiO_2 is a three-dimensional giant molecule.
19. There is distinct participation of *d* orbitals in pi bonding in heavier *p* block elements. Illustrate this statement.
20. How would you account for the following :
    (*i*) The dissociation energy of PO bond in (RR′R″)PO is in the range of 500 – 600 kJ mol^{-1} while that of (RR′R″)NO is in the range af 200 – 300 kJ mol^{-1}. (R in an alkyl or aryl radical).
    (*ii*) The dipole moment of $(CH_3)_3PO$ is less than that of $(CH_3)_3NO$.
    (*iii*) $(CH_3)_3N$ has C – N – C bond angle of 107·9° while $(SiH_3)_3N$ has Si – N – Si bond angle of 120°.
    (*iv*) $(CH_3)_3N$ is more basic than $(SiH_3)_3N$?
21. Electronegativities of elements of Group 14 are as follows :

C	Si	Ge	Sn	Pb
2·5	1·9	2·0	1·8	1·8

Show that these irregular values are fully supported by (*i*) the reduction of the halides of these elements (*ii*) hydrolysis of the hydrides of these elements.

22. How would you account for the following :
    (*i*) Ge–X is easily reduced by Sn–HCl to give Ge–H whereas Si–X is not.
    (*ii*) SiH_4 readily undergoes hydrolysis in the presence of catalytic amounts of OH^- ions whereas GeH_4 and SnH_4 are not hydrolysed even in the presence of large amounts of OH^- ions.

13 THE ELEMENTS OF GROUP 1

The *s* Block Elements. The elements of Groups 1 and 2 of the periodic table constitute the ***s* block elements.** The electronic configurations of these elements are given in Table 1.

TABLE 1

Electronic Configurations of *s* Block Elements

Group 1 (Alkali Metals)			Group 2 (Alkaline Earth Metals)		
Element	Atomic number	Electronic configuration	Element	Atomic number	Electronic configuration
Lithium, Li	3	[He] $2s^1$	Beryllium, Be	4	[He] $2s^2$
Sodium, Na	11	[Ne] $3s^1$	Magnesium, Mg	12	[Ne] $3s^2$
Potassium, K	19	[Ar] $4s^1$	Calcium, Ca	20	[Ar] $4s^2$
Rubidium, Rb	37	[Kr] $5s^1$	Strontium, Sr	38	[Kr] $5s^2$
Cesium, Cs	55	[Xe] $6s^1$	Barium, Ba	56	[Xe] $6s^2$
Francium, Fr	87	[Rn] $7s^1$	Radium, Ra	88	[Rn] $7s^2$

It is evident from Table 1 that while the outer electronic configuration of Group 1 elements is ns^1, that of Group 2 elements is ns^2.

The elements constituting **Group 1** are reactive metals and form *strongly alkaline* oxides and hydroxides. Therefore, they are called **alkali metals.** The last element, francium, is radioactive.

The elements belonging to **Group 2** are also metals and are commonly known as **alkaline earth metals.** The oxides of some of these metals were known much earlier than the metals themselves and they were called *alkaline earths* since they were alkaline and existed in the earth. Later, when these elements were discovered, they began to be called **alkaline earth metals.** The last member of the group, radium, being a radioactive element, is studied separately alongwith other radioactive elements.

THE ELEMENTS OF GROUP 1

The elements, **lithium, sodium, potassium, rubidium, cesium** and **francium,** constitute Group 1 of the periodic table. They are highly reactive and readily decompose water even at room temperature yielding metal hydroxides which are strong alkalies. These elements are, therefore, known as **alkali metals,** as stated above.

GENERAL CHARACTERISTICS

The general characteristics of alkali metals have already been discussed while describing the properties of main group elements, in Chapter 12. However, a brief discussion has been made in this chapter also.

Physical Properties

All the elements of Group 1 are silvery-white, soft and light metals. Some of their important physical constants are summed up in Table 2.

TABLE 2

Physical Properties of Alkali Metals

Property	Lithium	Sodium	Potassium	Rubidium	Cesium
Atomic number	3	11	19	37	55
Molar mass (g mol^{-1})	6·94	22·99	39·10	85·48	132·91
Density at 20°C (g cm^{-3})	0·634	0·972	0·859	1·530	1·903
Molar volume (cm^3 mol^{-1})	12·97	23·68	45·36	55·80	69·95
Melting point (°C)	180·0	97·8	64·0	38·9	28·5
Boiling point (°C)	1326	883	756	688	670
Atomic radius (Å)	1·34	1·54	1·96	2·11	2·25
Ionic radius (Å) M^+ ion	0·60	0·98	1·33	1·48	1·67
Heat of atomisation (kJ mol^{-1})	159·0	108·1	90·2	82·1	78·2
Ionization energy (kJ mol^{-1})	520·1	495·2	418·7	403·0	375·7
Electronegativity (Pauling's values)	1·0	0·9	0·8	0·8	0·7
Flame coloration	Crimson red	Golden yellow	Violet	Violet	Violet

1. Density. Density of a metallic element depends upon the type of packing of atoms in the metallic phase as also on their size. Group 1 elements have close packing of metal atoms in their lattices and because of the comparatively large size of these atoms, they have low densities. As can be seen from Table 2, density gradually *increases* in moving down from lithium towards cesium. Potassium, however, is lighter than sodium. Lithium, sodium and potassium are even lighter than water. The reason is that these metals have much larger molar volumes and hence much larger atomic radii than most other metals.

2. Molar Volumes. The ratio of molar mass (g mol^{-1}) and density (g cm^{-3}) is known as the molar volume (cm^3 mol^{-1}) of the element. Molar volume is seen to *increase* in moving down the group from Li to Cs. This is to be expected in view of increase in atomic radius in the same order, as shown in Table 2.

3. Melting Points. All the alkali metals are soft and have low melting points. This is due to the fact that they have only one valency electron per metal atom. Hence the energy binding the atoms in the crystal lattice of the metal is relatively low. The melting points invariably decrease in moving down from lithium towards cesium. Lithium, the first element, melts at 180·0 °C while cesium, the last element, melts at 28·5°C. Thus, the melting point decreases with increase in the size of the atom of the element.

4. Boiling Points. The boiling points also *decrease* in the same order as the melting points. The boiling point of lithium is 1326°C while that of cesium is 670°C.

5. Atomic and Ionic Radii. Atomic and ionic radii *increase* on moving down the group from lithium to cesium, as shown in Table 2. This is on account of the presence of an extra shell of electrons as we move down from one element to the other within the group.

An alkali metal changes into a positive ion by the loss of the solitary *s* electron of the outer shell. This leads to the elimination of the outer shell itself. At the same time, the charge on the nucleus becomes greater than the number of electrons and, therefore, the electrons are attracted all the more

strongly towards the nucleus. As a result of both these effects, a positive ion is smaller than the corresponding atom. Ionic radii of all the alkali metals are thus smaller than the corresponding atomic radii.

The electronic configurations of the alkali metal ions would evidently be similar to those of the noble gases, *viz.*, s^2 (for Li^+) or s^2p^6 (for Na^+, K^+, Rb^+, Cs^+). Since they have no unpaired electrons, these ions are *diamagnetic* and *colourless*.

6. Heat of Atomisation. *Heat* of atomization measures the strength of metal–metal bond in the lattice of an element. Heat of atomisation is maximum in the case of lithium and is much lower in the case of the next element which is sodium. The fall in the case of the subsequent elements is relatively small. Thus, metal–metal bond strength is maximum in the case of lithium.

7. Ionisation Energies. The solitary *s* electron in the outer shell of these elements can be taken out relatively easily. Consequently, the ionisation energies of these elements are relatively low. Further, as the atomic radius increases on moving down the group, the outer electron gets farther and farther away from the nucleus and, therefore, *ionisation energy decreases on moving down from lithium towards cesium.*

8. Electropositive Character. On account of their low ionisation energies, these metals have great tendency to lose their outermost electron and thus change into positive ions :

$$M \longrightarrow M^+ + e^-$$

These elements are, therefore, said to have strong *electropositive* character. Since ionisation energy decreases on moving down the group, *the electropositive character increases on moving down the group from lithium towards cesium.*

These elements are so highly electropositive that they emit electrons even when exposed to light (**photoelectric effect**). This property is responsible for their use in photoelectric cells. Cesium and potassium are used, in particular, for this purpose.

9. Formation of Univalent Positive Ions. As already mentioned, on account of relatively low ionisation energies, these elements have a strong tendency to change into M^+ ions. Hence, they form mostly ionic compounds. The chemistry of these elements, therefore, is the chemistry of M^+ ions (Li^+, Na^+, etc.). Since the ions have the stable noble gas configuration, *viz.*, ns^2 or ns^2p^6, in the valency shell, the energy required to pull out another electron from the valency shell is very high. Therefore, the second ionisation energies of alkali metals are very high. Under ordinary circumstances, therefore, there is no possibility for the formation of M^{2+} ions in any of their compounds. The alkali metals are thus *univalent* and form *ionic compounds.*

However, in certain cases, they do form covalently bonded diatomic molecules like Li_2 (Li:Li), Na_2 (Na:Na) and Cs_2 (Cs:Cs). Li also forms covalently bonded organometallic compounds due to its high polarizing power.

10. Hydration of Ions. The alkali metal ions are *extensively hydrated.* The smaller the size of the ion, the greater is the degree of hydration. Thus, Li^+ ion, which is smallest in size and has the highest charge/size ratio amongst the alkali metal ions, gets much more hydrated (*i.e.*, holds more water molecules in its hydration sphere) than Na^+ ion and the latter gets more hydrated than K^+ ion and so on. The degree of hydration decreases on moving down the group from Li^+ to Cs^+. As a result of the difference in degree of hydration, ionic radii of hydrated alkali metal ions *decrease* from Li^+ to Cs^+, *i.e.*, Li^+ ion, which should have been smallest, is actually largest in size in aqueous solutions. Thus, the ionic radii in aqueous solutions decrease in the order :

$$Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$$

It is for this reason that Li^+ ion has the lowest and Cs^+ ion has the highest mobility in an electric field.

11. Oxidation States. All the alkali metals exhibit an oxidation state of +1. This is because these metals can lose their solitary outermost electron easily. The second ionisation energy is so high that the second electron is very rarely lost.

12. Electronegativities. Since these metals are highly electropositive, their electronegativities, *i.e.*, their tendencies to attract electrons, are very low. Further, since electropositive character increases on moving down the group, *the electronegativity decreases in the same order.* When these elements react with other elements having high electronegativities (*e.g.*, the halogens), the compounds formed are ionic in character.

13. Reducing Properties, Oxidation Potentials. As is well known, **oxidation** *is a process in which electrons are lost* and **reduction** *is a process in which electrons are gained.* An *oxidising agent,* therefore, is a substance which can *accept* electrons while a *reducing agent* is a substance which can *lose* electrons. Consider the formation of sodium chloride by burning of sodium in chlorine. Sodium, on account of its low ionisation energy, can *lose* an electron readily while chlorine, on account of its high electron affinity, can *accept* it readily.

$$\begin{aligned}
Na\,(s) &\xrightarrow{heat} Na\,(g) \\
Na\,(g) &\longrightarrow Na^+(g) + e^- \\
1/2\,Cl_2\,(g) + e^- &\longrightarrow Cl^-(g) \\
Na^+(g) + Cl^-(g) &\longrightarrow Na^+Cl^-(s) \\
\hline
Na\,(g) + 1/2\,Cl_2\,(g) &\longrightarrow Na^+Cl^-(s)
\end{aligned}$$

Thus, sodium is a reducing agent while chlorine is an oxidising agent. Evidently, an element which is a *reducing agent* must have *low ionisation energy* while an element which is an *oxidising agent* must have *high electron affinity.* Since ionisation energy decreases on moving down from lithium to cesium, the reducing properties increase in the same order.

The tendency of an element to lose an electron *in solution* is measured by the standard oxidation potential of the element. The standard oxidation potentials of the alkali metals are given in Table 3.

TABLE 3
Standard Oxidation Potentials of Alkali Metals

Element	Oxidation Reaction	Standard Oxidation Potential (volts)
Lithium	$Li \longrightarrow Li^+ + e^-$	3·04
Sodium	$Na \longrightarrow Na^+ + e^-$	2·71
Potassium	$K \longrightarrow K^+ + e^-$	2·92
Rubidium	$Rb \longrightarrow Rb^+ + e^-$	2·99
Cesium	$Cs \longrightarrow Cs^+ + e^-$	3·02

These high values indicate that alkali metals have a strong tendency to lose electrons and thus act as strong reducing agents and that lithium is the strongest of them all. However, if we look at the ionisation energies of these elements (Table 2), it is seen that lithium has the highest value indicating that it holds its electron most tightly. This, at first sight, seems to be contrary to the maximum value of oxidation potential of lithium which indicates that lithium gives off its electron most readily. This anomaly can be explained if we recall that ionisation energy is the property of *isolated atom in the gaseous state* while oxidation potential concerns itself with *the metal as it goes into solution in the form of its ions.*

Thus, ionisation energy involves only the following change :

$$M(g) \longrightarrow M^+(g) + e^-$$

Oxidation potential, on the other hand, involves the process

$$M(s) \longrightarrow M^+(aq) + e^-$$

which is considered to take place in three consecutive steps given below :

$$M(s) \longrightarrow M(g)$$

$$M(g) \longrightarrow M^+(g) + e^-$$
$$M^+(g) + H_2O \longrightarrow M^+(aq)$$

In the first step, the metal (solid) is evaporated to the gaseous state in which the atoms get isolated from one another and become independent of one another. The energy required in this process is known as **sublimation energy** which is quite low and about the same for all the alkali metals. In the second step, the outer electron is pulled off from an isolated gaseous atom. The energy required for this change is the **ionisation energy** which, as mentioned above, is the highest for lithium. In the third step, the gaseous ion gets hydrated. In this process, energy, known as **hydration energy**, gets *liberated*. The oxidation potential which gives the tendency for the overall change to occur, naturally depends on the *net effect of all the three steps*. Lithium ion is hydrated to the maximum extent because of its highest charge/size ratio and, therefore, the energy *liberated* in the third step is maximum in the case of Li^+ ion. *The hydration energy of lithium ion (released in step 3) is so large that it more than compensates the sublimation energy (step 1) and the energy required to knock off the electron (step 2).* This explains the highest oxidation potential of lithium, *i.e.*, the greatest ease with which the overall change, $Li(s) \longrightarrow Li^+(aq) + e^-$ takes place. In other words, the greatest strength of lithium as a reducing agent lies in its greatest hydration energy.

14. Characteristic Flame Colouration. All the alkali metals give *characteristic colours* in bunsen flame. The reason is that when an alkali metal or any of its compounds is heated in a bunsen flame, the electrons get excited to higher energy levels. When these electrons return to their original (ground) level, the *excitation energy* which had been absorbed by them, is *released* in the form of light in the visible region of the spectrum. Now for the same excitation energy, the energy level to which the electron in Li rises is lower than that to which the electron in Na rises and this, in turn, is lower than the level to which the electron in K rises and so on. These differences are on account of differences in the forces of attraction between the nucleus and the outermost electron. Consequently, when the electron returns to the ground state, energy released is lowest in Li and increases in the order Li $\longrightarrow$ Cs. As a result of this, the frequency of the light emitted when the compound is placed in the bunsen flame will be minimum in the case of lithium. It increases in the order Li $\longrightarrow$ Cs. Thus, the colour of the flame is crimson red in the case of Li, golden yellow in the case of Na, violet in the case of K and almost the same in the case of Rb and Cs.

15. Lattice Energies. Salts of alkali metals consist of cations and anions only and are, therefore, called *ionic solids*. The **lattice energy of an ionic solid** is defined as *the energy released when cations and anions in gaseous state are brought from infinity to their respective crystal sites to form one mole of the ionic crystal*. Thus, we have

$$Li^+(g) + Cl^-(g) \longrightarrow Li^+Cl^-(s); \qquad \Delta H = \text{Lattice energy of } Li^+Cl^-$$
$$Cs^+(g) + Cl^-(g) \longrightarrow Cs^+Cl^-(s); \qquad \Delta H = \text{Lattice energy of } Cs^+Cl^-$$

Lattice energies of ionic solids are quite high. This is to be expected in view of *strong* electrostatic attraction between oppositely charged ions. When such ions come close together, the system acquires *minimum energy* and, therefore, a large amount of energy is released to the surroundings. Since coulombic forces of attraction vary directly as the product of the charges, it follows that the higher the charge on the ions (*i.e.*, the higher the valency of the ions), the greater should be the lattice energy of the ionic solid. Thus, lattice energy increases as we move from uni-univalent ionic solids like lithium flouride (Li^+F^-) to uni-bivalent solids like calcium fluoride ($Ca^{2+}2F^-$) and to bi-bivalent solids like magnesium sulphide ($Mg^{2+}S^{2-}$).

For cations of the same valency, lattice energy of ionic solids having the same anion, *decreases with increase in the size of the cation*. Thus, lattice energy of Li^+F^- is 1034 kJ mol^{-1} while that of Cs^+F^- is 743·9 kJ mol^{-1}. Similarly, *lattice energy of Li^+I^- is 718·4 kJ mol^{-1} while that of Cs^+I^- is* 584·5 kJ mol^{-1}. Since the fluoride ion in the first case and the iodide ion in the second case is common,

the higher values for lithium salts are due to the smaller size of Li^+ ion as compared to that of Cs^+ ion (Table 2) in the respective ionic solids. We may thus conclude that, as a general rule, lattice energies of salts of alkali metals having a given anion decrease with increase in atomic number of the alkali metal.

Chemical Properties

The alkali metals exhibit high chemical reactivity which is due to their low ionisation energies and relatively low heats of atomisation. The important chemical properties and their trends are discussed below.

1. Relative Reactivity. The reactivity of alkali metals goes on increasing in the following order :

$$Li < Na < K < Rb < Cs$$

2. Action of Air. All the alkali metals tarnish rapidly on exposure to air due to the formation of oxides at the surface. The oxides may further react with moisture and atmospheric CO_2 to form a layer of carbonates at the surface of alkali metals. They are, therefore, always kept under kerosene or paraffin oil to protect them from the action of air.

They burn vigorously in air or oxygen forming oxides. Lithium forms the monoxide, Li_2O; sodium forms a mixture of the monoxide Na_2O and the peroxide, Na_2O_2 and the rest of the elements form superoxides, MO_2.

3. Action of Water. The alkali metals react readily with water forming hydroxides and evolving hydrogen. For example,

$$2Li(s) + H_2O \longrightarrow 2LiOH + H_2$$

The reactivity with water increases on descending the group from lithium to cesium. This is because the electropositive character increases in this order. With potassium, rubidium and cesium, the reaction is so vigorous that the evolved hydrogen catches fire spontaneously.

These metals also react with alcohol giving oxides and evolving hydrogen. For example,

$$2Li + 2C_2H_5OH \longrightarrow 2C_2H_5OLi + H_2$$

The reactivity towards alcohol also increases on moving down the group.

4. Action of Acids. All alkali metals react with acids to produce hydrogen.

$$2M + 2HX \longrightarrow 2MX + H_2$$

5. Action with Hydrogen. The alkali metals react with hydrogen forming hydrides which are ionic in character and in which hydrogen is present as an anion. The hydrides are, therefore, represented as M^+H^-, where M is an alkali metal. The ease with which the alkali metals form hydrides decreases in moving down from lithium towards cesium.

6. Action with Halogens and Sulphur. The alkali metals combine readily with halogens and sulphur forming the halides and sulphides . These are ionic compounds.

7. Action with N_2. Only Li, out of all alkali metals, reacts with N_2 to produce Li_3N.

8. Reactions with NH_3 (gaseous). When ammonia gas is passed over alkali metals, the corresponding amides are formed.

$$2M + 2NH_3 \longrightarrow 2MNH_2 + H_2$$

The alkali amides are also formed when the solutions of alkali metals in liquid NH_3 are evaporated.

9. Solubility in Mercury. The alkali metals dissolve readily in mercury forming what are called **amalgams**. The process is highly *exothermic*.

10. Solubility in Liquid Ammonia. All the alkali metals dissolve in anhydrous liquid ammonia giving deep blue solutions. The colour deepens with increase in concentration of the solution. The concentrated solutions are bronze in colour and possess *metallic lustre*. The solutions are *good conductors*

of electricity and are *paramagnetic* in nature. The paramagnetic character decreases with increase in concentration.

The dissolution of the metal is accompanied by its ionisation :

$$M \longrightarrow M^+ + e^-$$

When the alkali metals are dissolved in liquid ammonia, the ammonia molecules solvate the cation as well as the electron, as represented below.

$$M + NH_3 \text{ (in excess)} \longrightarrow M^+(NH_3)_x + e^-(NH_3)_y$$

The values of x and y depend upon the extent of solvation of the alkali metal ion and the electron, respectively. The exact mechanism for the solvation of electrons is not clear. It is argued, however, that the electron released by the alkali metal causes polarisation of the charge of the electrons of the surrounding ammonia molecules and the repulsion between the electron released by alkali metal and the electrons of the surrounding ammonia molecules causes a 'hole' in which the released electron is trapped. It is the *ammoniated electron which is responsible for the blue colour of the solution.* The electrical conductivity is due to the ammoniated cation as well as the ammoniated electron. The dilute solutions are *paramagnetic* because they contain free electrons. The decrease in paramagnetic character with increase in concentration suggests that in concentrated solutions the ammoniated electrons associate to form electron pairs :

$$2e^-(NH_3)_y \longrightarrow [e^-(NH_3)_y]_2$$

The alkali metal solutions in liquid ammonia are stable and decompose only slowly liberating hydrogen. The presence of transition metals (such as Fe, Pt, Zn, etc.) even in traces, catalyses the reaction.

Due to the presence of the free or ammoniated electrons, these solutions behave as **strong reducing agents** as is evident from the following reactions :

These solutions reduce aerial oxygen to superoxide and peroxide ions without causing cleavage of O – O bond.

$$O_2 \xrightarrow{e^-(NH_3)_y} O_2^- \xrightarrow{e^-(NH_3)_y} O_2^{2-}$$

These solutions reduce metal ions to their unusually low oxidation states.

$$K_2[Ni(CN)_4] + 2K \xrightarrow{e^-(NH_3)_y} K_4[Ni(CN)_4] \quad \text{(Ni is in 0 oxidation state)}$$

$$Mn_2(CO)_{10} + 2K \xrightarrow{e^-(NH_3)_y} 2K[Mn(CO)_5] \quad \text{(Mn is in –1 oxidation state)}$$

$$Fe(CO)_5 + 2Na \xrightarrow{e^-(NH_3)_y} Na_2[Fe(CO)_4] + CO \quad \text{(Fe is in –2 oxidation state)}$$

The alkali metal solutions in liquid ammonia can reduce protonic species like acetylenes to liberate H_2.

$$RC \equiv CH \xrightarrow[Na]{e^-(NH_3)_y} RC \equiv C^-Na^+ + 1/2\ H_2$$

In some of the reactions in liquid ammonia solutions, a reducing species may absorb more than one electron. For example,

$$S_8 + 2e^-(NH_3)_y \longrightarrow S_8^{2-} + 2yNH_3$$

$$Ge_2H_6 + 2e^-(NH_3)_y \longrightarrow 2GeH_3^- + 2yNH_3$$

Sometimes, a specie after getting reduced reacts further with liquid ammonia solvent as follows :

$$(i) \quad N_2O + 2e^-(NH_3)_y \longrightarrow (N_2 + O^{2-}) + 2yNH_3$$

$$(N_2 + O^{2-}) + 2y(NH_3) \longrightarrow N_2 + OH^- + NH_2^- + (2y-1)NH_3$$

$$(ii) \quad C_2H_5Br + 2e^-(NH_3)_y \longrightarrow (Br^- + C_2H_5^-) + 2yNH_3$$

$$(Br^- + C_2H_5^-) + 2y(NH_3) \longrightarrow Br^- + C_2H_6 + NH_2^- + (2y-1)NH_3$$

The alkali metals are also soluble in a number of aliphatic amines, ethylene glycol, dimethyl ether, etc. These solutions are also coloured and have strong reducing properties similar to the liquid ammonia solutions of alkali metals.

11. Ionic Conductance. The alkali metal ions in aqueous solution have high electrical conductance. The electrical conductance of Li^+ ion, which is the smallest of alkali metal ions, is expected to be the highest. Since ionic size increases on moving from Li to Cs, the ionic conductance is expected to decrease in the order :

$$Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$$

However, we find by experiment that ionic conductance of Cs^+ is the highest and that of Li^+ is the lowest. Thus, ionic conductance actually decreases in the order :

$$Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$$

This is evidently the *reverse* of what we expect. This anomaly arises from the fact that *alkali metal ions are hydrated to different extents.* The Li^+ ion is hydrated to the maximum extent due to its high charge/size ratio compared to other alkali metal ions. The extent of hydration *decreases* on moving from Li^+ to Cs^+. Thus, Cs^+ ion is the least hydrated. As a result of the variation in the extent of hydration, Li^+ ion due to heavy hydration is the biggest while Cs^+ ion due to much smaller hydration is the smallest. Thus, the ionic size in aqueous solutions, instead of increasing, *actually decreases* on moving from Li^+ to Cs^+ as a result of which the ionic mobility *increases* as we move from Li^+ to Cs^+. Hence, *the ionic conductance,* instead of decreasing, *actually increases on moving from* Li^+ *to* Cs^+.

The ionic radii, radii of hydrated ions and ionic conductances of different alkali metal ions at infinite dilution are given in Table 4.

TABLE 4

Ionic Radii, Radii of Hydrated Ions and Ionic Conductances of Alkali Metal Ions

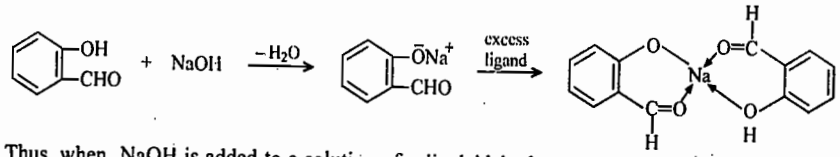
Property	Li^+	Na^+	K^+	Rb^+	Cs^+
Ionic radii (Å)	0·60	0·98	1·33	1·48	1·67
Radii of hydrated ions (Å)	3·40	2·76	2·32	2·28	2·28
Ionic conductance at infinite dilution ($ohm^{-1}\ cm^2\ mol^{-1}$)	33·5	43·5	64·6	67·5	68·0

Complexes of Alkali Metals

Alkali metal ions with the exception of Li^+ have very little polarising power due their large size and only a unit positive charge. As a result, they have only a weak tendency to form complexes with unidentate ligands. The common unidentate ligands with which the alkali metal ions form somewhat stable complexes are H_2O, NH_3, Ph_3PO, CH_3CONH_2, dioxane and C_5H_5N(py). Thus, there is concrete evidence for the existence of $[M(H_2O)_4]^+$ (where M is Li^+, Na^+ and K^+) and $[M'(H_2O)_6]^+$ (where M' is Rb^+ and Cs^+, in aqueous solutions. Also, lithium iodide reacts with liquid ammonia to produce $[Li(NH_3)_4]^+$. Similarly, lithium iodide, nitrate and perchlorate react with Ph_3PO to yield complex cation $[Li(Ph_3PO)_4]^+$. The complexes $[LiCl(H_2O)(py)_2]$ and $[LiCl(C_4H_8O_2)]_n$ are also reasonably stable. The complex

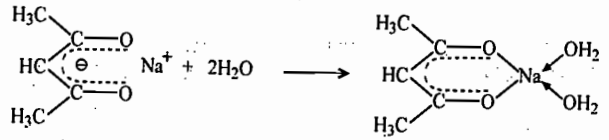
$[LiCl(C_4H_8O_2)]_n$ is polymeric containing Cl and dioxane bridges in which each Cl and each dioxane is coordinated to two lithium atoms. All the complexes mentioned above contain four-coordinated tetrahedral lithium ion. However, polymeric complex $[NaBr(CH_3CONH_2)_2]_n$ (obtained by heating NaBr with acetamide) has each sodium atom surrounded by two bromine atoms (which are trans to each other) and four planar oxygen atoms of acetamide molecule. The polymeric character of the complex is due to the presence of oxygen and bromine bridges in the structure so that the aggregate formula of the complex is as mentioned above.

However, alkali metal ions form reasonably stable complexes with some of the bidentate and polydentate ligands such as salicylaldehyde, β-diketones, nitro phenols, α-nitroso β-naphthol, etc.

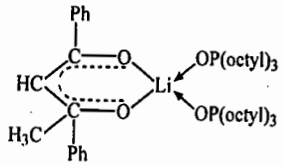


Thus, when NaOH is added to a solution of salicylaldehyde, a neutral complex is formed which is soluble in organic solvents.

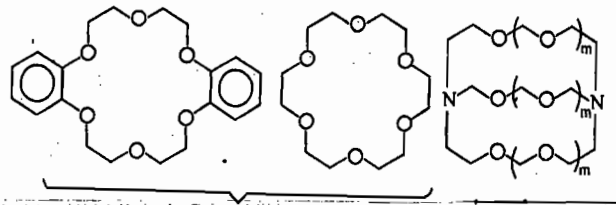
Similarly, the anhydrous sodium derivative of acetylacetone takes up water to produce a hydrated complex which is also soluble in organic solvents.



Quite often it may happen that a particular ligand is better suited to form complex with a particular metal ion. This fact is made use of for the separation of a particular alkali metal ion from others. For instance, the lithium-complex shown is more stable than similar complexes formed by other alkali metals. It is soluble in paraxylene. Through the formation of the above complex, therefore, Li^+ can be easily extracted from an aqueous solution containing a mixture of various alkali metal ions.



The 'Wrap Around' Complexes. Polydentate ligands such as *crown ethers* and *cryptates* are the most important ligands which form *highly stable complexes with alkali metal ions.* These ligands are also *highly selective* in complex formation.



The cause of selectivity lies in the size of the 'hole' available in a polydentate ligand of the type mentioned above. Only that alkali metal ion which *exactly fits into the 'hole'*, forms stable complex. The cations which are either too small or too big to fit in the hole, would not form stable complexes. For example, the 'hole' in cryptate-222 is just of the right size for the K^+ ion to fit in whereas Li^+ and Na^+ ions are *too small* to make contact with the oxygen atoms of the ligand. On the other hand, Rb^+ and Cs^+ ions are *too big* in size to fit in the hole without causing steric strain. The K^+ complex of cryptate-222 is thus most stable. Similarly, Na^+ complex of cryptate-221 is most stable out of all the alkali metal ion complexes formed with this ligand.

The above mentioned macrocyclic ligands 'wrap' the metal ions completely and thus protect them from coming into contact with the solvent molecules. This is the additional cause of the stability of these complexes which are also known as **'wrap around' complexes.**

A number of macrocyclic compounds such as valinomycin and ennatin-B are present in biological systems which are responsible for the transportation of Na^+ and K^+ ions through the hydrophobic lipid by-layers of the cell membranes.

Comparison of Lithium with Other Members of the Family Lithium, no doubt, has most of the characteristic properties of the metals of Group 1 *but it differs from them in many respects.* This is mainly due to the small size of the Li atom and the Li^+ ion. The small size of Li^+ ion is responsible for the highest polarising power of this ion amongst all the alkali metal ions. Lithium differs from the other alkali metals in the following respects.

1. Lithium is much harder than the rest of the alkali metals. Its melting and boiling points are also higher (Table 2).

2. Lithium is the least reactive of the alkali metals towards the various chemical reagents except hydrogen. Thus, it decomposes water only slowly at 25°C whereas sodium does so vigorously. The reaction with potassium, rubidium and cesium is so vigorous that the evolved hydrogen catches fire spontaneously.

3. Lithium is the only alkali metal which reacts with nitrogen to give lithium nitride, Li_3N.

4. Lithium hydride, LiH, is much more stable than any other hydride. Its heat of formation is the highest. However, lithium combines with hydrogen at 700 – 800°C whereas the other alkali metals do so at 350–430°C. Thus, lithium is not so reactive towards hydrogen as the other alkali metals although its hydride is most stable.

5. Lithium reacts with bromine very slowly. Other alkali metals react violently.

6. When burnt in air or oxygen, lithium gives only the monoxide Li_2O which does not react further to give higher oxides. However, the rest of the metals give the peroxides, M_2O_2. Potassium, rubidium and cesium also give the superoxides, MO_2.

7. Lithium hydroxide decomposes at red heat forming Li_2O. The other alkali metal hydroxides do not decompose even at red heat. Also, lithium hydroxide has the lowest solubility among the hydroxides of the alkali metals.

8. The carbonate of lithium is thermally less stable and decomposes into oxide on moderate heating.

$$Li_2CO_3 \longrightarrow Li_2O + CO_2$$

Other alkali metal carbonates are highly stable towards heat. The reason for this behaviour is that Li_2O lattice is more stable than Li_2CO_3 lattice. Other M_2O lattices are less stable than the M_2CO_3 lattices.

9. Its monoxide, Li_2O, is much less basic than the oxides of other alkali metals. Also, it dissolves in water much less readily than sodium or potassium monoxide.

10. Lithium hydroxide is a much weaker base than sodium hydroxide or potassium hydroxide. Its solubility is comparable with that of calcium hydroxide.

11. Lithium fluoride, phosphate, oxalate and carbonate are sparingly soluble in water like the corresponding salts of magnesium. The corresponding salts of sodium and potassium are freely soluble in water.

12. Lithium chloride and lithium nitrate are soluble in alcohol while the corresponding salts of other alkali metals are insoluble in alcohol.

13. Bromide and iodide of lithium are soluble in organic solvents. The corresponding salts of sodium and potassium are not soluble.

14. Lithium chloride separates out from aqueous solution as hydrated crystals, $LiCl.2H_2O$. Sodium and other alkali metal chlorides do not form hydrates at ordinary temperatures. Lithium chloride is deliquescent.

15. Lithium chloride undergoes hydrolysis in hot water though to a small extent but sodium and potassium chlorides do not hydrolyse at all.

16. Lithium nitrate evolves nitrogen dioxide and oxygen on heating leaving behind lithium oxide.

$$4LiNO_3 \longrightarrow 2Li_2O + 4NO_2 + O_2$$

Sodium and potassium nitrates evolve only oxygen, leaving behind nitrites. For example,

$$2NaNO_3 \longrightarrow 2NaNO_2 + O_2$$

17. Lithium sulphate, Li_2SO_4, unlike sulphates of other alkali metals, does not form alums.

18. Lithium ion, Li^+, on account of its small size and consequently high charge density, has a high polarising power as discussed in details in the last chapter. The Li^+ ion thus polarises the electron charge cloud of water molecules more effectively than is done by other alkali metal ions. The Li^+ ion is, therefore, *most extensively hydrated*. The degree of hydration decreases with increase in the ionic size as we move from Li^+ to Cs^+. For the same reason, several lithium salts are hydrated (*e.g.*, $LiClO_4.3H_2O$) whereas the salts of other alkali metals are not hydrated.

Due to excessive hydration, the effective size of Li^+ ion in aqueous solution is larger even than that of Cs^+ ion.

19. High polarising power of Li^+ ion is also responsible for lowering the ionic character of bonds formed in lithium compounds in general and in lithium halides in particular. Assuming, for example, that the bond in lithium iodide is fully ionic (Li^+I^-), the dipole moment of the compound in the gaseous state should be 11·5 debyes but the experimental value is 3·25. This departure is attributed to polarisation, *viz.*, the distortion of electron charge cloud of the iodide ion by the lithium ion (Fig. 1) which results in a partial overlap of orbitals of Li^+ and I^- ions and hence the formation of partial covalent bond in addition to the electrostatic attraction between the two ions. Since the process of overlapping involves filled valence orbital of I^- ion and empty valence orbital of Li^+ ion, the flow of electric charge occurs from I^- to Li^+ ion decreasing thereby the dipole moment of Li – I bond. Thus, the observed dipole moment of LiI is much less than the calculated value which is based on complete transference of one electron from lithium to iodine atom.

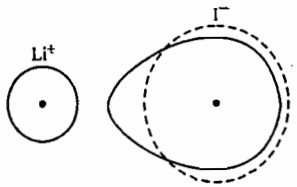


Fig. 1. Polarisation of electron charge cloud of iodide ion by lithium ion.

Diagonal Relationship of Lithium with Magnesium. As already mentioned, lithium differs from the rest of its family members in many respects. However, it shows resemblance with magnesium, the second element of Group 2. This is a case of **diagonal relationship** in which the first element of a group shows similarities with the second element in the next group of the periodic table, as indicated below.

Group 1	Group 2	Group 13	Group 14
Li	Be	B	C
Na	Mg	Al	Si

This diagonal relationship is due to *similar polarising powers* of Li^+ and Mg^{2+} ions despite the occurrence of different charges on these ions. This aspect has already been discussed in the last chapter.

Resemblance of Lithium and Magnesium

Because of the diagonal relationship, lithium resembles magnesium in several respects, as illustrated below.

1. Atomic radius of lithium is 1·34 Å while that of magnesium, being 1·364 Å, is not very much different.

2. The radii of Li^+ ion (0·60 Å) and Mg^{2+} ion (0·65 Å) are not much different from each other.

3. Polarising powers of Li^+ ion and Mg^{2+} ion are about the same.

4. Electronegativities of Li and Mg, being 1·0 and 1·3, respectively, are not much different from each other.

5. Like magnesium, lithium decomposes water only slowly liberating hydrogen.

6. Like magnesium, lithium hardly reacts with liquid bromine.

7. Lithium reacts with nitrogen to give lithium nitride, Li_3N. Magnesium also reacts with nitrogen to give magnesium nitride, Mg_3N_2

8. Lithium forms only the monoxide, Li_2O. Magnesium also prefers to form only the monoxide, MgO.

9. Lithium hydroxide, like magnesium hydroxide, is very slightly soluble in water.

10. Lithium hydroxide, like magnesium hydroxide, is a weak base.

11. Lithium fluoride, phosphate, oxalate and carbonate, like the corresponding salts of magnesium, are sparingly soluble in water.

12. Lithium chloride, like magnesium chloride ($MgCl_2.6H_2O$), separates out from aqueous solutions as hydrated crystals, $LiCl.2H_2O$.

13. Lithium chloride, like magnesium chloride, is deliquescent.

14. Lithium chloride, like magnesium chloride, undergoes hydrolysis in hot water though to a smaller extent than magnesium chloride.

15. Lithium, nitrate, like magesium nitrate, evolves nitrogen dioxide and oxygen on heating, leaving behind the oxide.

$$4LiNO_3 \longrightarrow 2Li_2O + 4NO_2 + O_2$$
$$2Mg(NO_3)_2 \longrightarrow 2MgO + 4NO_2 + O_2$$

Uses of Alkali Metals. Alkali metals are too expensive and too reactive to be used for ordinary purposes where other metals, less expensive and less reactive, can be used with almost the same results. These metals are used only for special purposes as mentioned below.

1. The alkali metals in the liquid state are excellent conductors of heat and are used in this state *for conducting heat from the centre of a nuclear reactor to the outside of the reactor* where it can be converted into useful work.

2. The alkali metals have low ionisation energies, *i.e.*, have relatively greater tendency to emit electrons. This tendency increases on moving from lithium to cesium, as already explained. Thus, electrons can be ejected most readily from cesium. This can happen even by the action of light. This metal, therefore, finds application in the fabrication of *photoelectric cells*.

3. Alkali metals are *strong reducing agents*, as already discussed. These are used in a number of reactions for reduction purposes. Thus, sodium is used as a reducing agent for the preparation of several metals from their chlorides.

4. Alkali metals are also used in the manufacture of several compounds, such as NaH, Na_2O_2, NaCN, $NaNH_2$.

5. Sodium metal is used in the manufacture of Na-Pb alloy required for the manufacture of anti-knocking materials such as $(C_2H_5)_4Pb$ and $(CH_3)_4Pb$ for gasoline.

EXTRACTION OF ALKALI METALS

Extraction of Lithium Lithium is fairly widely distributed in nature and is about twice as plentiful as lead. However, the amount present in any mineral is always small and the extraction is not so easy. The important lithium-bearing minerals are :

1. *Lepidolite or lithia mica* $(Li,Na,K)_2Al_2(SiO_3)_3,(F, OH)_2$ containing up to 1·5% of lithium.

2. *Petalite*, $LiAl(Si_2O_5)_4$, containing 2·7 to 3·7% of lithium.

3. *Spodumene*, $LiAl(SiO_3)_2$ containing 4 to 6% of lithium.

4. *Triphylite*, $(Li,Na)_3PO_4.(Fe,Mn)_3(PO_4)_2$ containing up to 4% of lithium.

Lithium salts also occur in certain spring waters and in some plants such as tobacco, beet and sugar-cane.

The procedure for the extraction of lithium from its silicate mineral *lepidolite* involves the following steps :

1. Preparation of lithium chloride. The silicate mineral, lepidolite, is first of all converted into lithium chloride by any one of the following methods.

a. Acid Treatment Method. The silicate mineral is finely powdered and boiled with sulphuric acid. The insoluble silica (SiO_2) thus formed is filtered off. The solution is treated with the requisite amount of sodium carbonate to precipitate aluminium and iron. Excess sodium carbonate is then added to the filtrate to precipitate lithium as the carbonate. The precipitate is separated by filtration and dissolved in hydrochloric acid to obtain lithium chloride which is purified by extraction with alcohol.

b. Fusion Method. The powdered silicate mineral is fused with a mixture of barium carbonate, barium sulphate and potassium sulphate. The fused mass is separated into two layers : the upper layer containing the sulphates of alkali metals and the lower layer containing barium sulphate along with alumina and silica. The upper layer is separated, dissolved in water and the solution treated with barium chloride solution. Barium sulphate gets precipitated while the chlorides of lithium, sodium and potassium remain in solution. The filtrate is evaporated to dryness and the residue is extracted with pyridine in which only lithium chloride dissolves. Pyridine is distilled off while lithium chloride is left behind.

2. Electrolysis of lithium chloride. A mixture of dry lithium chloride and potassium chloride is fused and electrolysed in an electrolytic cell shown in Fig. 2. The addition of potassium chloride increases the conductivity of lithium chloride and lowers its melting point. The cell is operated at a temperature close to 400°C and a voltage equal to 8 – 9 volts is applied.

The following reactions take place :

$$LiCl \rightleftharpoons Li^+ + Cl^-$$

$$Li^+ + e^- \longrightarrow Li \quad \text{(at cathode)}$$

$$2Cl^- - 2e^- \longrightarrow Cl_2 \quad \text{(at anode)}$$

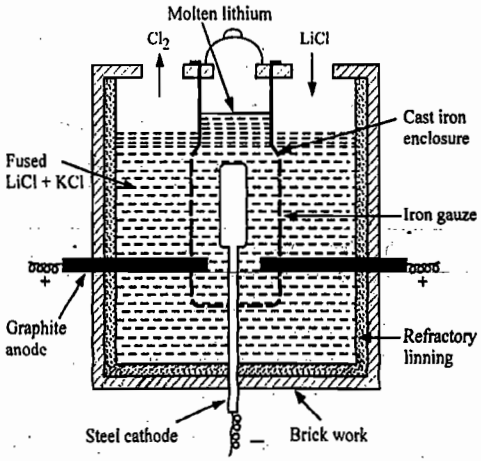

Fig. 2. Electrolytic preparation of lithium.

Chlorine gas liberated at the anode leaves the cell through an exit and the molten lithium metal rises to the surface of the fused electrolyte and collects in the cast iron enclosure surrounding the cathode.

Extraction of Sodium. Sodium occurs in nature in the form of its salts such as NaCl (*rock salt*), $NaNO_3$ (*chile saltpetre*), $Na_2CO_3.NaHCO_3.2H_2O$ (*sodium sesquicarbonate*) and Na_3AlF_6 (*cryolite*).

The metal is extracted by the electrolysis of fused sodium chloride in the presence of calcium chloride and alkali fluorides which themselves do not decompose at the voltage applied but lower the melting point of NaCl from 800° to about 600°C at which the corrossive action of sodium and chlorine is also reduced considerably. Chlorine is a valuable by-product.

Extraction of Potassium. Potassium, like sodium, occurs in nature in the form of its salts such as $KCl.MgCl_2.6H_2O$ (*carnallite*), $K_2SO_4.MgSO_4.CaSO_4.2H_2O$ (*polyhalite*), $KCl.MgSO_4.3H_2O$ (*kainite*), $K_2SO_4.MgSO_4.6H_2O$ (*schonite*), KNO_3 (*saltpetre*) and $K_2SO_4.2MgSO_4$ (*langbenite*).

However, the metal is not extracted from any of the above salts. It is obtained by heating potassium fluoride with calcium carbide in steel cylinders at about 1000°C :

$$2KF + CaC_2 \longrightarrow 2K + CaF_2 + 2C$$

Extraction of Rubidium. Rubidium is a scarce element although it occurs fairly widely in nature alongwith other alkali metals. Carnallite contains up to 0·04 per cent of rubidium chloride, RbCl and is probably the most important source of the metal. *Lepidolite* may contain up to about 1 per cent of rubidium. Other lithium ores like *tryphylite* also contain traces of rubidium.

The metal is extracted either by the electrolysis of *fused* RbCl or RbOH, or by the reduction of rubidium carbonate or hydroxide by aluminium or magnesium.

Extraction of Cesium. Cesium, like rubidium, is a rare element. The chief ores of cesium are *pollucite* ($Cs_4Al_4Si_9O_{26}.6H_2O$) which contains about 27 per cent of cesium ; *lepidolite*, a lithium ore, which contains 0·2 to 0·7 per cent of cesium and *beryl*, a beryllium ore, which contains about 3 per cent of cesium.

The metal is obtained from *pollucite* by heating the mineral with calcium metal at 900°C. About 85% of the cesium formed volatilises. The vapour of the metal are cooled and the crude condensate purified by sublimation in vacuum at 350 – 400°C to get the pure metal.

Cesium metal can also be obtained by the reduction of the hydroxide or the carbonate with Al or Mg in an atmosphere of hydrogen or by heating CsCl with Ca.

Preparation of Francium. This element was discovered by Mlle Perry in 1939 who showed that actinium-237 undergoes an α-ray radioactive change producing a new element which she named francium (after France).

$$^{237}_{89}Ac \longrightarrow ^{233}_{87}Fr + ^{4}_{2}He$$

Francium is a radioactive element with a half-life period of 21 minutes.

PROPERTIES OF ALKALI METALS AND THEIR USES

Properties of Lithium. Lithium is a silvery-white metal. It is harder than sodium or potassium but is soft enough to be cut with a knife. It is the lightest metal known (density 0·634 g cm^{-3}). It has higher melting point (180°C) and a higher boiling point (1326°C) than any of the other alkali metals. When volatilized, it imparts a crimson red colour to the flame. Chemical properties of lithium have already been described along with the properties of other alkali metals.

a. Uses of lithium metal. 1. Lithium forms a number of alloys which are highly useful in industry. For example, lithium-lead alloy (0·05% Li) is used for making bearings and sheaths for electric cables. Lithium-aluminium alloy possesses great tensile strength and elasticity like that of mild steel. 2. Since lithium combines readily with oxygen and nitrogen, it is used for removing the last traces of oxygen and

nitrogen from copper and nickel. 3. Lithium is used for producing thermonuclear energy required for propelling rockets and guided missiles.

b. Uses of lithium compounds. 1. *Lithium carbonate* is used in making a special variety of glass which is very strong and resists weather. 2. *Lithium chloride* is used in air-conditioning plants to regulate the humidity. It is also used in Ni – Fe accumulators. 3. *Lithium salicylate* and *bicarbonate* have been used in medicine for the treatment of rheumatism since the resulting lithium urate is highly soluble. 4. *Lithium bromide* is used in medicine as a sedative. 5. *Lithium hydride* and *lithium aluminium hydride* ($LiAlH_4$) are used in synthetic organic chemistry as reducing agents.

Properties of Sodium. Sodium is a soft, silvery-white metal. It is lighter than water, its density being .0·972 g cm^{-3}. It melts at 97·8°C and boils at 883°C. It is sufficiently malleable and ductile and, like other metals, is a good conductor of heat and electricity. Chemical properties of sodium have already been described along with properites of other alkali metals.

Uses of Sodium. 1. Sodium is used in the manufacture of a number of chemicals like sodium peroxide, sodium cyanide and sodamide. 2. Sodium is largely used in industry for the production of artificial rubber, dyes, drugs, etc. 3. In the laboratory, sodium is employed as a reducing agent in the form of sodium amalgam as well as in the synthesis of many organic compounds. It is also used for detecting nitrogen, halogens and sulphur in organic compounds. 4. It is used in the extraction of boron and silicon. 5. Because of its lightness and high thermal conductivity, it is employed for filling exhaust valves of aeroplane engines.

Properties of Potassium Potassium resembles sodium in its physical as well as chemical properties. However, it is softer and chemically more reactive. Thus, it reacts with water more violently and the heat of reaction is so high that the hydrogen evolved catches fire. When burnt in excess of oxygen, it forms the super oxide, KO_2 (sodium under similar conditions gives the peroxide, Na_2O_2). Potassium is slightly radioactive owing to the presence of traces of the radioactive isotope, $^{40}_{19}K$.

Uses. Very few uses have been found for metallic potassium. It is occasionally used in photoelectric cells and in the synthesis of organic compounds.

Properties of Rubidium, Cesium and Francium.

Rubidium is a soft white metal with low melting point (38·9 °C) and low boiling point (688°C). It is more reactive than potassium. It catches fire spontaneously in air and reacts vigorously with water.

Cesium is a soft white metal with very low melting point (28·7°C). When exposed to air, it first melts and then bursts into flame. It decomposes cold water with great violence forming the hydroxide CsOH which is the strongest of all the bases.

Francium, as already mentioned, is a radioactive element with a half-life period of 21 minutes only. Because of its very short life, chemistry of francium has been studied by radio-chemical methods. Our knowledge of its chemistry is derived almost entirely from the researches of Mlle Perry which show that francium has properties that might be expected of the heaviest alkali metal.

COMPOUNDS OF ELEMENTS OF GROUP 1

I. A Comparative Study

All the common compounds of alkali metals are ionic in character and contain the alkali metals as colourless electropositive monovalent ions. Most of the compounds are soluble in water. With the exception of a few lithium salts, all the alkali metal salts are insoluble in alcohol. The alkali metal cations are extremely stable because of noble gas configurations. The compounds of alkali metals are colourless except those having coloured anions, like MnO_4^-, CrO_4^{2-}, etc.

Oxides. When the alkali metals are burnt in air, they form oxides. Different kinds of oxides are formed depending upon the alkali metal. Thus, lithium forms monoxide Li_2O (and some peroxide Li_2O_2) when burnt in oxygen. Sodium forms peroxide Na_2O_2 (and some oxide Na_2O). Potassium, rubidium and cesium form superoxides of the type MO_2 (where M = K, Rb and Cs) when burnt in air.

The normal oxides contain O^{2-} ion, the peroxides contain O_2^{2-} ion and superoxides contain O_2^- ion. The peroxides and superoxides become more stable with increase in atomic number of the alkali metal. The formation and stability of these oxides can be explained on the basis of their *lattice energy* (Chapter 6). Li^+ ion being a small ion has a strong positive field around it and can stabilize only a small anion, O^{2-}, whereas Na^+ ion being a large cation can stabilize a large anion and so on. Thus, smaller cation can stabilize smaller anion and larger cation can stabilize larger anion.

Oxides of any required type can, however, be prepared by dissolving the metal in ammonia and treating the solution with the required amount of oxygen. Ozonides of the formula MO_3 are also formed on treatment with ozone.

The typical oxides are the monoxides, M_2O, which are strongly basic and highly soluble in water. They give strongly alkaline solutions due to formation of hydroxides, M^+OH^-, which are very largely ionised.

The higher oxides, *viz.*, peroxides and superoxides are important oxidising agents. They react with dilute acids forming hydrogen peroxide and oxygen, respectively.

$$Na_2O_2 + H_2SO_4 \longrightarrow Na_2SO_4 + H_2O_2$$

$$4KO_2 + 2H_2SO_4 \longrightarrow 2K_2SO_4 + 2H_2O + 3O_2$$

Structures of oxides. Lithium, sodium and potassium oxides are said to have *anti-fluorite* structure which is similar to the structure of calcium fluoride (called *fluorite structure*). The specific difference is that whereas in calcium fluoride, the fluoride ions are tetrahederally surrounded by Ca^{2+} ions (Chapter 6), in lithium oxide and sodium oxide, etc., the metal ions (Li^+, Na^+, etc.) are surrounded by O^{2-} ions. Thus, alkali metal oxides have the same structure as calcium fluoride with the difference that positions of positive and negative ions have been interchanged. This structure is, therefore, known as *anti-fluorite structure*.

Due to high electropositive character of the alkali metals, their oxides get excessively hydrolysed by water yielding hydroxides. The hydroxides, being strong bases, ionise to yield OH^- ions.

$$M_2O + H_2O \longrightarrow 2M^+ + 2OH^-$$

Hydroxides. The hydroxides of alkali metals have the general formula MOH. These are white crystalline solids, highly soluble in water as well as in alcohol. They act as strong bases in aqueous solutions, as shown above. Since electropositive character of the alkali metals increases on moving from Li to Cs, their hydroxides become more and more basic on moving down the group. Thus, out of the hydroxides of lithium, sodium and potassium, lithium hydroxide is the weakest and potassium hydoxide is the strongest alkali.

All the hydroxides are stable towards heat and this stability increases on moving from Li to Cs. They melt without decomposing and are good conductors of electricity in the fused state.

The hydroxides sublime at about 400°C giving vapours which consist of dimers, $(MOH)_2$.

Halides. Halides of alkali metals have, generally, high melting points. They are good conductors of electricity in fused state and are readily soluble in water.

Their structure is determined by the radius ratio and lattice energy effects. The radius ratio M^+/Cl^- for chlorides of various alkali metals are given in Table 5. The coordination number expected from a given radius ratio, as discussed in Chapter 6, is shown in the next column. The actual coordination numbers as observed from X-ray structure of the crystals, are shown in the last column.

TABLE 5

Radius Ratios and Coordination Numbers of Alkali Metal Halides

Formula of chloride	Radius ratio $M^+ : Cl^-$	Coordination number expected from the radius ratio	Observed coordination number
LiCl	0·338	4	6
NaCl	0·524	6	6
KCl	0·732	6	6
RbCl	0·822	8	6 or 8
CsCl	0·930	8	8

Thus, while the observed coordination numbers for Na, K, Rb and Cs are according to expectations, that for Li is higher. The anomaly in the case of Li is due to the fact that higher coordination number leads to higher lattice energy and, therefore, adds to the stability of the crystal.

The alkali metal halides have essentially ionic character. Lithium halides, however, have partly covalent character in addition to ionic character. This is due to the polarisation of the halide ion by the lithium ion, as has already been discussed.

Carbonates and Bicarbonates. Since the alkali metals are highly electropositive, their carbonates (M_2CO_3) and in most cases, also the bicarbonates ($MHCO_3$), are highly stable to heat. As the electropositive character increases on moving down the group, the stability of the carbonates and bicarbonates increases in the same order. Thus, lithium carbonate is not so stable to heat as the other alkali metal carbonates. Lithium bicarbonate does not exist as solid.

Hydrides. As already mentioned, hydrides of alkali metals contain hydrogen as an anion and are represented as M^+H^-. Hydrogen, in these compounds, gets liberated at the anode, on electrolysis. The hydrides are not very stable. They react with water readily liberating hydrogen. These hydrides are, therefore, used as reducing agents.

Lithium aluminium hydride, $Li[AlH_4]$, is a strong reducing agent and is used as such in organic chemistry.

Organometallic Compounds. Alkali metals, especially lithium, form a number of organometallic compounds which are frequently employed in the synthesis of a variety of organic compounds.

Organolithium compounds are generally synthesised as follows :

(*i*) $Li(n\text{-}C_3H_7) + C_6H_5I \xrightarrow[\text{ether}]{\text{Solvent}} Li(C_6H_5) + n\text{-}C_3H_7I$

(*ii*) $4Li(C_6H_5) + Sn(CH_2-CH_2=CH_2)_4 \xrightarrow[\text{ether}]{\text{Solvent}} 4Li(CH_2-CH=CH_2) + Sn(C_6H_5)_4$

(*iii*) $2Li + C_2H_5I \xrightarrow[\text{ether}]{\text{Solvent}} LiI + Li(C_2H_5)$

Organometallic compounds of other alkali metals such as $Na(C_6H_5)$, $Ph_2C(Na)C(Na)Ph_2$, $CsCH_2CH_2Cs$, are also known. These are generally prepared from the corresponding mercury compounds, as, for example,

$$2K + HgR_2 \longrightarrow Hg + 2KR$$

The monomeric organometallic compounds of alkali metals are not very stable thermodynamically. However, polymeric compounds are comparatively stable. For example, some polymeric lithium alkyls do not decompose even up to 100°C.

Lithium alkyls are extensively used in the synthesis of organic compounds and organometallic

compounds of other elements, as is evident from the following reactions :

(*i*) $3LiR + BCl_3 \longrightarrow 3LiCl + BR_3$

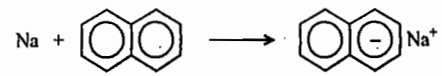
(*ii*) $Li(C_6H_5) + (CH_3C_6H_4)_2CO \longrightarrow (CH_3C_6H_4)_2C(C_6H_5)OLi \xrightarrow{H_2O} (CH_3C_6H_4)_2C(OH)C_6H_5 + LiOH$ (Tertiary carbinol)

(*iii*) $Li(C_6H_5) + CO_2 \longrightarrow [C_6H_5CO_2Li] \xrightarrow{H_2O} C_6H_5COOH + LiOH$ (Carboxylic acid)

(*iv*) $LiR + R'CON(CH_3)_2 \longrightarrow LiN(CH_3)_2 + R'COR$ (Ketones)

Alkyl and aryl compounds of lithium are polymeric having considerable covalent character in their Li – C bonds whereas such organometallic compounds of other alkali metals have predominantly ionic character so that these can be represented as M^+R^-. The alkyl and aryl sodium, potassium, etc., are much more reactive than the corresponding alkyls and aryls of lithium. For instance, the former catch fire in air more violently compared to alkyl or aryl compounds of lithium.

A particular ionic organometallic compound of sodium is formed when the metal is shaken with naphthalene or phenanthrocene in a nonaqueous solvent. The solution is paramagnetic and has strong reducing properties like the solution of Na metal in liquid ammonia. The reaction can be represented as



The electron of sodium metal is captured by partially filled $p\pi$ orbitals which are delocalised on all the carbon atoms of naphthalene or phenanthrocene.

The student is advised to consult Chapter 34 on Organometallic Compounds for the structures of alkyls and aryls of alkali metals.

II. Some Important Compounds of Elements of Group 1

Lithium Monoxide, Li_2O. It may be prepared by burning lithium in oxygen. It is obtained in the pure state by heating carbonate or hydroxide in an atmosphere of hydrogen (to prevent the formation of Li_2O_2)

$$Li_2CO_3 \longrightarrow Li_2O + CO_2$$

Lithium oxide is a white solid that reacts slowly with water to form lithium hydroxide.

$$Li_2O + H_2O \longrightarrow 2LiOH$$

It resembles other alkali metal hydroxides in possessing caustic properties and in its power to absorb carbon dioxide.

Lithium Peroxide, Li_2O_2. It is prepared by adding hydrogen peroxide and alcohol to a concentrated solution of lithium hydroxide. A white precipitate having the composition $Li_2O_2.H_2O_2.3H_2O$ is obtained.

When dehydrated over phosphorus pentoxide, it loses both water and hydrogen peroxide and leaves behind Li_2O_2.

Lithium Hydroxide, LiOH. It is usually prepared by the action of baryta water ($Ba(OH)_2$ solution) on lithium sulphate.

$$Li_2SO_4 + Ba(OH)_2 \longrightarrow 2LiOH + BaSO_4$$

The filtrate is evaporated when $LiOH.H_2O$ crystallises out from the solution. On heating these crystals in an atmosphere of hydrogen, a white mass of lithium hydroxide, LiOH, remains.

Lithium hydroxide is less soluble (about 80 g per litre at room temperature) than the other alkali metal hydroxides and is also much less thermally stable. On strong heating it decomposes forming the oxide.

$$2LiOH \longrightarrow Li_2O + H_2O$$

Lithium Hydride, LiH. *It is obtained by heating lithium metal in a current of hydrogen.*

$$2Li + H_2 \longrightarrow 2LiH$$

Lithium hydride is a white solid which melts at 680°C. If electrolysed at temperatures slightly below its melting point, hydrogen is given off at the anode indicating that lithium hydride is an electrovalent compound and contains Li^+ and H^- ions. It reduces carbon dioxide to carbon and reacts vigorously with water with the liberation of hydrogen.

Lithium Aluminium Hydride, $LiAlH_4$. It is obtained by the action of anhydrous aluminium chloride on lithium hydride in ethereal solution.

$$4LiH + AlCl_3 \xrightarrow{\text{ether}} LiAlH_4 + 3LiCl \downarrow$$

It is a powerful reducing agent and reduces a number of covalent halides to the hydrides. Thus, silicon tetrachloride is reduced to silane, SiH_4.

A detailed description of this salt has been given in Chapter 15.

Lithium Carbonate, Li_2CO_3. It is prepared by adding ammonium carbonate to a solution of a soluble salt of lithium in the presence of ammonia.

$$2LiCl + (NH_4)_2CO_3 \longrightarrow Li_2CO_3 + 2NH_4Cl$$

Lithium carbonate, being sparingly soluble, gets precipitated. It is filtered and dried.

It is a white stable powder which decomposes to oxide and CO_2 on heating to above 600°C ($Li_2CO_3 \longrightarrow Li_2O + CO_2$). Li_2CO_3 dissociates into Li_2O more easily than other alkali metal carbonates. The is due to the fact that Li_2O is more stable than other alkali metal oxides. Because of its small size, Li^+ ion has greater polarising power than the other alkali metal cations. It, therefore, polarises the electron charge cloud of O^{2-} ion towards itself to a considerable extent. This allows partial overlap between the orbitals of Li^+ and O^{2-} ions introducing some covalent character in Li – O bond apart from the ionic character in Li_2O. This gives extra stability to Li_2O. The other alkali metal oxides, M_2O, are almost entirely ionic in character. Lithium carbonate, as already stated, is only sparingly soluble in water like the carbonates of calcium and magnesium. On passing carbon dioxide through a suspension of lithium carbonate, the latter dissolves due to the formation of soluble lithium bicarbonate.

The solution of lithium bicarbonate is used in medicine as a remedy for gout and rheumatism under the name *lithia water*. Lithium carbonate is used in glass industry.

Sodium Cyanide, NaCN. It is a chemical of industrial importance and is, therefore, prepared on a large scale by the following methods.

1. From Sodium. Dry ammonia gas is passed over fused metallic sodium in iron retorts when sodamide is first formed.

$$2NH_3 + 2Na \longrightarrow 2NaNH_2 + H_2$$

The liquid sodamide formed is taken to another chamber and dropped on red hot charcoal to yield sodium cyanide.

$$NaNH_2 + C \longrightarrow NaCN + H_2$$

2. From Calcium Cyanamide. Crude calcium cyanamide is mixed with sodium carbonate or sodium chloride and heated with coke.

$$CaN.CN + Na_2CO_3 + C \longrightarrow 2NaCN + CaCO_3$$

$$CaN.CN + 2NaCl + C \longrightarrow 2NaCN + CaCl_2$$

3. From Gas Works. A good deal of sodium cyanide is obtained as a by-product in the purification of coal gas which contains some hydrocyanic acid and ammonia. The crude coal gas is passed through copper sulphate solution when ammonium tricyanocuperate(I) is formed.

$$2CuSO_4 + 8NH_3 + 8HCN \longrightarrow \underset{\text{Ammonium tricyano cuperate (I)}}{2(NH_4)_2[Cu(CN)_3]} + 2(NH_4)_2SO_4 + \underset{\text{Cyanogen}}{(CN)_2}$$

When all the copper salt has been converted into the complex cyanide, the coal gas is turned on to a second vessel. Dilute sulphuric acid is added to the first vessel and the hydrocyanic acid gas evolved is absorbed in caustic soda solution to form sodium cyanide.

$$(NH_4)_2[Cu(CN)_3] + H_2SO_4 \longrightarrow (NH_4)_2SO_4 + 2HCN + CuCN$$

$$HCN + NaOH \longrightarrow NaCN + H_2O$$

When all the complex cyanide has been decomposed by dilute sulphuric acid, the coal gas is turned again into the first vessel where ammonium tricyanocuperate (I) is formed again and the reaction goes on continuously.

$$CuCN + 2HCN + 2NH_3 \longrightarrow (NH_4)_2[Cu(CN)_3]$$

Properties. Sodium cyanide is a colourless solid readily soluble in water. The solution is alkaline due to hydrolysis of the cyanide ion.

$$CN^- + H_2O \rightleftharpoons HCN + OH^-$$

It is highly poisonous and has a characteristic smell like that of bitter almonds.

It forms soluble complex cyanides with salts of transition metals like copper, silver, gold, cadmium, zinc and iron. Thus,

$$CdSO_4 + 4NaCN \longrightarrow Na_2[Cd(CN)_4] + Na_2SO_4$$

A dilute solution of sodium cyanide can dissolve gold and silver in the presence of air or oxygen forming soluble complex cyanides.

$$4Au + 8NaCN + 2H_2O + O_2 \longrightarrow \underset{\text{Sodium dicyano-aurate (I)}}{4Na[Au(CN)_2]} + 4NaOH$$

Uses. Large quantities of sodium cyanide are used in the extraction of silver and gold. It is also employed in electroplating of gold and silver which involves the electrolysis of their complex cyanides. In the laboratory it is used for preparing other cyanides and as a reducing agent in the synthesis of organic compounds. On account of its highly poisonous character it is used as a germicide in spraying over fruit trees.

Sodium Amide or Sodamide, $NaNH_2$. It is prepared by passing a stream of dry ammonia gas over metallic sodium at 300 – 400°C, contained in an iron vessel.

$$2Na + 2NH_3 \longrightarrow 2NaNH_2 + H_2$$

Sodamide is a waxy solid melting at 210°C. It gets hydrolysed on being treated with water.

$$NaNH_2 + H_2O \longrightarrow NaOH + NH_3$$

It reacts with dry hydrogen at 150 — 300°C to give sodium hydride.

$$NaNH_2 + H_2 \longrightarrow NaH + NH_3$$

When warmed with carbon monoxide it gives sodium cyanide.

$$2NaNH_2 + CO \longrightarrow NaCN + NaOH + NH_3$$

With carbon dioxide it gives cyanamide $CN.NH_2$

$$2NaNH_2 + 2CO_2 \longrightarrow Na_2CO_3 + H_2O + CN.NH_2$$

With nitrous oxide it gives sodium azide.

$$NaNH_2 + N_2O \longrightarrow \underset{\text{Sodium azide}}{NaN_3} + H_2O$$

Potassium Cyanide, KCN. It is obtained by heating dry potassium hexacyanoferrate(II), $K_4[Fe(CN)_6]$, to white heat or better by heating it with metallic potassium.

$$K_4[Fe(CN)_6] \longrightarrow 4KCN + Fe + 2C + N_2$$

$$K_4[Fe(CN)_6] + 2K \longrightarrow 6KCN + Fe$$

It can also be obtained by fusing potassium hexacyanoferrate (II) with potassium carbonate when a mixture of potassium cyanide and potassium cyanate, KCNO, is produced.

$$K_4[Fe(CN)_6] + K_2CO_3 \longrightarrow 5KCN + KCNO + Fe + CO_2$$

Potassium cyanide is a white crystalline solid, m.p. 635°C. It is highly hygroscopic and very soluble in water. The aqueous solutions are alkaline to litmus because of hydrolysis.

$$KCN + H_2O \rightleftharpoons K^+ + OH^- + HCN$$

Potassium cyanide is a **deadly poison !**

Potassium cyanide is extensively used in electroplating and extraction of gold and silver. It is also used as a laboratory reagent.

Role of Na^+ and K^+ ions in Biological Systems. Sodium cation is a major cation of extracellular fluids of animals including human beings which is known to activate certain enzymes in the animal body. Sodium ions are relatively harmless except when present in excess amounts in which case they may cause hypertension. The saline water containing excessive amounts of NaCl is harmful to plant and aquatic life because of the toxicity of Na^+ ions.

The potassium ion is essential to all organisms with the possible exception of blue green algae. It is a major cation of intracellular fluid of animal cells. It is moderately toxic to mammals but only when injected intravenously.

The sodium and potassium ions, taken together, constitute what is known as **'Na^+–K^+ pump'** or simply as **'sodium pump'.** The functioning of this pump is actually a biological process which goes on occurring in each and every cell of all animals. Although the discussion of the exact mechanism of the functioning of this pump is beyond the scope of the book yet it may suffice to say that it transfers Na^+ ions from the intracellular fluids to the extracellular fluids with the help of 'carrier proteins'. Simultaneously it transfers K^+ ions from the extracellular fluids to the intracellular fluids. Since each operation of the pump (*i.e.*, each cycle of this biological process) pumps out larger number of sodium ions from the cell than the number of K^+ ions that it pumps into the cell, the interior of the cell acquires an excess negative charge and the exterior of the cell acquires an excess positive charge. This results in the development of electrical potential gradient across the cell membrane which is responsible for the transmission of nerve signals in animals. The Na^+–K^+ pump also maintains the volume of the cell. Without the existence of the Na^+–K^+ pump in the cell, the latter would have swelled in volume and ultimately bursted.

QUESTIONS

1. (*a*) What are *s* block elements ?
   (*b*) Why are the elements of Group 1 called the alkali metals ? Give their electronic configurations. Why are they so reactive ?
2. (*a*) Explain why the elements of Group 1 are soft, electrically conducting, good reducing agents and form univalent ions.

   (*b*) Account for the fact that alkali metals form basic hydroxides and their basic strength increases on descending the group.
   (*c*) 'Alkali metals lose electrons even when exposed to light'. How would you account for this behaviour ?
3. (*a*) Discuss the general trends in Group 1 metals with respect to
   (*i*) melting point (*ii*) density (*iii*) ionisation energy (*iv*) atomic and ionic radii (*v*) chemical reactivity.
   (*b*) With the help of electronic configurations, how would you account for different colours produced by alkali metals in bunsen flame ?
4. (*a*) Explain the terms oxidation potential and ionisation energy.
   'An element having high oxidation potential will normally have low ionisation energy and vice versa.' How would you explain this ?
   (*b*) Amongst the alkali metals, lithium has the highest ionisation energy but at the same time it has the highest electrode potential. How would you explain this contradictory behaviour
5. Why and in what ways does Li resemble Group 2 metals ?
6. (*a*) Discuss the important characteristics of alkali metals. How would you explain the various properties on the basis of their electronic configurations ?
   (*b*) Why are the hydroxides (MOH) of alkali metals so strongly basic in character ? Why does the basic strength increase as we move down the group ?
7. The extent of hydration of alkali metal ions decreases as we move down the group. How would you account for it?
8. On the basis of ionic size we expect that the ionic conductance of alkali metal ions should decrease in the order $Li^+ > Na^+ > K^+ > Kb^+ > Cs^+$. But actually the trend is just the *reverse*. How would you explain this anomaly ?
9. (*a*) Give a detailed account of the complexes of alkali metals formed with polydenate ligands.
   (*b*) How would you account for the unusual stability of complexes of alkali metals formed with polydenate ligands such as crown ethers and cryptates. Why are these ligands so selective in complex formation.
10. Account for the following :
    (*a*) Li forms normal oxide, Na forms peroxide and K, Rb and Cs form superoxides.
    (*b*) In spite of the fact that lithium is an alkali metal, its halides are covalent.
    (*c*) All alkali metals give flame colouration.
    (*d*) The alkali metals dissolve in liquid ammonia to give paramagnetic and blue coloured solutions.
11. (*a*) How does lithium differ from its congeners ?
    (*b*) Conductivity of Li^+ ion in water is less than that of Cs^+ ion although their sizes suggest an opposite order. Explain.
    (*c*) Give important uses of alkali metals.
12. (*a*) Lithium iodide is quite soluble in nonpolar solvents, the order of solubility in such solvents decreases in the order : LiI > LiBr > LiCl > LiF. How would you account for this ?
    (*b*) Why does the chemical reactivity of the alkali metals increase from Li to Cs ?
13. What is meant by diagonal relationship ? In what respects does lithium resemble magnesium?
14. Give the names of important minerals containing lithium. How is lithium recovered from the silicate minerals ? In what respects do lithium and its compounds differ from other alkali metals and their compounds ?
15. Give a brief account of the oxides and hydroxides of alkali metals. Comment on the structures of the oxides.
16. From the radius ratio, the coordination number of lithium in LiCl should be 4. But actually it is 6. How would you account for it ?
17. Give the preparation and properties of the following :
    Lithium monoxide, lithium peroxide, lithium hydroxide, lithium hydride, lithium carbonate, sodium cyanide, sodamide, potassium cyanide.

14 THE ELEMENTS OF GROUP 2

The elements, **beryllium, magnesium, calcium, strontium, barium** and **radium**, constitute Group 2 of the periodic table.

As mentioned in the previous chapter, all these elements are metals. The oxides of calcium, strontium and barium were known much earlier than the metals themselves and they were called **alkaline earths** since they were alkaline and existed in the earth. Later, when the elements were discovered, they were named as **alkaline earth metals**. Radium corresponds to the alkaline earth metals in its chemical properties but, being a radioactive element, it is studied separately along with the other radioactive elements. The electronic configurations of these elements have been given in Table 1 in the last chapter.

GENERAL CHARACTERISTICS

The general characteristics of alkaline earths have already been discussed in details while describing the properties of the main group elements in Chapter 12. Only a brief discussion has been made in this chapter.

TABLE 1

Some Important Physical Properties of Alkaline Earth Metals

Property	Be	Mg	Ca	Sr	Ba	Ra
Atomic number	4	12	20	38	56	88
Molar mass (g mol^{-1})	9·01	24·31	40·08	87·67	137·34	226·05
Molar volume (cm^3 mol^{-1})	4·90	13·97	25·91	34·54	36·72	38·00
Density (g cm^{-3})	1·84	1·74	1·55	2·54	3·75	6·00

Physical Properties

Some of the important physical properties and other constants of alkaline earth metals are given in Table 1.

1. Metallic Properties. Elements of Group 2 have typical metallic properties. They show good metallic lustre and high electrical as well as thermal conductivity.

2. Metallic Bonding. While in alkali metals (Group 1), there is a single valence electron per atom, in alkaline earth metals (Group 2), there are two valence electrons per atom. Hence metallic bonding in Group 2 elements is stronger than that in Group 1 elements. As a result, the elements of Group 2 are *harder* and *denser* and have *higher melting* and *boiling points* than the elements of Group 1. As already explained in Chapter 4 on Chemical Bonding, the filled valence *s* energy band in these elements overlaps with the empty valence *p* energy band so that valence electrons can easily jump from filled energy levels of valence *s* energy band to empty energy levels of valence *p* energy band. These elements are, therefore, good conductors of heat and electricity.

3. Hardness. The alkaline earth elements are moderately hard. Although they are harder than alkali metals yet they can be cut with a sharp knife.

4. Molar Volume. Molar volume is seen to increase regularly in moving from beryllium to radium. This is to be expected in view of increase in atomic radius (due to increase in the number of shells) on moving down the group in the same order.

5. Density. Density is seen to decrease slightly on moving down the group upto calcium but it increases considerably thereafter upto radium. These metals are seen to be considerably denser than the corresponding alkali metals of Group 1.

6. Melting Points and Boiling Points. Melting points and boiling points do not show regular trends. However, these are higher than those of alkali metals.

7. Atomic and Ionic Radii. The atoms of these elements are smaller than those of the corresponding elements of Group 1. This is due to higher nuclear charge of these atoms which tends to draw the orbital electrons inwards, *i.e.*, towards the nucleus. On account of the smaller atomic size, these elements are harder, have higher densities and higher melting points than the elements of Group 1.

The ionic radii are seen to be smaller than the atomic radii. This is to be expected in view of the removal of two orbital electrons in the formation of the bivalent cation (*e.g.*, Mg^{2+}, Ca^{2+}, Ba^{2+}) accompanied by the disappearance of the *M* shell.

The electronic configurations of the ions are similar to those of noble gases, *i.e.*, s^2p^6 configuration (s^2 for Be^{2+}), in the outer shell. They have also no unpaired electrons. Accordingly, these ions, like the alkali metal ions, are *diamagnetic* and *colourless*. The outer configurations of the ions being highly stable, they resist the elimination of another electron. Hence, the valency of the alkaline earth metals remains 2, *i.e.*, the oxidation state remains +2 in all ionic compounds.

Atomic as well as ionic radius is seen to increase on moving down the group from Be to Ra on account of the presence of an extra shell of electrons at each step.

8. Heat of Atomisation. Heat of atomisation is seen to fall considerably on moving from Be to Mg. The subsequent change is rather small. This shows that metal–metal bond strength is maximum in the case of beryllium.

9. Ionisation Energies. The first as well as the second ionisation energy is seen to *decrease* on going down the group from beryllium to barium. This is to be expected on account of increase in the atomic radius and, therefore, greater distance between the nucleus and the outer electrons as we move down the group.

The ionisation energy of radium, however, is slightly higher than that of barium. It has not been possible to offer any satisfactory explanation for this.

The second ionisation energy in each case is higher than the first, as expected.

In view of the lower value of first ionisation energy, it would appear that the alkaline earth metals should prefer to form + 1 ions (M^+) rather than + 2 ions (M^{2+}). However, in actual practice, these metals give only + 2 ions, *e.g.*, Mg^{2+}, Ca^{2+}, etc. If ionisation energy was the only factor involved, we would have got the monovalent ions (*e.g.*, Mg^+, Ca^+, etc.,) rather than the divalent ions (*e.g.*, Mg^{2+}, Ca^{2+}, etc.). This anomaly may be explained by taking into consideration the magnitude of energy changes involved, say, in the formation of CaCl and $CaCl_2$.

Let us first calculate the enthalpy of formation of CaCl(*s*) from its elements in their standard states from the data given below.

$$Ca\,(s) \longrightarrow Ca\,(g)\text{ ; (Sublimation energy)} \qquad \Delta H_1 = S\text{ kJ mol}^{-1}$$
$$Ca\,(g) \longrightarrow Ca^+\,(g) + e^-\text{ ; (Ionization energy)} \qquad \Delta H_2 = 600\text{ kJ mol}^{-1}$$
$$1/2\,Cl_2\,(g) \longrightarrow Cl\,(g)\text{ ; (Dissociation energy)} \qquad \Delta H_3 = 120\text{ kJ mol}^{-1}$$
$$Cl\,(g) + e^- \longrightarrow Cl^-\,(g)\text{ ; (Electron affinity)} \qquad \Delta H_4 = -350\text{ kJ mol}^{-1}$$
$$Ca^+\,(g) + Cl^-\,(g) \longrightarrow CaCl\,(s)\text{ ; (Lattice energy)} \qquad \Delta H_5 = -720\text{ kJ mol}^{-1}$$
$$\therefore\quad Ca\,(s) + 1/2\,Cl_2\,(g) \longrightarrow CaCl\,(s)\text{ ; (Heat of formation)} \qquad \Delta H_f = (-350 + S)\text{ kJ mol}^{-1}$$

Let us now calculate the enthalpy of formation of $CaCl_2$ (*s*) from its elements in standard states from the data given below.

$$Ca\,(s) \longrightarrow Ca\,(g)\text{ ; (Sublimation energy)} \qquad \Delta H_1 = S\text{ kJ mol}^{-1}$$
$$Ca\,(g) \longrightarrow Ca^{2+}\,(g) + 2e^-\text{ ; (Ionization energy)} \qquad \Delta H_2 = 1800\text{ kJ mol}^{-1}$$
$$Cl_2\,(g) \longrightarrow 2Cl\,(g)\text{ ; (Dissociation energy)} \qquad \Delta H_3 = 240\text{ kJ mol}^{-1}$$
$$2Cl\,(g) + 2e^- \longrightarrow 2Cl^-\,(g)\text{ ; (Electron affinity)} \qquad \Delta H_4 = -700\text{ kJ mol}^{-1}$$
$$Ca^{2+}\,(g) + 2Cl^-\,(g) \longrightarrow CaCl_2\,(s)\text{ ; (Lattice energy)} \qquad \Delta H_5 = -2200\text{ kJ mol}^{-1}$$
$$\therefore\quad Ca\,(s) + Cl_2\,(g) \longrightarrow CaCl_2\,(s)\text{ ; (Heat of formation)} \qquad \Delta H_f = (-860 + S)\text{ kJ mol}^{-1}$$

Now, consider the transformation reaction :

$$2CaCl\,(s) \longrightarrow CaCl_2\,(s) + Ca\,(s)$$

For this reaction, $\Delta H_{Transformation} = \Delta H_{f(Products)} - \Delta H_{f(Reactants)}$

$$= [(-860 + S) + 0] - [2\,(-350 + S)] = -(160 + S)\text{ kJ mol}^{-1}$$

Evidently, the enthalpy of transformation is a *negative quantity* indicating that the conversion of CaCl (*s*) to $CaCl_2$ (*s*) is *spontaneous*. It follows from above that $CaCl_2$ is more stable than CaCl in the solid state. The lattice energies of CaCl(*s*) and $CaCl_2$(*s*), calculated with the help of Born equation (Chapter 6) come out to be –720 and –2200 kJ mol^{-1}, respectively. This clearly shows that $CaCl_2$(*s*) is more stable than CaCl(*s*). Thus, calcium would prefer to form Ca^{2+} ion rather than Ca^+ ion. The same is true of other alkaline earth metals.

A perusal of energy data given above reveals that the factor which tilts the balance in favour of the formation of $CaCl_2$ is the high lattice energy of $CaCl_2$ (– 2200 kJ mol^{-1}) compared to that of CaCl (– 720 kJ mol^{-1}).

The ease of formation of Ca^+ ion due to lower ionization energy is also counterbalanced by the higher heat of hydration of Ca^{2+} ion compared to that of Ca^+ ion.

$$Ca^+\,(g) \xrightarrow{H_2O} Ca^+\,(aq)\text{ ;} \qquad \Delta H = -320\text{ kJ mol}^{-1}$$
$$Ca^{2+}\,(g) \xrightarrow{H_2O} Ca^{2+}\,(aq)\text{ ;} \qquad \Delta H = -1650\text{ kJ mol}^{-1}$$

This makes Ca^{2+} ion more stable in aqueous solution than Ca^+ ion.

Similarly, it can be seen from the following data that Mg^{2+} ion is more stable than Mg^+ ion in its aqueous solutions.

$$Mg\,(s) + Cl_2\,(g) \longrightarrow MgCl_2\,(s)\text{ ;} \qquad \Delta H_f = -642\text{ kJ mol}^{-1}$$
$$2Mg\,(s) + Cl_2\,(g) \longrightarrow 2MgCl\,(s)\text{ ;} \qquad \Delta H_f = -250\text{ kJ mol}^{-1}$$

Rearranging and adding the two equations, we have

$$2MgCl\,(s) \longrightarrow 2Mg(s) + Cl_2 \qquad \Delta H_f = +250\text{ kJ mol}^{-1}$$
$$Mg\,(s) + Cl_2 \longrightarrow 2MgCl_2\,(s) \qquad \Delta H_f = -642\text{ kJ mol}^{-1}$$
$$2MgCl\,(s) \longrightarrow Mg\,(s) + MgCl_2\,(s) \qquad \Delta H_f = -392\text{ kJ mol}^{-1}$$

Also the heat of hydration is greater in magnitude for Mg^{2+} ion than for Mg^+ ion.

Thus, MgCl formed, if any, will at once get converted into $MgCl_2$.

The compounds of alkaline earth metals are more extensively hydrated than those of alkali metals. For example, magnesium chloride and calcium chloride crystals exist as $MgCl_2.6H_2O$ and $CaCl_2.6H_2O$ whereas sodium chloride and potassium chloride, under ordinary conditions, do not form any hydrate.

10. Hydration of Ions. As is evident from the heats of hydration of alkaline earth metal cations given in Table 1, the extent of hydration of these ions decreases with increase in atomic number and molar mass.

11. Electropositive Character. Ionisation energies of these elements are higher than those of the alkali metals and do not permit the change

$$M \longrightarrow M^{2+} + 2e^-$$

to occur readily. Hence these elements, although fairly strongly electropositive, are not as strongly electropositive as the metals of Group 1. For example, unlike the alkali metals, these elements do not emit electrons on exposure to light. Since ionisation energy decreases on moving down the group, the electropositive character increases on moving down the group.

TABLE 2.
Standard Oxidation Potentials of Alkali Metals

Element	Oxidation Reaction	Standard Oxidation Potential (volts)
Be	$Be \longrightarrow Be^{2+} + 2e^-$	1·85
Mg	$Mg \longrightarrow Mg^{2+} + 2e^-$	2·37
Ca	$Ca \longrightarrow Ca^{2+} + 2e^-$	2·87
Sr	$Sr \longrightarrow Sr^{2+} + 2e^-$	2·89
Ba	$Ba \longrightarrow Ba^{2+} + 2e^-$	2·90

12. Reducing Properties. Oxidation Potentials. All the alkaline earth metals have a tendency to release electrons and change into bivalent cations :

$$M \rightleftharpoons M^{2+} + 2e^-$$

Hence, *they are strong reducing agents.*

The oxidation potential which is a measure of the tendency of an element to lose electrons (*i.e.*, a measure of its electropositive character and strength as a reducing agent) increases on moving down the group, as shown in Table 2.

Hence the electropositive character as well as the strength as a reducing agent increase on moving from beryllium to barium. However, these oxidation potentials are lower than those of alkali metals. Hence, the alkaline earth metals are less electropositive and weaker reducing agents than the alkali metals.

13. Electronegativities. Since these elements have strong electrospositive character, as mentioned above, they have low electronegativities which decrease on moving down the group, as shown in Table 1. The value for calcium, however, is an exception.

Trends in electronegativities of alkaline earth metals have already been discussed in details in Chapter 2.

14. Flame Coloration. When energy is supplied to these elements in a flame, their electrons are excited to higher energy states, as is the case with alkali metals under similar conditions. As the electrons drop back to the original energy level, the extra energy is emitted in the form of visible light with characteristic

colours as given below :

Ca : *brick red* Sr : *crimson* Ba : *grassy green* Ra : *crimson*

Beryllium and magnesium atoms are smaller. The electrons in these atoms are, therefore, more strongly bound. Hence these are not excited by the energy of the flame to higher energy states. These elements, therefore, do not give any colour in bunsen flame.

Chemical Properties

The important chemical properties of elements of Group 2 are given below.

1. Action of Air and Water. The alkaline earth metals, being less electropositive than the alkali metals, are less reactive. Thus they are only slowly oxidised on exposure to air. However, they burn in oxygen to form ionic oxides, MO. Calcium burns in air to give a mixture of the oxide CaO and the nitride Ca_3N_2.

These metals react slowly with water liberating hydrogen and forming metal hydroxides. It is not certain if beryllium reacts with water at all. Magnesium reacts only with hot water. The other metals do react with cold water but not as energetically as the alkali metals.

2. Action with Hydrogen. All the elements, except beryllium, combine with hydrogen to form hydrides, MH_2.

Beryllium hydride cannot be prepared by direct combination of beryllium and hydrogen. It can, however, be produced by reacting beryllium chloride with lithium aluminium hydride.

$$2BeCl_2 + Li[AlH_4] \longrightarrow 2BeH_2 + LiCl + AlCl_3$$

Beryllium and magnesium hydrides are covalent compounds while calcium, strontium and barium hydrides are largely ionic compounds.

The small size and high charge make Be^{2+} a highly polarising ion which effectively polarises the electron charge cloud of H^- ion permitting partial overlapping of orbitals of H^- and Be^{2+} ions. This induces considerable covalent character in BeH_2. The same is true in MgH_2 but to a lesser extent. Ca, Sr and Ba have very weak polarising power so that little or no covalent character is imparted to the otherwise ionic hydrides.

3. Action with Halogens. All the alkaline earth metals combine with the halogens at elevated temperatures forming halides, MX_2. Beryllium halides are covalent while the rest are electrovalent and readily soluble in water. The solubility of the halides (except fluorides) decreases on moving down the group.

4. Formation of Amalgams and Alloys. They form amalgams with mercury and alloys with other metals.

5. Action with Acids. These metals, on account of their high oxidation potentials, readily liberate hydrogen from dilute acids. Beryllium reacts very slowly as its oxidation potential is very low. However, Be becomes *passive* when exposed to concentrated or dilute nitric acid.

6. Action with Nitrogen. These elements burn in nitrogen to form nitrides, M_3N_2, which react with water to liberate ammonia.

$$3Ca + N_2 \longrightarrow Ca_3N_2$$

$$Ca_3N_2 + 6H_2O \longrightarrow 3Ca(OH)_2 + 2NH_3$$

Gradation in Properties. On account of gradual increase in size and mass of the atoms of Group 2 elements, we expect a regular gradation in their properties. The gradation in some of the properties is discussed below :

1. The atomic and ionic radii increase on going from beryllium to barium.
2. The first as well as second ionisation energies decrease on moving from beryllium to barium.
3. The electropositive character as well as the reducing action and chemical reactivity increase gradually on moving down the group. These trends can be attributed to the gradual decrease in ionisation energies of these elements.

4. The oxides of all the metals dissolve in water to form basic hydroxides. The heat of formation of the hydroxides increases from beryllium to barium.
5. The basic character of the hydroxides increases gradually on moving down the group.
6. The tendency to form higher oxides, such as peroxides, increases on moving down the group.
7. The stability of the carbonates of the alkaline earth metals increases on moving down the group. This is illustrated by the temperature at which the carbonates decompose :

$BeCO_3$: < 100°C $MgCO_3$: 540°C $CaCO_3$: 900°C

$SrCO_3$: 1290°C $BaCO_3$: 1360°C

8. Beryllium and magnesium have hexagonal close packed (hcp) structure while calcium and strontium have face-centred cubic (fcc) structure

Comparison of Beryllium with Other Elements of Group 2. Beryllium, the first element of Group 2, differs considerably from the rest of the elements of this group. This is partly due to its *small size* and partly due to its *relatively high electronegativity*. The main points of difference are as follows.

1. Tendency to form ionic compounds. Ionisation energy of beryllium (899 kJ mol^{-1}) is the highest. Consequently, it has the lowest tendency to form the ion, Be^{2+}. Accordingly it does not form ionic compounds readily.

2. Tendency to form covalent compounds. Electronegativity of beryllium (1·5) is more than that of any other element of the family (Table 1). Hence, its compounds with oxygen, chlorine, nitrogen, sulphur, etc., are more **covalent** in character than the corresponding compounds of magnesium, calcium, strontium and barium.

3. Reaction with water. Beryllium does *not* react with water even at elevated temperatures. Its reaction with steam forming beryllium oxide, BeO and liberating hydrogen is doubtful.

4. Oxidation potential. Beryllium has the lowest oxidation potential (Table 2) which indicates that it has the lowest electropositive character. Consequently, BeO and $Be(OH)_2$ are not at all basic in character. They are, in fact, amphoteric and dissolve in acids to form salts and in alkalies to form beryllates, Na_2BeO_2.

The oxides and hydroxides of the other metals are basic in character. The basic character increases on moving down the group. Magnesium hydroxide is weakly basic while calcium, strontium and barium hydroxides are distinctly basic, their strengths increasing in the order of their mention.

5. Reaction with acids. Beryllium, on account of its relatively lower oxidation potential, does not liberate hydrogen from acids so readily as the rest of the metals of Group 2 do.

6. Reaction with hydrogen. Beryllium does not combine directly with hydrogen to give the hydride. All other elements of the group do. Beryllium hydride is a covalent compound. Magnesium hydride is also a covalent compound. The hydrides of the remaining elements are, however, electrovalent in character.

7. Reaction with halogens. All the metals of this group form halides by direct combination with the halogens at appropriate temperatures. Beryllium halides are, however, covalent while the other halides are electrovalent compounds.

8. Reaction with nitrogen. All the elements of this group react with nitrogen to give nitrides, M_3N_2, as already stated. However, beryllium nitride is volatile while the other nitrides are not.

9. Formation of carbides. All the elements, from magnesium to barium, give ionic carbides, MC_2, when the metals or their oxides are heated with carbon. Beryllium, on the other hand, gives Be_2C and not BeC_2 when heated with carbon. Beryllium carbide, Be_2C, evolves methane on treatment with water while the other carbides evolve acetylene.

$$Be_2C + 2H_2O \longrightarrow 2BeO + CH_4$$

$$CaC_2 + 2H_2O \longrightarrow Ca(OH)_2 + C_2H_2$$

10. Formation of complexes. The alkaline earth metal ions do not form many complexes. However, beryllium ion, on account of its small size, gives a number of stable complexes, such as $[BeF_3]^-$ and $[BeF_4]^{2-}$.

The tendency to form complexes decreases on moving down the group. Thus, barium forms very few complexes.

Diagonal Relationship between Beryllium and Aluminium. Beryllium differs from other alkaline earth metals, as has already been discussed. It shows some similarities with aluminium, the second element of the next (third) group, a case of *diagonal relationship*. The polarising power of Be is comparable with that of Al. This is the main cause of the diagonal relationship, as explained in Chapter 12.

The similarities in the chemistry of Be and Al are given below.

1. Beryllium atom is small and, therefore, has a high charge density. It has, therefore, a strong tendency to form covalent compounds. Aluminium, too, has a strong tendency to form covalent compounds.
2. Standard oxidation potentials of these elements are quite close to each other.
3. Beryllium, like aluminium, is rendered passive on treatment with concentrated nitric acid.
4. Beryllium, like aluminium, forms many complexes.
5. Beryllium oxide, like aluminium oxide, is amphoteric. It dissolves in acids as well as in alkalies.

$$BeO + 2HCl \longrightarrow BeCl_2 + H_2O$$
$$BeO + 2NaOH \longrightarrow Na_2BeO_2 + H_2O$$
$$Al_2O_3 + 6HCl \longrightarrow 2AlCl_3 + 3H_2O$$
$$Al_2O_3 + 2NaOH \longrightarrow 2NaAlO_2 + H_2O$$

6. Beryllium and aluminium both react with sodium hydroxide liberating hydrogen.

$$Be + 2NaOH \longrightarrow Na_2BeO_2 + H_2$$
$$2Al + 2NaOH + 2H_2O \longrightarrow 2NaAlO_2 + 3H_2$$

7. Beryllium carbide Be_2C and aluminium carbide (Al_4C_3) both evolve methane on treatment with water.

$$Be_2C + 2H_2O \longrightarrow CH_4 + 2BeO$$
$$Al_4C_3 + 6H_2O \longrightarrow 3CH_4 + 2Al_2O_3$$

8. Halides of beryllium and aluminium are similar in their solubilities.

Uses of Alkaline Earth Metals. Pure beryllium and beryllium oxide are used in nuclear reactors. Beryllium is also used in alloys. It causes hardening of metals, notably of copper, when added in traces.

Magnesium is used as structural material because of its lightness and its property to form alloys with other metals. Its alloys with aluminium, manganese and zinc are particularly important as structural materials. It forms Grignard reagents, RMgX, which are important reagents in organic chemistry. Finely divided magnesium burns brightly emitting intense white light.

Calcium, strontium and barium when exposed to air get oxidised and after sometime the oxides strip off exposing fresh surface again to air and so on. This property makes them useful as deoxidisers in the manufacture of steel. Radio tubes have generally an inner lining of barium metal so as to eliminate any oxygen that may be present in the tube.

EXTRACTION OF ALKALINE EARTH METALS

Extraction of Beryllium. Beryllium occurs mostly in complex silicates like felspar and mica. The mineral *beryl*, which is a crude emerald of composition [$Be_3Al_2(SiO_3)_6$], is the only important source of the element.

The first step in the extraction of beryllium is to obtain BeO from the mineral *beryl*. For this purpose, the mineral is pulverised and the powder treated with sulphuric acid when beryllium sulphate and aluminium sulphate are formed. Aluminium sulphate is removed by the addition of ammonium sulphate when the

double salt of aluminium sulphate and ammonium sulphate crystallises out. Beryllium sulphate alone remains in solution. It is separated and calcined in a rotary kiln at 1450°C to get beryllium oxide.

BeO is then reduced with carbon and copper in an electric arc furnace shown in Fig. 1. The lower part of the furnace is made of carbon and serves not only as a receptacle for the charge but also acts as one of the electrodes for the arc. The other carbon electrodes are held vertically and dip in the charge. They can be lowered or raised to a desired extent so as to strike the arc in the furnace. Beryllium oxide is well powdered and mixed with powdered coke and charged in the furnace through the door shown on the right. When the temperature of the furnace rises, carbon takes away oxygen of the oxide forming carbon monoxide which escapes through the outlet shown on the left. The metal beryllium is removed through the tapping hole at the bottom of the furnace.

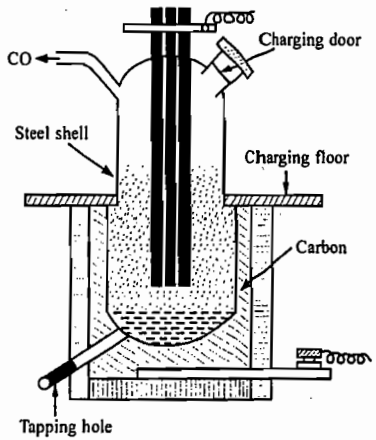

Fig. 1. Extraction of beryllium.

Extraction of Magnesium. Magnesium is widely distributed in nature. Its important ores are *Magnesite*, $MgCO_3$; *dolomite*, $MgCO_3.CaCO_3$; *carnallite*, $KCl.MgCl_2.6H_2O$; *asbestos*, $CaMg_3(SiO_3)_4$, etc. It is an essential constituent of chlorophyll, the green colouring matter of plants. Halides of magnesium are found in sea water.

The metal is usually extracted by the electrolysis of *fused* magnesium chloride or magnesium oxide. Carnallite ore is used as the source of $MgCl_2$ and magnesite ore is calcined to get MgO. $MgCl_2$ can also be obtained from sea water in which magnesium is present as $MgSO_4$ and $MgCl_2$. These salts are first precipitated as $Mg(OH)_2$ by treatment with slaked lime and $Mg(OH)_2$ is then converted to $MgCl_2$ by treatment with HCl.

From MgO, the metal can also be obtained by its reduction by carbon, silicon or aluminium at about 2000°C in vacuum. The metal is distilled away and condensed.

Extraction of Calcium. Calcium occurs largely in the form of carbonates and sulphates. Calcium carbonate occurs in a number of forms, the more important of which are *limestone, chalk, calcite, marble, spardolomite, stalactite, stalacmite,* etc. As sulphate, it occurs in the form of *gypsum* ($CaSO_4.2H_2O$) and *anhydrite* ($CaSO_4$).

Calcium also occurs as phosphate, $Ca_3(PO_4)_2$, in the phosphorite rock and in bones ; as fluoride, CaF_2, in *fluorspar* and as calcium silicate, $CaSiO_3$, in many complex rocks. Calcium is an essential constituent of bones, teeth, sea shells and egg shells. Its soluble compounds are found in sea water and are assimilated by sea animals and changed into calcium carbonate which forms their outer protective shells.

The metal is extracted by the electrolysis of *fused* calcium chloride mixed with about 10 per cent of calcium fluoride in a graphite vessel using iron cathode and graphite anode.

Extraction of Strontium. Strontium occurs as $SrSO_4$ in the mineral *celestine* and as $SrCO_3$ in the mineral *strontianite*.

The metal is obtained by the electrolysis of a *fused* mixture of strontium chloride and ammonium chloride using iron cathode and graphite anode.

Extraction of Barium. Barium occurs as $BaCO_3$ in the mineral *witherite* and more widely as $BaSO_4$ in the mineral *barytes*.

The metal is obtained by the electrolysis of *fused* barium chloride using mercury cathode and graphite anode when barium amalgam separates out. On distilling, mercury volatilises off leaving behind barium.

Extraction of Radium. All uranium minerals contain radium in minute quantities. *Pitchblende* and *carnotite*, the two important uranium ores, are the chief sources of radium.

The metal is obtained by the electrolysis of *fused* radium chloride using a platinum-iridium anode and a mercury cathode. The radium amalgam formed is distilled at 400 – 600°C when mercury distils off leaving behind radium.

PROPERTIES AND USES OF ALKALINE EARTH METALS

Properties of Beryllium. Physical Properties. Beryllium is a steel-grey, light and hard metal. It has the highest melting point (1277°C) and boiling point (2770°C) of all the elements of Group 2. Be is slowly oxidised in moist air. On heating in air it burns with dazzling light. The other chemical properties of beryllium have already been discussed along with general properties of alkaline earth metals.

Uses. Beryllium, although a rare metal, finds many applications. Its importance has increased all the more due to its use in nuclear reactors. The most important uses of beryllium are : *1. In Making Alloys.* A large number of alloys containing beryllium are being used in industry. The presence of 0·005 per cent of beryllium in magnesium greatly reduces its combustibility and thus renders casting much easier. Addition of 0·2 per cent of beryllium improves the casting properties of aluminium. The addition of 0·1 per cent of beryllium to platinum gives an alloy as hard as is obtained by the addition of 10 – 15 per cent of iridium. *2. In X-ray Tubes.* Because of its high permeability to X-rays, beryllium sheets are used for windows of the X-ray tubes. *3. In Nuclear Reactors.* Beryllium salts are used as a source of neutrons. When a beryllium salt is bombarded with alpha particles, neutrons are produced.

$$^{9}_{4}Be + ^{4}_{2}He\ (\alpha \text{ particles}) \longrightarrow ^{12}_{6}C + ^{1}_{0}n$$

Properties of Magnesium. Magnesium is a silvery-white metal which soon becomes dull in air. It is a light metal with a specific gravity of 1·74. It is fairly malleable and ductile. It melts at 650°C and boils at 1107°C.

Magnesium is a fairly reactive metal although much less reactive than calcium, strontium and barium of the same group.

It is stable in dry air but is slowly tarnished in moist air due to the formation of a film of the oxide, MgO. It burns in oxygen or air with a dazzling light forming a dense white smoke of the oxide.

On account of its great affinity for oxygen, magnesium keeps burning even in carbon dioxide.

$$2Mg + CO_2 \longrightarrow 2MgO + C$$

Magnesium forms a number of organometallic compounds which are of special importance in the synthesis of organic compounds. These are discussed in details in Chapter 34 on Organometallic Compounds.

The other chemical properties of Mg have already been discussed along with general properties of alkaline earth metals.

Uses of Magnesium. Magnesium, on account of its lightness, great affinity for oxygen and toughness, is used for many purposes in industry as well as in laboratory. It is thus used 1. *For Making Alloys.* Magnesium is used in making a number of useful alloys which are light but strong and durable. They are used for many purposes as in automobile industry and engineering, fabrication of aircraft and optical instruments and so on. *2. For Extraction of Boron and Silicon.* Magnesium is used for the extraction of boron and silicon by the ignition of the metal in the presence of B_2O_3 and SiO_2. *3. In Aluminothermic Process.* Magnesium ribbon is used for igniting the thermite in aluminothermic process. *4. As a Deoxidizer.* It is used as a deoxidizer for removing last traces of oxygen from copper, steel, etc. *5. As Grignard Reagents.* Magnesium in the form of Grignard reagents is largely used for synthesis of many organic compounds.

Properties of Calcium. Calcium is a greyish white crystalline metal with silvery lustre. It is harder than lead and is malleable. It may be stored without any special precaution. However, moisture should be

kept away from it. Chemical properties of calcium have already been described while discussing properties of alkaline earth metals in general.

Uses. The metal is used in preference to sodium in removing traces of water from alcohol because, unlike sodium, it does not react with alcohol. It is used as a deoxidiser for copper, cast iron and steel and a desulphurizer in oil refining. When alloyed with lead it is used as a cable covering. When alloyed with aluminium it is used in casting and forging. It is also used in reducing oxides and fluorides of beryllium, uranium, plutonium, thorium, etc.

Properties of Strontium, Barium and Radium. ***Strontium*** is a soft silvery-white metal of specific gravity 2·54, melting at 768°C. It is malleable and ductile. It closely resembles calcium both in physical and chemical properties although it is more reactive.

Barium resembles calcium and strontium in its physical as well as chemical properties although it is most reactive of the three metals. It decomposes water more readily and combines with oxygen more easily than either calcium or strontium. When in the powdered state it catches fire spontaneously on exposure to air. It is malleable at 850°C. Its specific gravity is 3·75.

Radium, in many of its physical and chemical properties, resembles barium. It is a silvery-white metal. It melts at about 700°C and vaporizes at a slightly higher temperature. It is thus more volatile than barium. Radium at once turns black when exposed to atmosphere because of the formation of a film of radium nitride, Ra_3N_2. The metal decomposes water forming the hydroxide and liberating hydrogen.

The most outstanding property of radium is the spontaneous emission of radiations, *viz.*, alpha, beta and gamma rays. This is the well known phenomenon of radioactivity. Radium and its salts are strongly radioactive.

COMPOUNDS OF ALKALINE EARTH METALS

I. A Comparative Study

Oxides. The oxides are formed either by heating the metals in oxygen or by heating carbonates at high temperature.

Beryllium oxide is a very hard solid. It can scratch even quartz. Beryllium oxide has a wurtzite structure with 4 : 4 coordination while the rest of the oxides have NaCl type lattices with 6 : 6 coordination. The oxides are highly stable due to large ionic crystal lattice energies. The values are so high in the case of oxides of beryllium and magnesium that these compounds are almost insoluble in water. The oxides of the rest of the elements react with water to yield hydroxides which are basic in character.

Beryllium oxide is amphoteric while the oxides of the rest of the elements are basic in character. Magnesium oxide and calcium oxide (lime) are used as basic linings in furnaces.

In addition to the oxides MO (M = alkaline earth metal), peroxides MO_2 of Ca, Ba, Sr are also known. There is also some evidence for the existence of superoxides $Ca(O_2)_2$ and $Sr(O_2)_2$.

The ozonides $Ba(O_3)_2$ and $Ca(O_3)_2$ have also been reported.

Hydroxides. The oxides, except beryllium oxide and magnesium oxide, dissolve in water forming hydroxides evolving a large amount of heat.

The hydroxides though basic in character are less basic than the hydroxides of alkali metals. The basic character, however, increases on moving down the group. $Be(OH)_2$ is amphoteric in character.

The solubility of the hydroxides increases with increase in atomic number of the element. Thus, beryllium hydroxide and magnesium hydroxide are almost insoluble in water. The hydroxides of other metals are slightly soluble and the solubility increases on moving down the group, as shown by their solubility products (Table 3).

Sulphates. Beryllium sulphate is slightly soluble in water. However, solubility of sulphates *decreases* regularly on going down the group so much so that barium sulphate and radium sulphate are practically insoluble. The solubility products of the various sulphates at ordinary temperatures are given in Table 3.

TABLE 3
Solubility Products of Hydroxides and Sulphates of Alkaline Earth Metals

Hydroxides	Solubility Product	Sulphates	Solubility Product
$Be(OH)_2$	$1{\cdot}6\times10^{-26}$	$BeSO_4$	very high
$Mg(OH)_2$	$8{\cdot}9\times10^{-12}$	$MgSO_4$	high
$Ca(OH)_2$	$1{\cdot}3\times10^{-4}$	$CaSO_4$	$2{\cdot}4\times10^{-5}$
$Sr(OH)_2$	$3{\cdot}2\times10^{-4}$	$SrSO_4$	$7{\cdot}6\times10^{-7}$
$Ba(OH)_2$	$5{\cdot}4\times10^{-2}$	$BaSO_4$	$1{\cdot}5\times10^{-9}$
		$RaSO_4$	$4{\cdot}0\times10^{-11}$

Magnesium sulphate is available in the form of its heptahydrate, $MgSO_4.7H_2O$ (*epsom salt*) and is used in medicine as a purgative.

Calcium sulphate occurs as the mineral *gypsum* ($CaSO_4.2H_2O$). When heated carefully, it gets partially dehydrated giving *plaster of paris*, $CaSO_4.1/2\ H_2O$. The semihydrate is also written as $(CaSO_4)_2.H_2O$.

Barium sulphate, $BaSO_4$, is used as a white pigment.

Comparison of solubility products of hydroxides and sulphates. It may be interesting to note that the solubility products of the hydroxides of these metals increase on going down the group (Table 3). Then, why do the solubility products of the sulphates follow the reverse order ?

The solubility of an ionic solid in water depends upon two factors : *Lattice energy, i.e.,* the energy with which the ions of the solid are held together in a crystal and (*ii*) *hydration energy, i.e.,* the energy evolved as heat when the ions of the solid get hydrated. These two factors tend to oppose each other. If lattice energy is high, it would imply that the ions are packed tightly in a crystal and, therefore, the solubility will be low. If hydration energy is high, the ions will have a greater tendency to be hydrated and, therefore, the solubility will be high.

In the case of the sulphates of alkaline earth metals, the lattice energies are about the same. The sulphate ion itself is so large (radius ≈ 3Å) that relatively small changes in metallic ionic sizes from Be^{2+} to Ba^{2+} do not make any material difference. However, the hydration energies of the metal cations, from Be^{2+} to Ba^{2+}, *decrease* in this order (Table 1). Hence, the solubilities of the sulphates decrease in the same order, *i.e., the solubilities decrease with increase in ionic size.*

In the case of the hydroxides, the lattice energies are different because hydroxide ion is not large and, therefore, even small changes in metallic ionic sizes do make a difference. Thus, as the metallic ionic size increases on moving from beryllium to barium, the lattice energy decreases. This tends to enhance the solubility and to overcome the counter-effect produced by the decrease in hydration energy. Hence, *the solubilities of the hydroxides increase on moving down the group.*

Hydrides. Beryllium hydride is prepared by reducing beryllium chloride with lithium aluminium hydride.

$$2BeCl_2 + Li[AlH_4] \longrightarrow 2BeH_2 + LiCl + AlCl_3$$

The rest of the metals form hydrides when heated with hydrogen.

The hydrides are white powders and react with water liberating hydrogen. Calcium hydride thus serves as a portable supply of hydrogen.

BeH_2 is covalent while MgH_2 is partly covalent and partly ionic. The remaining hydrides are largely ionic.

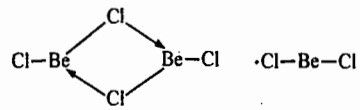
Carbonates and Bicarbonates. The carbonates of these metals are insoluble in water and, therefore, occur as solid rock minerals in nature. Limestone is the most important mineral containing calcium carbonate.

The carbonates, however, dissolve in water containing carbon dioxide yielding bicarbonates.

The soluble bicarbonates of calcium and magnesium impart hardness to water. This type of hardness is known as temporary hardness since it disappears on heating on account of the precipitation of the carbonates.

The bicarbonates are *stable only in solution.* Their decomposition to carbonates is responsible for the formation of *stalactites* and *stalagmites.*

Halides. The metals combine directly with halogens on heating at appropriate temperatures forming halides, MX_2. The halides can also be obtained by reacting metal carbonates with dilute halogen acids. Beryllium halide $BeCl_2$ in which Be orbitals are *sp* hybridised, has zero dipole moment. The structures of dimeric and monomeric beryllium chloride are given below :



Most of the anhydrous halides have fluorite-type structure.

Carbides. Metals from magnesium to barium or their oxides, when heated with carbon, give carbides with formula, MC_2. For example,

$$CaO + 3C \longrightarrow CaC_2 + CO$$

Beryllium under similar conditions gives beryllium carbide with formula Be_2C.

$$2BeO + 3C \longrightarrow Be_2C + 2CO$$

The carbides with formula MC_2 (*e.g.,* CaC_2) react with water to yield acetylene while Be_2C under similar conditions yields methane.

$$CaC_2 + 2H_2O \longrightarrow Ca(OH)_2 + C_2H_2$$

$$Be_2C + 2H_2O \longrightarrow 2BeO + CH_4$$

Organometallic Compounds of Group 2 Elements

These have been discussed in details in Chapter 34 on Organometallic Compounds.

II. Some Important Compounds of Group 2 Elements

Beryllium oxide, BeO. It is prepared by burning beryllium in air or by heating beryllium hydroxide, carbonate or nitrate.

Beryllium oxide is a white powder and is insoluble in water. It is amphoteric and, when freshly prepared, it dissolves in both acids and alkalies. On fusion, it changes to a very hard mass which is difficult to dissolve in acids or alkalies.

It remains unchanged by heating in air. When strongly heated with carbon, silicon or boron, it yields the carbide, Be_2C_2 ; silicide, Be_2Si or the boride, Be_3B_2.

Because of its very high melting point (2570°C), beryllium oxide is used as refractory material.

Beryllium Chloride, $BeCl_2$. It is prepared by burning the metal in an atmosphere of chlorine or by the action of hydrogen chloride on the metal.

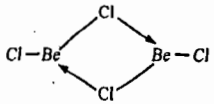
Beryllium chloride is a white crystalline solid, melting at 44°C. It fumes in air like PCl_5 and is very readily hydrolysed in the presence of water.

$$BeCl_2 + H_2O \longrightarrow BeO + 2HCl \ ; \ BeCl_2 + 2H_2O \longrightarrow Be(OH)_2 + 2HCl$$

Beryllium chloride dissolves freely in water with the evolution of heat. The ion $[Be(H_2O)_4]^{2+}$ is formed and on crystallization, the salt $[Be(H_2O)_4]Cl_2$ is deposited. It holds its water of crystallisation so strongly that it is not dehydrated at all even by several month's exposure to P_2O_5.

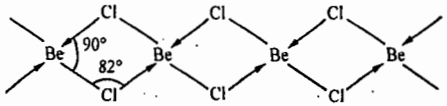
$BeCl_2$ in vapour phase at above 900°C is *monomeric* having a linear structure Cl – Be – Cl. The bonding in $BeCl_2$ is covalent and Be atom accommodates 2 + 2 = 4 electrons in the two *sp* hybrid orbitals.

Below 900°C, beryllium chloride in vapour phase exists as a mixture of monomer $BeCl_2$ and dimer Be_2Cl_4. The dimer has the bridge structure, as shown :



Apart from this, each Be atom in Be_2Cl_4 dimer has two Be – Cl bonds. Thus, each Be atom in Be_2Cl_4 utilises three sp^2 hybrid orbitals to accommodate $2 + 2\times1 + 1\times2 = 6$ electrons.

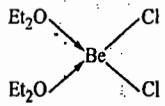
In solid state, $BeCl_2$ has a polymeric structure as shown below :



In this structure, each Be atom is covalently bonded to two Cl atoms. Two of the bridging Cl atoms from two different Cl bridges coordinate with each Be atom donating $2\times2 = 4$ electrons for the Be←Cl bond formation. Thus, each Be atom utilises four sp^3 hybrid orbitals to accommodate $2 + 2\times1 + 2\times2 = 8$ electrons and the geometry around each Be atom is tetrahedral.

$BeCl_2$ in Solution. When solid $BeCl_2$ is dissolved in a coordinating solvent, the infinitely long bridge structure breaks down to liberate $BeCl_2$ monomers in solution. If the solvent molecules are weak coordinators, $BeCl_2$ forms species of the type L_2BeCl_2 where L represents the weak coordinating solvent molecule. Thus, we have

$$BeCl_2 + 2Et_2O \rightleftharpoons$$



The structure of L_2BeCl_2 formed is tetrahedral and the Be atom utilises the four sp^3 hybrid orbitals to accommodate $2 + 2\times1 + 2\times2 = 8$ electrons.

If, however, the solvent molecule is comparatively a stronger coordinator, $BeCl_2$ forms an ionic species of the type $[BeL_4]^{2+}2Cl^-$ where L is NH_3 or H_2O. Thus, we have

$$BeCl_2 + 4H_2O \longrightarrow [Be(H_2O)_4]^{2+}2Cl^-$$

Each coordinated atom donates two electrons to Be^{2+} ion so that the central ion requires four sp^3 hybrid orbitals to accommodate $0 + 4\times2 = 8$ electrons. The geometry of $[BeL_4]^{2+}$ ion would, evidently, be tetrahedral.

Beryllium Sulphate, $BeSO_4.4H_2O$. It is prepared by dissolving beryllium oxide in hot concentrated sulphuric acid. It crystallizes from an aqueous solution as the tetrahydrate, $BeSO_4.4H_2O$.

Beryllium sulphate tetrahydrate loses water at 400°C to give the anhydrous salt. The anhydrous beryllium sulphate does not decompose below 500°C. On heating beyond this temperature, it decomposes to form the oxide.

The tetrahydrate is highly soluble in water but the anhydrous sulphate is almost insoluble in cold water. With hot water, however, the anhydrous salt reacts to form the tetrahydrate which dissolves freely.

All the four water molecules in $BeSO_4.4H_2O$ are, in fact, coordinated to Be^{2+} ion and the actual structure is $[Be(H_2O)_4]^{2+}SO_4^{2-}$. The Be^{2+} ion utilises four sp^3 hybrid orbitals to accommodate 8 electrons from the coordinating water molecules and the structure of $[Be(H_2O)_4]^{2+}$ ion is thus tetrahedral.

Basic Beryllium Acetate. When BeO or $Be(OH)_2$ reacts with acetic acid, it gives a compound of the formula $Be_4O(CH_3COO)_6$ which is known as basic beryllium acetate. This compound is a white crystalline solid and is readily soluble in organic solvents. It is insoluble in polar solvents indicating that it is not an ionic compound.

The structure of basic beryllium acetate contains a tetrahedral Be_4 cluster with an O atom at the centre of this tetrahedron. The six edges of the Be_4 tetrahedron are occupied by the six acetato groups in such a way that each Be atom is also tetrahedrally coordinated to four O atoms of the acetato groups, as shown in Fig. 2. The solid lines between the atoms in Fig. 2. simply show the association between the atoms and *not the exact bond order*.

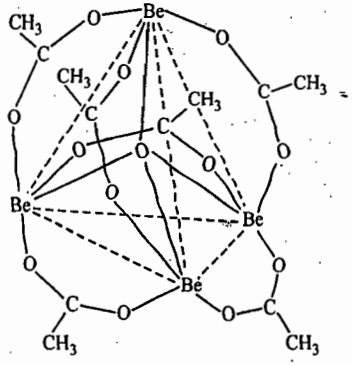


Fig. 2. Structure of basic beryllium acetate, $Be_4O(CH_3COO)_6$.

Basic beryllium acetate melts at 285°C and boils at 333°C. It is slowly hydrolysed by hot water. It is rapidly decomposed by mineral acids to give the corresponding salts and free acetic acid.

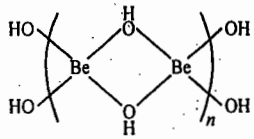
$$Be_4O(CH_3COO)_6 + 8HCl \longrightarrow 4BeCl_2 + H_2O + 6CH_3COOH$$

Basic Beryllium Nitrate. When $BeCl_2$ is heated with N_2O_4, the product is $[Be_4O(NO_3)_6]$. This is called basic beryllium nitrate.

$$4BeCl_2 + 7H_2O + 6N_2O_4 \longrightarrow [Be_4O(NO_3)_6] + 8HCl + 6HNO_2$$

The structure of basic beryllium nitrate is similar to that of basic beryllium acetate with the only difference that while the basic beryllium acetate contains acetato bridges Be – O – C(CH_3)– O – Be, the basic nitrate contains the nitrato bridges Be – O – N(O) – O – Be. The lines between the atoms in both the types of bridges do not indicate the exact bond order.

Tetrahydroxo Beryllate Ion, $[Be(OH)_4]^{2-}$. Beryllium salts hydrolyse readily in the presence of an alkali to give hydroxo complexes of ill-defined composition. Further addition of alkali redissolves the precipitated hydroxo complexes to give hydroxo bridged structures of the type shown :



Still further addition of alkali breaks the hybroxo bridge by adding more OH^- ions per Be atom and leads to the formation of $Be[(OH)_4]^{2-}$ complex ion in which Be atom is tetrahedrally bonded to four OH^- ions.

Calcium Carbide, CaC_2. This is one of the most important compounds of calcium. It is manufactured by heating lime with powdered coke at about 3000°C in an electric furnace.

$$CaO + 3C \longrightarrow CaC_2 + CO$$

The furnace is made of fire-clay bricks and has a thick layer of graphite at the bottom. This serves as one electrode. A block of graphite suspended from the middle serves as the second electrode. Calcium carbide formed in the molten state is taken out from a tapping hole provided near the bottom of the furnace.

Calcium carbide is a hard crystalline solid. The pure product is white but the commercial product is generally grey, the depth of the colour increasing with the extent of impurities.

It reacts with water yielding acetylene.

It reacts with nitrogen at red heat to yield calcium cyanamide.

$$CaC_2 + N_2 \longrightarrow CaNCN + C$$

The mixture of calcium cyanamide and carbon is used as such as a fertilizer under the name **nitrolim**. It gets hydrolysed supplying ammonia to the soil :

$$CaNCN + 3H_2O \longrightarrow CaCO_3 + 2NH_3$$

Calcium carbide is used for the preparation of acetylene gas and for the manufacture of calcium cyanamide which is used as a fertilizer.

Calcium carbide is an ionic solid. Its lattice consists of Ca^{2+} and $(C\equiv C)^{2-}$ ions. The radius ratio $Ca^{2+}/(C\equiv C)^{2-}$ is 0·52 which is close to Na^+/Cl^- ratio in sodium chloride. Its structure, therefore, should be essentially similar to that of sodium chloride, *i.e.*, with coordination number equal to 6. Thus, each Ca^{2+} ion should be surrounded by six carbide ions which should lie at the six corners of a regular octahedron. The shape of the carbide ion itself, however, is such that the unit cell undergoes some elongation in one direction.

Calcium Cyanamide, $CaCN_2$. It is prepared by heating calcium carbide in nitrogen at 1000°C, in an electric furnace. The reaction is highly exothermic evolving a considerable amount of heat.

$$CaC_2 + N_2 \longrightarrow CaCN_2 + C; \qquad \Delta H = -304{\cdot}2\ kJ$$

Calcium cyanamide, mixed with carbon, as obtained in the reaction, is used as a nitrogenous fertilizer as mentioned above. In the soil it first changes into calcium carbonate and cyanamide.

$$CaCN_2 + H_2O + CO_2 \longrightarrow CaCO_3 + \underset{\text{Cyanamide}}{H_2N.CN}$$

The cyanamide then hydrolyses in two stages ultimately giving ammonia.

$$H_2N.CN + H_2O \longrightarrow \underset{\text{Urea}}{CO(NH_2)_2}$$

$$CO(NH_2)_2 + H_2O \longrightarrow CO_2 + 2NH_3$$

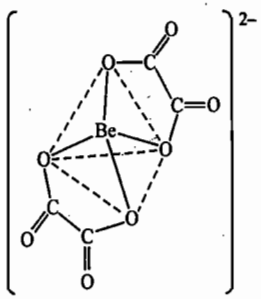


Fig. 5. Structure of beryllium oxalate, $[Be(Ox)_2]^{2-}$ ion.

Ammonia is converted into nitrates through the agency of nitrifying bacteria. On account of its slow conversion into ammonia and nitrates, calcium cyanamide is a valuable fertilizer as its effects are of a prolonged nature. The formation of calcium carbonate in the process is also useful from agricultural point of view.

Calcium cyanamide is also used in the manufacture of ammonia on treatment with superheated water.

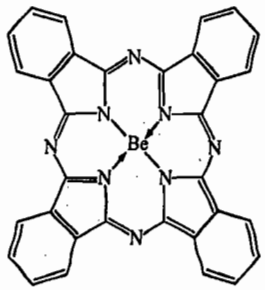
$$CaCN_2 + 3H_2O \longrightarrow CaCO_3 + 2NH_3$$

(superheated)

Complexes of Beryllium

Complexes with highly conjugated planar ligands. Although the complexes of beryllium containing Be–X and Be–O bonds are quite common, its complexes with N-containing ligands are quite rare. However, highly conjugated N-containing ligands form fairly stable complexes with Be. The rigid, planar ring system of the ligand imposes upon Be a square planar geometry of BeN_4.

The Be complex of one such ligand is known to have the structure as shown.



This complex readily picks up two water molecules, one of which coordinates from above the plane of the chelate ring and the other from below it so that the N→Be bonds in the complex are replaced by two H_2O→Be bonds in such a way that a tetrahedral BeN_2O_2 structure is obtained.

Halide Complexes of Beryllium. Be, because of its small size, forms stable complexes with halogens, as, for example, $[BeF_3]^-$ and $[BeF_4]^{2-}$.

The complex ion, $[BeF_3]^{2-}$, involves sp^2 hybridisation and, therefore, has a planar trigonal structure, as shown in Fig. 3.

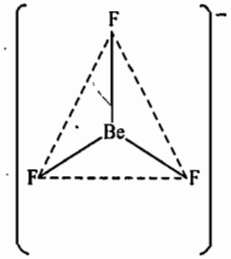


Fig. 3. Planar trigonal structure of $[BeF_3]^-$ complexion.

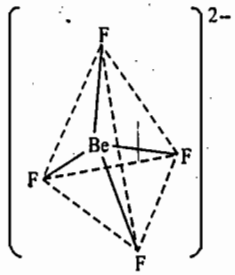

Fig. 4. Tetrahedral structure of $[BeF_4]^{2-}$ complexion.

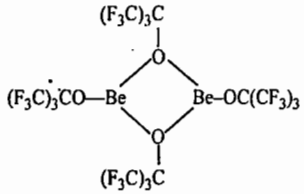
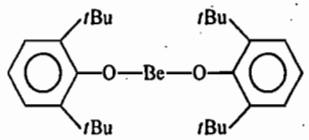
The complex ion $[BeF_4]^{2-}$ involves sp^3 hybridisation and hence has a tetrahedral structure (Fig. 4.).

Beryllium also forms a complex compound with oxalic acid. The complex anion $[Be(OX)_2]^{2-}$ is known to have a tetrahedral structure.

Although the coordination number of Be in its complexes is usually four, it can reduce its coordination number to three or even to two if there is crowding of the ligands to prevent the adjustment of four ligands around the Be atom. The structures of two complexes in which the bulk of the ligands reduces the coordination number of Be are given below :



(Be has a coordination number 3)



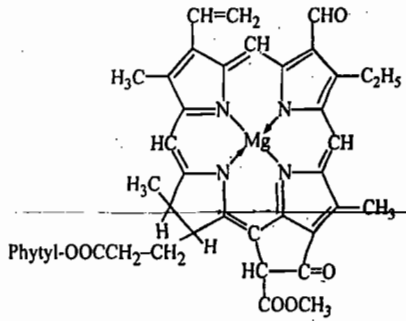
(Be has a coordination number 2)

Complexes of Magnesium. Magnesium forms tetrahedral halide complexes of the type $[(C_2H_5)_4N]_2[MgCl_4]$. The chelates of magnesium with EDTA and pyrophosphates are also known. However, the most important complex of magnesium is the naturally occurring **chlorophyll,** the green pigment present in plants, which photosensitises the synthesis of carbohydrates in nature from CO_2 and H_2O :

$$6CO_2 + 6H_2O \xrightarrow[\text{sunlight}]{\text{chlorophyll}} C_6H_{12}O_6 + 6O_2$$

The structure of chlorophyll is as shown. The macrocyclic ligand involved is derived from the parent tetrapyrrole molecule, porphylin.

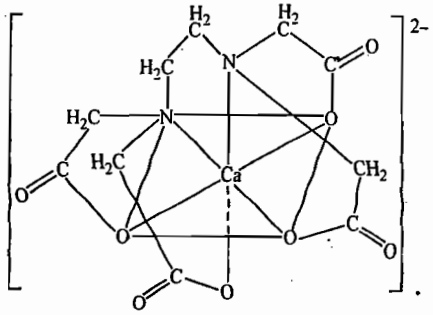
The Mg atom in chlorophyll lies slightly above the plane of the rigid chelate ring structure. The chlorophyll molecule can add to it one or two water molecules axially. Such coordinated water molecules then help in associating other chlorophyll molecules through hydrogen bonding.



Structure of chlorophyll

Complexes of Calcium, Strontium and Barium. Amongst the complexes of Ca^{2+}, Sr^{2+} and Ba^{2+}, the water soluble complex of Ca^{2+} with EDTA is the most important because of its analytical application. Its

structure is as shown :



Ca^{2+}, Sr^{2+} and Ba^{2+} also form complexes with certain specific crown ethers and cryptates.

PORTLAND CEMENT

Portland cement is one of the most important building materials at the present time. It was first discovered in England in the last century. As on setting it hardened to a stone-like mass, it was likened to the famous Portland rock of England and named as Portland cement. It is essentially a mixture of calcium silicates and calcium aluminates with small amounts of added gypsum. The essential constituents are lime, silica, aluminium oxide, magnesium oxide and ferric oxide. The approximate composition is :

Calcium oxide	(CaO) =	50 – 60 per cent
Silica	(SiO_2) =	20 – 25 per cent
Alumina	(Al_2O_3) =	5 – 10 per cent
Magnesium oxide	(MgO) =	2 – 1 per cent
Ferric oxide	(Fe_2O_3) =	1 – 2 per cent
Sulphur trioxide	(SO_3) =	1 – 2 per cent

The essential **raw materials** used are lime stone and clay. Lime stone provides calcium oxide and clay provides silica as well as alumina and ferric oxide. The ratio of silica to alumina lies between 4 and 2·5 while that of calcium oxide to silica + alumina + ferric oxide, should be as close to 2 as possible. If lime is in excess, the cement cracks during setting. If lime is less than required by the above ratio, the cement is weak in strength. There is very little free lime in the cement. Almost the entire amount of it is present in the combined state as calcium silicates and calcium aluminates.

Manufacture. The raw meterials, limestone and clay, are first crushed separately in a suitable machine. The clay is washed with water in a wash mill to remove the foreign material and then powdered lime is added and the two ingredients are finely ground and homogenised. This slurry, containing about 40 per cent of water is introduced into the upper end of the rotary kiln (Fig. 5) which consists of an inclined steel rotating cylinder, 150—200 feet long and 10 feet in diameter lined with bricks. The rotary kiln is heated by coal gas.

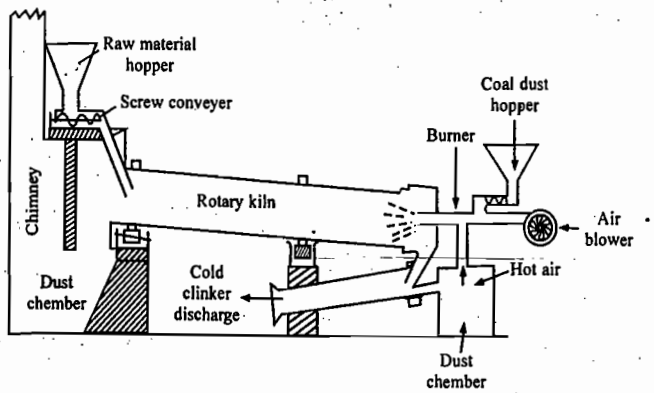


Fig. 5. Manufacture of Cement

In the upper portion of the kiln, the material is heated to about 750°C whereby its moisture is completely eliminated. In the middle portion, the temperature of the material rises to 1000°C. Here the limestone decomposes to give calcium oxide. At the lower end, the temperature rises to 1600°C. At this temperature, the mixture is partly fused and sintered. Chemical combinations occur between lime, alumina, ferric oxide and silica resulting in the formation of calcium aluminates and silicates.

$$2CaO + SiO_2 \longrightarrow \underset{\text{Dicalcium silicate}}{2CaO.SiO_2}$$

$$3CaO + SiO_2 \longrightarrow \underset{\text{Tricalcium silicate}}{3CaO.SiO_2}$$

$$3CaO + Al_2O_3 \longrightarrow \underset{\text{Tricalcium aluminate}}{3CaO.Al_2O_3}$$

$$4CaO + Al_2O_3 + Fe_2O_3 \longrightarrow \underset{\text{Tetracalcium alumino ferrite}}{4CaO.Al_2O_3.Fe_2O_3}$$

The reactions are exothermic in nature. The temperature has to be properly controlled in order to avoid excessive vitrification of the mass.

Out of the above compounds, the most important is tricalcium silicate. This substance has the property of setting quickly and developing considerable strength within a few days. It usually constitutes about 50 per cent of cement.

Dicalcium silicate sets only slowly and develops appreciable strength after a fortnight or so.

Tricalcium aluminate sets instantaneously in the presence of water. The internal strength acquired by cement is primarily due to the setting of tricalcium aluminate.

Tetracalcium aluminoferrite also sets rapidly but not as rapidly as tricalcium aluminate.

The product is known as *cement clinker*. After cooling, it is mixed with 2–3 per cent gypsum and ground to a fine powder. The function of gypsum is to slow down the setting of the cement so that it gets sufficiently hardened.

Setting of Cement. Cement has the property of **setting** to a hard mass after being mixed with water. The exact mechanism of this process has not been fully understood. But it is known that it involves many complicated reactions. This is also shown by the fact that while the first setting takes place within 24 hours, the subsequent hardening requires about a fortnight. The absorption of carbon dioxide by lime or by any other constituent is not involved at all. This is supported by the fact that subsequent hardening of the cement takes place when it is covered by a layer of water.

Primarily, the reactions involved are the hydration of calcium aluminates and calcium silicates which change into their colloidal gels. At the same time, some calcium hydroxide and aluminium hydroxide are formed as precipitates due to hydrolysis. Calcium hydroxide binds the particles of calcium silicate together while aluminium hydroxide fills the interstices rendering the mass impervious.

The various reactions involved may be represented as below.

1. *Hydration of tricalcium aluminate to give hydrated colloidal gel.*

$$\underset{\text{Tricalcium aluminate}}{3CaO.Al_2O_3} + 6H_2O \longrightarrow \underset{\text{Hydrated colloidal gel of tricalcium aluminate}}{3CaO.Al_2O_3.6H_2O}$$

2. *Hydrolysis of tricalcium silicate to liberate free lime.*

$$\underset{\text{Tricalcium silicate}}{3CaO.SiO_2} + H_2O \longrightarrow Ca(OH)_2 + \underset{\text{Dicalcium silicate}}{2CaO.SiO_2}$$

3. *Hydration of dicalcium silicate to give a hydrated colloidal gel* (a slow process).

$$2CaO.SiO_2 + x\,H_2O \longrightarrow \underset{\text{Hydrated colloidal gel of dicalcium silicate}}{2CaO.SiO_2xH_2O}$$

4. *Partial hydrolysis of tricalcium aluminate to liberate free aluminium hydroxide.*

$$3CaO.Al_2O_3 + 6H_2O \longrightarrow 3Ca(OH)_2 + 2Al(OH)_3$$

5. *Hydration of tetracalcium aluminoferrite to give hydrated tricalcium aluminate,* a colloidal gel.

$$4CaO.Al_2O_3.Fe_2O_3 + 6H_2O \longrightarrow 3CaO.Al_2O_3.6H_2O + CaO.Fe_2O_3$$

6. *Role of gypsum.* Gypsum combines with tricalcium aluminate to form calcium sulphoaluminate.

$$3CaO.Al_2O_3 + 3CaSO_4 + 2H_2O \longrightarrow \underset{\text{Calcium sulphoaluminate}}{3CaO.Al_2O_3.3CaSO_4.2H_2O}$$

The removal of the fast-setting tricalcium aluminate results in slowing down the setting process.

A quick setting results in the formation of crystalline hydrated calcium aluminate whereas a comparatively slow setting yields the colloidal gel which imparts much greater strength to the set mass.

Heat of hydration. The hydration of calcium aluminates and calcium silicates involved in the setting of cement is an exothermic process. Hence cement structures have to be cooled during setting. In the case of small structures, heat of hydration is removed by sprinkling water. In the case of bigger structures such as dams, the cement-concrete mixtures are prechilled to avoid excessive rise of temperature otherwise uneven expansion of the mass due to heat of hydration is liable to produce cracks in the structure. As an additional safeguard, cold water is circulated through pipes embedded in the concrete mass.

Concrete. It is a mixture of cement with sand and ballast or aggregates of crushed stone. Water is added to get a proper consistency. It sets to a hard solid mass and is used in foundations, floors and walls of buildings as well as on roads. It is also used in building roofs, piers for bridges, dams and canal locks.

Role of Mg^{2+} and Ca^{2+} Ions in Biological Systems

Magnesium is an important constituent of chlorophyll which initiates the process of photosynthesis in green plants as discussed earlier.

Magnesium ions are concentrated more in intracellular than in extracellular fluids in animal bodies. The presence of Mg^{2+} ions is a necessary requirement for the activation of phosphate transfer enzymes which participate in the energy releasing biochemical process occurring in animal body. Magnesium ions are also required for carbohydrate metabolism.

Mg^{2+} and Ca^{2+} ions are also responsible for the transmission of electrical impulses along the nerve fibre and for the contraction of muscles.

Calcium ions are essential for the formation of bones and teeth and for maintaining rythem of heart and for clotting of blood. The enamel on teeth is also a double salt of calcium, $3Ca_3(PO_4)_2.CaF_2$.

QUESTIONS

1. (*a*) Give the electronic configurations of the alkaline earth metals. Why are they so reactive ?
   (*b*) Compare the properties of the alkaline earths with those of alkali metals.
2. (*a*) Why does beryllium differ so much from the rest of the alkaline earths ? Discuss the main points of difference.
   (*b*) Compare and contrast the properties of beryllium and aluminium.
3. (*a*) Why are the alkaline earth metals harder and denser than the alkali metals ? Why do they have higher melting points than the alkali metals ?
   (*b*) The first ionisation energies of alkaline earths are very low as compared to the second ionisation energies. How would you account for it ?
   (*c*) In view of much lower first ionisation energies, the alkaline earth metals should prefer to form +1 ions (M^+) rather than + 2 ions (M^{2+}). But actually these metals give only M^{2+} ions. How would you explain this behaviour ?
4. (*a*) What are alkaline earth metals ? Why are they so called ? Discuss their general physical and chemical properties.
   (*b*) How would you account for different colours produced by alkaline earth metals in the bunsen flame ?.
5. Explain giving reasons why :
   (*a*) Beryllium shows covalency whereas other members of the family show electrovalency ?

   (*b*) NaOH is stronger base than $Ba(OH)_2$?
   (*c*) Na is more electropositive than Ba ?
   (*d*) K is much more reactive than Ca ?
6. (*a*) The solubilities of sulphates of alkaline earths decrease whereas the solubilities of their hydroxides increase on moving down the group. How would you explain this behaviour ?
   (*b*) Calcium imparts brick red, strontium imparts crimson and barium imparts grassy green colour to bunsen flame. How would you explain this behaviour ?
   (*c*) Be and Mg do not impart any colour to bunsen flame ? Why is it so ?
7. Give an account of the occurrence, esxtraction and uses of beryllium.
8. Compare the alkaline earth metals with alkali metals with regard to the following properties :
   (*a*) ionisation energies (*c*) solubilities of compounds
   (*b*) melting and boiling points (*d*) reducing behaviour.
9. (*a*) Indicate with reasons in which direction the following changes occur in Group 2 elements :
   (*i*) The cations become more strongly hydrated.
   (*ii*) The hydroxides become less soluble in water.
   (*iii*) The standard oxidation potentials decrease.
   (*iv*) The size of M^{2+} ions decreases.
10. (*a*) The first ionisation energy of beryllium is greater than that of lithium but the position is reversed in the case of second ionisation energy. Why ?
    (*b*) What is the structure of $BeCl_2$ in the gaseous and solid state ?
    (*c*) Compare the reactions of Group 1 and Group 2 metals with water.
    (*d*) Which alkaline earth metal ion has lowest ionic mobility in water and why ?
11. Explain why
    (*a*) The chemistry of alkaline earth metals is the chemistry of their dipositive ions.
    (*b*) Alkaline earth metal oxides are less basic than those of alkali metals.
    (*c*) Calcium is more reactive than magnesium
    (*d*) The hydroxides of Group 2 metals are less basic than those of Group 1.
    (*e*) The metals of Group 2 are harder and have higher melting points than those of Group 1.
12. Give a brief account of the chemistry of beryllium, bringing out clearly why does it differ from the rest of its family members.
13. How does beryllium occur in nature ? How is it extracted from the mineral beryl ? How does beryllium differ from the rest of the alkaline earths and why ?
14. Write a brief note on complexes of beryllium with highly conjugated planar ligands.
15. (*a*) Give the preparation and properties of $BeCl_2$. In which form does it exist
    (*i*) in vapour phase (*ii*) in solution (*iii*) in solid state.
    (*b*) Write down the structure of chlorophyll.
16. (*a*) How is calcium carbide obtained on a commercial scale ? How can it be converted into calcium cyanamide ? Give the important properties and uses of calcium cyanamide.
    (*b*) Discuss the preparation and structure of calcium carbide.
    (*c*) Draw the structures of beryllium oxalate and basic beryllium acetate.
17. Discuss the stereochemistry of the halide complexes of beryllium. What type of complexes are formed with highly conjugated planar ligands. Give at least one example.
18. Give the approximate composition of Portland cement. Give details of its manufacture. Explain the chemistry of the process of setting of cement.
19. How does magnesium occur in nature ? How is the metal extracted ? Give the important properties and used of the metal.

15 THE ELEMENTS OF GROUP 13

Group 13 of the periodic table contains five elements, namely, **boron, aluminium, gallium, indium** and **thallium.** Aluminium is the most abundant of these elements. Boron occurs rather sparsely. Gallium, indium and thallium are not found in concentrated deposits and do not find much of commercial applications.

Electronic Configurations. The electronic configurations of the various elements of this family are shown in Table 1.

The general outer electronic configuration of the elements of this group may thus be written as ns^2p^1.

TABLE 1

Electronic Configurations of Elements of Group 13

Element	Atomic Number	Electronic Configuration
Boron, B	5	[He] $2s^2p^1$
Aluminium, Al	13	[Ne] $3s^2p^1$
Gallium, Ga	31	[Ar] $3d^{10}\,4s^2p^1$
Indium, In	49	[Kr] $4d^{10}\,5s^2p^1$
Thallium, Tl	81	[Xe] $4f^{14}\,5d^{10}\,6s^2p^1$

GENERAL CHARACTERISTICS

General characteristics of *p* block elements have already been discussed in Chapter 12 while describing the properties of the main group elements. However, we shall briefly discuss these properties in this chapter also. Some of the important properties of Group 13 elements are given in Table 2.

1. Density, Melting Point, Boiling Point and Heat of Sublimation. *Density* increases on moving down the group. Aluminium, however, has an exceptionally low density. *Melting point* decreases considerably on moving down the group upto Ga and increases again in the case of In and Tl. *Boiling point*, however, follows a more regular trend. It decreases regularly on moving down the group. *Heat of sublimation* also follows the same trend. This indicates that the atoms of the elements are held less and less closely as we move down the group.

TABLE 2

Some Important Properties of Group 13 Elements

Property	Boron	Aluminium	Gallium	Indium	Thallium
Atomic number	5	13	31	49	81
Molar mass (g mol^{-1})	10·81	26·98	69·72	114·82	204·37
Density (g cm^{-3})	3·30	2·70	5·91	7·31	11·90
Melting point (°C)	2030	659	29·8	156·4	303
Boiling point (°C)	2550	2450	2237	2000	1457
Atomic radius (Å)	0·82	1·18	1·26	1·44	1·48
Molar volume (cm^3 mol^{-1})	4·62	10·0	11·8	15·1	17·2
Radius of trivalent ion (Å)	0·20	0·50	0·61	0·81	0·91
Ionisation energy (kJ mol^{-1})	800	577	579	558	589
Electronegativity (Pauling's values)	2·0	1·6	1·6	1.8	1·8*
Oxidation states	+3	+3	+1, +3	+1, +3	+1, +3
Heat of sublimation (kJ mol^{-1})	564·8	324·3	273·2	241·4	179·1

2. Ionisation Energies. The Group 13 elements have two *s* electrons and one *p* electron in their outermost (valency) shell. Since *p* electrons are invariably held less tightly than *s* electrons, the ionisation energy of each element is rather low as compared to the ionisation energies of *s* block elements of the same period.

As can be seen from Table 2, the ionisation energy is the highest in the case of boron. It decreases sharply from B to Al, remains practically the same in Ga, again decreases in In and increases in the last element Tl. Normally, there should have been a regular decrease in ionisation energy as we move down the group from B to Tl, as happens in the case of *s* block elements. The anomalous behaviour has already been explained in details in Chapter 12 dealing with the general characteristics of the main group elements. Although ionization energy depends on several factors and an exact explanation is not so easy, yet the trends in ionisation energy may be broadly explained in the following manner.

The ionisation energy of boron is the highest in the group since its atomic size is the smallest and the shielding effect is the lowest. The sharp decrease from B to Al is due to an appreciable increase in atomic size and the effective shielding of the nuclear charge by the intervening *s* and *p* electrons. In the case of Ga, there are ten *d* electrons in its inner electronic configuration. Since *d* electrons shield the nuclear charge less effectively than the *s* and *p* electrons (Chapter 1), the outer electron is held fairly strongly by the nucleus. As a result, the ionisation energy remains practically the same in spite of the increase in atomic size as we move from Al to Ga. In the case of In, the number of *d* electrons and hence their screening effect remains the same as in Ga. However, since there is an increase in atomic size as we move from Ga to In, there is a noticeable decrease in ionisation energy. The last element, Tl, has 14 *f* electrons in its inner electronic configuration. Since the shielding effect of *f* electrons is much smaller than that of *d* electrons and also since there is only a marginal increase in atomic size (from 1·44 Å to 1·47 Å) as we move from In to Tl, the outer electron in Tl is held quite firmly and hence there is a considerable increase in its ionisation energy.

The second and third ionisation energies also follow the same trend.

Since the total of the three successive ionisation energies of the elements of this group is known to be very large, these elements have very little tendency to form trivalent ions, M^{3+}.

3. Oxidation States. Boron shows consistently +3 oxidation state in its compounds. The rest of the elements, however, show +1 as well as +3 oxidation states. The +1 oxidation state becomes more and more stable as we move down the group from B to Tl. As a matter of fact, the compounds in which thallium is univalent, are more stable than those in which it is trivalent. The compounds of Tl(I) show close resemblance to those of alkali metals. For example, TlOH is highly soluble and is a strong base like NaOH ; Tl_2O_3 is also soluble and resembles the corresponding sodium and potassium compounds.

The cause of stability of lower oxidation states of heavier elements of Group 13 has already been discussed in details in Chapter 12.

Gallium, the third element of the group, appears to be bivalent in a few of its compounds, *e.g.*, $GaCl_2$. However, it is believed that this compound has the structure $Ga^+[GaCl_4]^-$ which contains the univalent and trivalent gallium ions, Ga^+ and Ga^{3+}.

4. Electropositive (Metallic) Character. Electropositive (metallic) character increases from boron to aluminium. Boron, in fact, is regarded as a *semi-metal*. It is closer to non-metals than to metals in its properties. It has high ionisation energy and is also a poor conductor of electricity. Aluminium and the rest of the elements are typically metallic and have more or less an equal electropositive character. This is indicated by their first ionisation energies which differ only slightly from one another.

5. Tendency to form Ionic Compounds. From the electronic configurations of the elements (Table 1), it might be expected that all of them would form +3 ions. However, the second and third ionisation energies of boron are so high that this element has little tendency to form B^{3+} ion. This ion in any case is not stable and is not important chemically. The other members of the family, because of comparatively lower ionisation energies involved in the change $M \rightarrow M^{3+}$, have a relatively higher tendency to form Al^{3+}, Ga^{3+} and In^{3+} ions under suitable conditions.

6. Tendency to form Covalent Compounds. The trivalent boron ion, B^{3+}, is exceedingly small. Such an ion would exert large *polarizing effect* on neighbouring atoms, *i.e.*, it would *tend to pull off electrons from neighbouring atoms.* This would result in the transference of electrons to the boron ion from its neighbours resulting in electron sharing and covalent bonding. According to Fajan's rule also, *the smaller the size of the cation, the greater is the tendency for covalent bonding.* Thus, while boron, generally, forms covalent compounds, the other elements form electrovalent compounds also.

7. Action of Air and Water. Pure boron is almost unreactive at ordinary temperatures. It reacts with air only when heated. It does not react with water. Aluminium reacts readily in air, even at ordinary temperatures, forming a layer of the oxide. The impervious oxide film protects it from further action of air.

Aluminium decomposes boiling water to give hydrogen. Gallium and indium are attacked neither by cold nor by hot water unless oxygen is present. Thallium is a little more reactive than gallium and forms an oxide on the surface.

Diagonal Relationship between Boron and Silicon. Boron resembles silicon, the second element of the next group in the next period of the periodic table. This is a case of **diagonal relationship**. Boron, in fact, shows more resemblance with silicon than with aluminium. The various points of resemblance between boron and silicon are discussed below.

1. Non-metallic character. Both boron and silicon have non-metallic character. Both of them have high melting points, high ionisation energies and are bad conductors of electricity.

2. Densities and Boiling points. Both have nearly equal densities ($B = 3{\cdot}30$ g cm^{-3} and $Si = 3{\cdot}52$ g cm^{-3}). Both boil at temperatures which are close to each other, *i.e.*, 2550°C and 2680°C, respectively.

3. Occurrence. Neither boron nor silicon occurs free in nature. Both occur in combined state.

4. Stability of cations. Boron and silicon do not form stable cations normally.

5. Tendency to form covalent compounds. Most of the compounds of boron and silicon are covalent in nature.

6. Oxides and oxoacids. Boron and silicon form stable oxides, B_2O_3 and SiO_2. These oxides are weakly acidic. In water they yield the corresponding weak acids, namely, *boric acid* (H_3BO_3, $K_a = 6{\cdot}0\times10^{-10}$) and *silicic acid* ($H_4SiO_4$, $K_a = 1\times10^{-10}$).

7. Formation of borates and silicates. The oxides, B_2O_3 and SiO_2, being weakly acidic, dissolve in strong alkalies forming metaborates and metasilicates.

$$B_2O_3 + 2NaOH \longrightarrow \underset{\text{Sodium metaborate}}{2NaBO_2} + H_2O$$

$$SiO_2 + 2NaOH \longrightarrow \underset{\text{Sodium meta-silicate}}{Na_2SiO_3} + H_2O$$

8. Formation of esters. Orthoboric acid and orthosilicic acid form esters when treated with alcohols in the presence of sulphuric acid. Thus,

$$H_3BO_3 + 3C_2H_5OH \xrightarrow[-3H_2O]{H_2SO_4} \underset{\text{Triethyl borate}}{(C_2H_5)_3BO_3}$$

The ester burns with a green edged flame. This is used as a qualitative test for borates.

Similarly, orthosilicic acid forms tetraethyl ester with ethyl alcohol.

$$H_4SiO_4 + 4C_2H_5OH \xrightarrow[-4H_2O]{H_2SO_4} \underset{\text{Tetraethyl silicate}}{(C_2H_5)_4SiO_4}$$

9. Formation of hydrides. Hydrides of boron and silicon are formed in almost identical manner, *e.g.*, by the reduction of their halides with lithium aluminium hydride.

$$4BCl_3 + 3LiAlH_4 \longrightarrow 3LiCl + 3AlCl_3 + 2B_2H_6$$

$$SiCl_4 + LiAlH_4 \longrightarrow LiCl + AlCl_3 + SiH_4$$

10. Hydrolysis of halides. Halides of boron and silicon get readily hydrolysed to yield orthoboric and orthosilicic acid, respectively. In each case, hydrogen halide is also formed in solution. Thus,

$$BF_3 + 3H_2O \longrightarrow H_3BO_3 + 3HF$$

$$SiF_4 + 4H_2O \longrightarrow H_4SiO_4 + 4HF$$

If boron trifluoride is added in excess, it dissolves in the hydrofluoric acid formed yielding **hydrofluoboric acid, $H[BF_4]$.**

$$BF_3 + HF \longrightarrow H[BF_4]$$

If SiF_4 is present in excess, fluosilicic acid, H_2SiF_6, results.

$$SiF_4 + 2HF \longrightarrow H_2SiF_6$$

EXTRACTION OF ELEMENTS OF GROUP 13

Extraction of Boron. Boron occurs in the form of salts of boric acid. Some of these are : (*i*) *Borax* ($Na_2B_4O_7.10H_2O$), (*ii*) *Colemanite* ($Ca_2B_6O_{11}.5H_2O$), (*iii*) *Panderinite* ($Ca_2B_6O_{11}.3H_2O$), (*iv*) *Boracite* ($2Mg_3B_8O_{15}.MgCl_2$) and (*v*) *Boronatrocalcite* ($CaB_4O_7.NaBO_2.H_2O$). Boron is generally obtained from borax.

Extraction. The following steps are involved in getting boron from borax.

a. Preparation of boric anhydride. When hot concentrated hydrochloric acid is added to borax, the sparingly soluble boric acid formed is slowly thrown down which on subsequent heating gives boric anhydride, B_2O_3.

$$(i)\ Na_2B_4O_7 + 2HCl + 5H_2O \longrightarrow 2NaCl + H_2B_4O_7 + 4H_3BO_3$$

$$(ii)\quad 2H_3BO_3 \xrightarrow{\text{Heat}} B_2O_3 + 3H_2O$$

b. Reduction of boric anhydride. The boric anhydride is then heated with sodium, potassium or magnesium powder in a crucible when it is reduced to boron.

$$B_2O_3 + 6K \longrightarrow 2B + 3K_2O$$

$$B_2O_3 + 3Mg \longrightarrow 2B + 3MgO$$

Pure boron is prepared by striking an electric arc between water-cooled copper electrodes in an atmosphere of hydrogen and boron trichloride vapour in a glass globe.

$$2BCl_3 + 3H_2 \longrightarrow 2B + 6HCl$$

Boron obtained in this manner is a brown amorphous mass.

Pure boron can also be obtained by heating BBr_3 with hydrogen over a heated tantalum filament at temperatures between 1000 – 1200°C.

Extraction of Aluminium. Next to silica and oxygen, aluminium is the most widely distributed element. It is present to the extent of 7·3 per cent in the earth's crust. The important ores are : (*i*) *Bauxite*, $Al_2O_3.3H_2O$ (*ii*) *Cryolite*, Na_3AlF_6 and (*iii*) *Corundum*, Al_2O_3. Aluminium is generally obtained from the bauxite ore.

The bauxite ore is powdered and digested with sodium hydroxide in an autoclave under pressure at 130°C for several hours when alumina of the ore dissolves as sodium meta aluminate whereas impurities

such as ferric oxide, silica, etc., being insoluble in NaOH, settle down. The sodium meta aluminate solution is then stirred with carbon dioxide gas when a precipitate of $Al(OH)_3$ is obtained. It is ignited at 1500°C to get pure alumina Al_2O_3 which is dissolved in molten cryolite at 800 – 1000°C and the melt electrolysed to get the pure metal.

Extraction of Gallium, Indium and Thallium. Gallium, indium, and thallium occur in nature very rarely. They are usually obtained by the electrolysis of aqueous solutions of their salts.

PROPERTIES OF ELEMENTS OF GROUP 13

Properties of Boron. Physical Properties. Boron exists in amorphous and crystalline forms. Amorphous boron is a brown powder of specific gravity 2·34. It melts at 2030°C and volatilises appreciably even at 1600°C.

Chemical Properties. 1. Action of air. Boron burns brilliantly when heated in oxygen giving boric anhydride (B_2O_3). When heated in air at 700°C, it forms boric anhydride (B_2O_3) and boron nitride (BN).

$$4B + 3O_2 \longrightarrow 2B_2O_3$$

$$2B + N_2 \longrightarrow 2BN$$

2. Action of acids. It is not attacked by hydrochloric acid but is oxidised by nitric acid and sulphuric acid to boric acid.

$$B + 3HNO_3 \longrightarrow H_3BO_3 + 3NO_2$$

$$2B + 3H_2SO_4 \longrightarrow 2H_3BO_3 + 3SO_2$$

3. Action of alkalies. Boron reacts with fused alkali metal hydroxides forming borates and evolving hydrogen.

$$2B + 6NaOH \longrightarrow 2Na_3BO_3 + 3H_2$$

However, extra pure boron is not attacked by aqueous NaOH or fused NaOH upto 500°C.

4. Action with metals. Boron combines with many metals on heating to give the corresponding borides, *e.g.*,

$$3Mg + 2B \longrightarrow Mg_3B_2$$

5. Action with non-metals. Boron combines with nitrogen when heated in air giving boron nitride.

It also combines with halogens at high temperatures to yield covalent boron trihalides, *e.g.*, BF_3, BCl_3.

It combines with carbon at high temperatures to give boron carbide, B_4C.

Crystalline boron is very hard and heat-resistant. It can be ignited with difficulty in air. Its specific gravity is 3·3. It is not acted upon by nitric acid and sulphuric acid. It is a bad conductor of electricity.

Uses. Boron is used, in the form of its salts such as calcium boride, as a deoxidiser. Borax and boric acid are also important technically.

Properties of Aluminium. Physical Properties. Aluminium is a bluish-white metal having a brilliant lustre which, however, is soon destroyed due to the formation of an oxide layer. It is malleable and ductile and can be rolled into sheets, foils and wires. It is a very light metal (specific gravity 2·7). It is a good conductor of heat and electricity. It melts at 659°C and boils at 2450°C.

Chemical Properties. 1. Action of air. Aluminium is not affected by pure dry air but in moist air a film of oxide is formed at the surface which protects the metal from further corrosion. It burns readily in oxygen giving brilliant light.

$$4Al + 3O_2 \longrightarrow 2Al_2O_3; \qquad \Delta H = -3230 \text{ kJ}$$

The heat evolved in the oxidation of aluminium is used in the *thermite process* for the reduction of oxides of chromium, iron, manganese, etc.

2. Action of water. Pure aluminium is not affected by pure water. However, the impure form is readily corroded by water containing salts. It decomposes boiling water evolving hydrogen.

Aluminium-mercury couple is, therefore, used as a reducing agent.

3. Action of alkalies. Aluminium readily dissolves in alkalies such as sodium and potassium hydroxides evolving hydrogen and forming the corresponding aluminates.

It also dissolves in a hot concentrated solution of sodium carbonate evolving hydrogen,

$$2Al + Na_2CO_3 + 3H_2O \longrightarrow 2NaAlO_2 + CO_2 + 3H_2$$

4. Action of acids. Aluminium dissolves in dilute hydrochloric and sulphuric acids evolving hydrogen. With hot concentrated sulphuric acid, sulphur dioxide is given out. Concentrated nitric acid has no action because the metal is rendered *passive* due to surface oxidation.

5. Action of halogens and nitrogen. Aluminium when heated with halogens and nitrogen gives aluminium halides and aluminium nitride, respectively.

6. Displacement of other metals. Aluminium displaces copper, zinc and lead from the solutions of their salts.

$$3ZnSO_4 + 2Al \longrightarrow Al_2(SO_4)_3 + 3Zn$$

Uses. 1. Aluminium, being very light, is used in manufacturing household utensils, aeroplane parts, precision and surgical instruments, etc. 2. Since it is unattacked by nitric acid, it is used in chemical plants and also for transporting nitric acid. 3. Mixed with oil, it is used in paints for steam pipes and other metal objects. 4. Aluminium foil is used for packing chocolates, cigarettes, etc. 5. Alums are used as mordants in dyeing and paints. 6. It is used as a reducing agent for the production of certain metals such as chromium, manganese, etc. 7. Alumina is used in making refractory bricks and ultramarine 8. In certain forms such as felspar and mica it is used in the construction of buildings. 9. Along with organic colloids, it is used for sizing of paper. 10. The evolution of enormous quantities of heat in the oxidation of aluminium is made use of in thermite welding of metals.

Properties of Gallium. Gallium is a silvery-white metal and is hard and brittle. It melts at 29·8°C and boils at 2237°C.

It is stable in dry air and does not decompose water, hot or cold, in the absence of free oxygen.

It dissolves in caustic alkalies as well as in hydrochloric acid and sulphuric acid but not in nitric acid. Nitric acid renders it *passive*.

It combines directly with halogens and sulphur but not with nitrogen or hydrogen.

Its chemistry is similar to that of aluminium.

Uses. Gallium, on account of its scarcity, does not find much commercial use. However, since under ordinary pressure it remains liquid over a wide range of temperature (between 29·8°C and 2237°C), it has been used in quartz thermostats for maintaining high temperatures. Liquid gallium, like mercury, does not wet glass or quartz. It is also used in lamps for spectroscopic analysis just as mercury is used in mercury lamps.

Properties of Indium. Indium is a soft white metal and is malleable and ductile. It melts at 156·4°C and boils at 2000°C. It alloys readily with copper, silver and gold.

It is not attacked by dry air at ordinary temperatures but when heated it gets covered with an oxide film.

It does not decompose water in cold or even on heating. However, it decomposes steam evolving hydrogen.

It burns in chlorine and combines with other halogens, sulphur, selenium and tellurium on heating.

It differs from aluminium and gallium in its insolubility in caustic alkalies even on heating. However, it dissolves slowly in cold and dilute acids and quickly in hot and concentrated acids.

Uses. Indium, like gallium, on account of its scarcity, does not find much commercial application. However, its alloys with copper and silver are used in dental work and jewellery.

Properties of Thallium. Thallium is a soft grey metal. It melts at 303°C and boils at 1457°C. It is so soft that it can be scratched even by finger nails. It is malleable but not ductile. It exists in two allotropic forms known as α and β varieties. It alloys with a number of metals including copper, silver, gold, zinc and cadmium.

It is more reactive than indium and gallium. This is due to its tendency to form unipositive ion, Tl^+.

It oxidises in moist air and decomposes steam at red heat.

It dissolves readily in dilute mineral acids except hydrochloric acid, yielding thallium(I) compounds. It does not dissolve readily in hydrochloric acid because of the insolubility of TlCl.

It combines directly with the halogens at ordinary temperatures and with sulphur, selenium and tellurium on heating.

Uses. Thallium does not find any worthwhile application as a metal. But its salts find a number of uses. Thus, thallous salts, being toxic, are used as fungicides, germicides and in ointments used for the treatment of ring worms. Thallium compounds also find application in preparing optical glasses on account of their high refractive indices.

COMPOUNDS OF GROUP 13 ELEMENTS

I. A Comparative Study

1. Hydrides. Boron forms a number of stable covalent hydrides with general formulae B_mH_{m+4} and B_mH_{m+6}. These are called **boranes**. The representative compounds of the two series are B_2H_6 and B_4H_{10}. These will be discussed in details a little later in this chapter.

Aluminium forms a polymeric hydride of formula $(AlH_3)_n$. It decomposes on heating above 200°C into its elements. Gallium hydride, GaH_3, is less stable while indium hydride, InH_3 and thallium hydride, TlH_3, are extremely unstable.

Boron, aluminium and gallium form complex anionic hydrides like lithium borohydride, $Li[BH_4]$, lithium aluminium hydride, $Li[AlH_4]$ and lithium gallium hydride, $Li[GaH_4]$. The formation of these anionic complexes is due to the presence of a vacant *p* orbital in their outermost shells which readily accepts electron pair from the hydride ion (H^-).

$$XH_3 + H^- \longrightarrow [XH_4]^-$$

where X = Al, Ga and also B.

Evidently, in these cases the hydride ion acts an an electron donor while the XH_3 behaves as an electron acceptor.

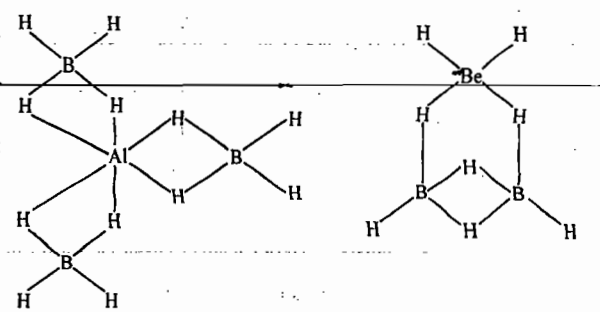
The alkali metal tetrahydridoborates are predominantly ionic in character although $Li[BH_4]$ has some covalent character as well. $Li[BH_4]$ reacts violently with water liberating hydrogen.

$$Li[BH_4] + 2H_2O \longrightarrow LiBO_2 + 4H_2$$

$Na[BH_4]$ reacts only slowly with water whereas $K[BH_4]$ is stable towards water.

$Be[BH_4]_2$, $Al[BH_4]_3$ and many other transition metal tetrahydridoborates have considerable covalent character.

The structures of $Be[BH_4]_2$ and $Al[BH_4]_3$ are as shown :



As can be seen from these structures, the presence of hydrogen bridges in the covalent tetrahydrides, *i.e.*, tetrahydridoborates of Be^{2+} and Al^{3+} is quite a common feature.

Lithium aluminium hydride, $Li[AlH_4]$, is more important of these compounds. It is prepared by reacting lithium hydride with anhydrous aluminium chloride in ether.

$$4LiH + \underset{\text{(anhydrous)}}{AlCl_3} \xrightarrow{\text{Ether}} Li[AlH_4] + 3LiCl$$

The complex hydride $Li[GaH_4]$ can also be prepared by a similar method. The tetrahydridoborates and aluminates are strong reducing agents. Lithium aluminium hydride (or lithium tetrahydridoaluminate) and sodium tetrahydridoborate are used particularly for this purpose.

2. Oxides and Hydroxides. All the elements of this group form oxides of the general formula M_2O_3 in which the elements are in + 3 oxidation state. Examples are B_2O_3, Al_2O_3, Ga_2O_3, In_2O_3 and Tl_2O_3.

Oxides and Hydroxides of Boron. The principal oxide of boron is boron oxide, B_2O_3. It is called diboron trioxide and more commonly boric oxide. It is actually an anhydride of orthoboric acid, H_3BO_3 and is obtained on dehydrating this acid by heating at 100°C.

$$2H_3BO_3 \xrightarrow{100°C} B_2O_3 + 3H_2O$$

It is a highly stable substance but hydrolyses in water yielding boric acid, H_3BO_3.

The trivalent boron ion, B^{3+}, being very small, has high (positive) charge density. Therefore, when placed in water, it tends to pull off electrons from water molecule towards itself sufficiently strongly to rupture the O – H bond. This results in the release of H^+ ion. Hence, hydroxides and oxides of boron, $B(OH)_3$ and B_2O_3, are feebly acidic. They dissolve in strong alkalies forming *metaborates*.

$$B(OH)_3 + NaOH \longrightarrow Na^+BO_2^- + 2H_2O$$

The sodium metaborate is readily hydrolysed and, therefore, orthoboric acid cannot be titrated against sodium hydroxide. However, in the presence of certain polyhydroxy compounds, it behaves as a strong acid and can thus be titrated successfully against strong bases. This aspect would be discussed a little later in this chapter.

Oxides and Hydroxides of Aluminium. The oxide of aluminium, Al_2O_3, is commonly known as alumina. It is obtained on heating aluminium in oxygen. It also occurs in nature in various forms. The two common forms of anhydrous Al_2O_3 are α-Al_2O_3 called corundum and γ-Al_2O_3 called activated alumina. α-Al_2O_3 is stable at high temperatures. It is very hard and is resistant to hydration and to attack by acids. It is used as an abrasive. γ-Al_2O_3 is readily soluble in acids and is used in column chromatography.

Aluminium hydroxide is obtained as a gelatinous precipitate when an alkali solution is added to the solution of an aluminium salt.

$$Al(NO_3)_3 + 3NaOH \longrightarrow Al(OH)_3 + 3NaNO_3$$

Aluminium oxide and hydroxide are amphoteric in nature. They dissolve both in acids as well as in alkalies.

Oxides and Hydroxides of Other Elements. Gallium like aluminium forms gallium oxide, Ga_2O_3, which is also amphoteric like alumina. It is formed by direct combination of gallium with oxygen at moderate heat. It is a white solid.

Indium oxide, In_2O_3, is obtained on heating nitrate or sulphate of the metal. It is a yellow solid and is distinctly basic in aqueous medium.

Thallium forms two oxides in which the oxidation state of the metal is +1 and +3. Thallium(I) oxide, Tl_2O, is more stable than thallium(III) oxide, Tl_2O_3. The former is obtained by direct combination of the metal with oxygen. The latter is obtained indirectly by heating thallium(III) hydroxide, $Tl(OH)_3$. It is a

dark brown solid. Being less stable it starts decomposing even below 100°C into Tl_2O and O_2. TlOH is a strong base and is highly soluble in water.

Acidic, Amphoteric and Basic Character of Oxides and Hydroxides. As mentioned above, B_2O_3 and $B(OH)_3$ are acidic, Al_2O_3 and $Al(OH)_3$ and Ga_2O_3 and $Ga(OH)_3$ are amphoteric while In_2O_3 and $In(OH)_3$ are distinctly basic. Thus, on moving down the group, there is a gradual change from acidic to amphoteric and then to basic character of the oxides and hydroxides of the elements. In the case of ***hydroxides**, this behaviour may be explained as follows :*

$B(OH)_3$ in aqueous medium coordinates a molecule of water to form the hydrated species $H_2O{\rightarrow}B(OH)_3$. In this species, B^{3+} ion, because of its small size, exercises a high polarizing power thereby pulling the sigma electron charge of the coordinated O atom towards itself. The coordinated oxygen, in turn, pulls the sigma electron charge of the OH bond of the attached H_2O molecule towards itself. This facilitates the removal of H^+ ion from the O-H bond, as shown below :

$$H_2O{\rightarrow}B(OH)_3 \rightleftharpoons [B(OH)_4]^- + H^+$$

Thus, the solution of $B(OH)_3$ in water acts as a *weak acid*. That is why it reacts with NaOH solution to produce the sodium salt :

$$B(OH)_3 + NaOH \rightleftharpoons Na^+[B(OH)_4]^- \rightleftharpoons \underset{\text{Sodium metaborate}}{Na^+BO_2^-} + 2H_2O$$

Of all the trivalent cations of Group 13 elements, B^{3+} ion has the highest positive charge density (charge/size) and the highest polarizing power. The positive charge density and the polarizing power go on decreasing with increase in the size of the cation. Since the trivalent Al^{3+} and Ga^{3+} ions are relatively larger, their polarizing power is less than that of B^{3+} ion and hence their capacity to release H^+ ions from the hydrated species $H_2O{\rightarrow}Al(OH)_3$ and $H_2O{\rightarrow}Ga(OH)_3$ is relatively smaller. As a result, the oxides and hydroxides of these elements, instead of being acidic, are *amphoteric*. The trivalent In^{3+} and Tl^{3+} ions are even larger than Al^{3+} and Ga^{3+} ions. Their positive charge density and polarizing power are, therefore, so small that they cannot affect the release of H^+ ions from the hydrated species $H_2O{\rightarrow}In(OH)_3$ and $H_2O{\rightarrow}Tl(OH)_3$ at all. Apart from this, the large size of In^{3+} and Tl^{3+} ions and the large energy differences in the sigma orbitals of these cations and the sigma orbitals of the oxygen atoms of OH groups considerably decrease the covalent character of M – O bond and, therefore, increase its ionic character. The hydroxides of In and Tl, in fact, disproportionate in water giving OH^- ions and thus behave as *bases*. This is illustrated below.

(*i*)
$$H_2O + In(OH)_3 \longrightarrow H_2O{\rightarrow}In(OH)_3$$
$$H_2O{\rightarrow}In(OH)_3 \rightleftharpoons [H_2O{\rightarrow}In(OH)_2]^+ + OH^-$$

(*ii*)
$$H_2O + Tl(OH)_3 \longrightarrow H_2O{\rightarrow}Tl(OH)_3$$
$$H_2O{\rightarrow}Tl(OH)_3 \rightleftharpoons [H_2O{\rightarrow}Tl(OH)_2]^+ + OH^-$$

The **oxides** of the elements with formula M_2O_3 (*e.g.*, B_2O_3, Al_2O_3, Ge_2O_3, etc.) may be considered as dehydrated $M(OH)_3$.

$$2M(OH)_3 \longrightarrow M_2O_3 + 3H_2O$$

The acid/base behaviour of the oxides of Group 13 elements can also be explained on similar lines.

3. Halides. The elements of Group 13 form a number of trihalides as well as lower halides. These are discussed below.

Trihalides of Boron. Boron trihalides, BX_3, are covalent compounds. They involve hybridisation of one *s* and two *p* orbitals (sp^2 hybridisation) of boron atom and have, therefore, trigonal planar structure.

All the four halides of boron, namely, boron trifluoride, BF_3, boron trichloride, BCl_3, boron tribromide, BBr_3 and boron triiodide, BI_3 are known. All of them are volatile, highly reactive and monomeric. BF_3 and BCl_3 are gases at room temperature ; BBr_3 is a volatile liquid while BI_3 is a solid.

They do not conduct elecricity in the liquid state. Their boiling points are also very low as compared to the halides of the elements of Groups 1 and 2. These properties are in contrast with those expected from ionically bonded substances. These are the principal reasons for regarding these halides as covalent compounds.

Boron trifluoride, BF_3. This is the most important of the trihalides of boron. It is obtained by heating boron trioxide or borax with calcium fluoride and concentrated sulphuric acid.

$$B_2O_3 + 3CaF_2 + 3H_2SO_4 \longrightarrow 3CaSO_4 + 3H_2O + 2BF_3$$
$$Na_2B_4O_7 + 6CaF_2 + 8H_2SO_4 \longrightarrow 2NaHSO_4 + 6CaSO_4 + 7H_2O + 4BF_3$$

Pure BF_3 can be obtained by thermal decomposition of diazonium tetrafluoroborate.

$$C_6H_5N_2BF_4 \longrightarrow C_6H_5F + N_2 + BF_3$$

It is a colourless pungent gas (m.p. – 127·1°C and b.p. – 99·9°C). It is exceedingly soluble in water and is, therefore, collected over mercury.

It combines with water forming two hydrates, $BF_3.H_2O$ and $BF_3.2H_2O$. The first hydrate melts at 10·18°C and the second at 6·36°C.

It gets hydrolysed in aqueous solution yielding boric acid and hydrofluoric acid:

$$BF_3 + 3H_2O \longrightarrow H_3BO_3 + 3HF$$

If boron trifluoride is passed in excess, it dissolves in the hydrofluoric acid formed, yielding hydrofluoboric acid, $H[BF_4]$.

$$BF_3 + HF \longrightarrow H[BF_4]$$

Boron trifluoride, being an electron-deficient compound, can accept a lone pair of electrons from ammonia, hydrogen sulphide and also a fluoride ion and thus behaves as a Lewis acid. It is this tendency to accept electrons which makes BF_3 useful as a catalyst in a number of reactions such as alkylation and acylation, in organic chemistry.

Boron trichloride, BCl_3. It is obtained by passing chlorine over a heated mixture of boron trioxide and powdered charcoal at about 500°C.

$$B_2O_3 + 3C + 3Cl_2 \xrightarrow{500°C} 2BCl_3 + 3CO$$

The gases evolved are passed through a U-tube cooled in a freezing mixture. Boron trichloride condenses as a colourless liquid while carbon monoxide and unreacted chlorine pass over.

It can also be prepared by heating boron trioxide with phosphorus pentachloride in a sealed tube at 15°C.

$$B_2O_3 + 3PCl_5 \xrightarrow{15°C} 2BCl_3 + 3POCl_3$$

It is a colourless liquid boiling at 12·5°C and freezing at – 107°C. It fumes in moist air.

It is completely hydrolysed by water yielding boric acid and hydrochloric acid.

Boron tribromide, BBr_3. It is prepared in the same way as boron trichloride with the difference that now bromine, instead of chlorine, is passed over a heated mixture of boron trioxide and powdered charcoal.

$$B_2O_3 + 3C + 3Br_2 \longrightarrow 2BBr_3 + 3CO$$

It is a colourless liquid boiling at 91·3°C and freezing at – 46°C. It fumes in moist air and is completely hydrolysed in aqueous solution.

$$BBr_3 + 3H_2O \longrightarrow H_3BO_3 + 3HBr$$

Boron triiodide, BI_3. It is prepared by the action of iodine on sodium borohydride.

$$4I_2 + NaBH_4 \longrightarrow BI_3 + 4HI + NaI$$

It may also be prepared by the action of hydriodic acid on boron trichloride.

It is a white solid, melting at 49·9°C. It is completely hydrolysed by water, like other boron trihalides.

Relative Strengths of Trihalides as Lewis Acids. Effect of Back Bonding. The relative strengths of trihalides of boron to accept a pair of electrons and thus to act as Lewis acids have been determined by measuring their heats of formation as well as by studying their infra-red spectra. The power to accept an electron pair has been found to decrease in the order :

$$BF_3 < BCl_3 < BBr_3$$

This order is just the *reverse* of what should be expected normally from the electronegativites of the halogens. This *anomalous behaviour* can be explained on the basis of the *tendency of the halogen atom to* **back-donate** *its electrons to the boron atom*, as illustrated below.

In BF_3 molecule, while the $2p$ orbitals of each fluorine atom are fully filled, one of the $2p$ orbitals of the boron atom is *vacant* (Fig. 1). The two $2p$ orbitals involved in the formation of B – F bond, therefore, overlap *laterally* resulting in the transference of the fluorine electrons into the vacant $2p$ orbital of the boron atom. An effective overlapping is easily possible because both the orbitals belong to the same energy level. In other words, an additional $p\pi - p\pi$ **bond** is established between boron and fluorine atoms. The B – F bond, thus, acquires some double bond character. This type of bond formation is known as **back bonding**. This is illustrated in Fig. 1.

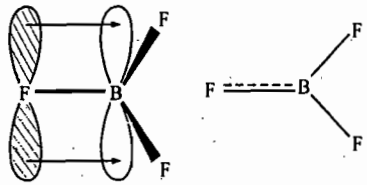


Fig. 1. The phenomenon of back bonding in BF_3 molecule.

Similar structures for the other two B – F bonds are equally probable. The back bonding in BF_3 may, thus, be represented as in Fig. 2.

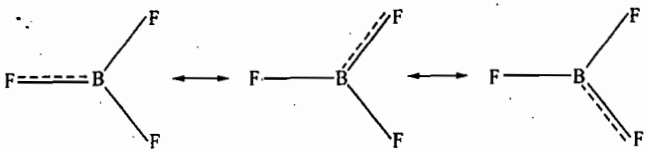

Fig.2. Various resonating structure of BF_3 molecule involving back bonding.

As a result of the **back donation** *of electrons from fluorine to boron, the electron deficiency of boron atom gets compensated and, therefore, the Lewis acid character of BF_3 decreases.*

The tendency to form $p\pi - p\pi$ bond is maximum in the case of BF_3 and falls rapidly as we move to BCl_3 and BBr_3. The probable reason for this appears to be the inability of the vacant $2p$ orbital of boron to overlap effectively with the $3p$ orbital of chlorine in B – Cl bond and with the $4p$ orbital of bromine in B – Br bond because of appreciable differences in the energies of the overlapping orbitals.

Trihalides of Aluminium. Trihalides of aluminium with all the four halogens are known. Thus, we have AlF_3, $AlCl_3$, $AlBr_3$ and AlI_3.

Aluminium trifluoride, AlF_3. Metallic aluminium or its oxide or hydroxide when dissolved in excess of hydrofluoric acid, deposits hydrated aluminium fluoride. It is colourless when pure. The common hydrate, $AlF_3.3H_2O$, exists in soluble and insoluble forms. It dissolves in hydrofluoric acid forming *fluo-aluminic acid*, H_3AlF_6, the mineral *cryolite*, Na_3AlF_6, being its sodium salt.

Aluminium trichloride, $AlCl_3$. When aluminium is dissolved in excess of hydrochloric acid, crystals of $Al_2Cl_6.12H_2O$ are deposited. The hydrate on heating decomposes to give alumina.

$$Al_2Cl_6.12H_2O \longrightarrow Al_2O_3 + 6HCl + 9H_2O$$

Anhydrous aluminium chloride is prepared by heating aluminium in a stream of dry chlorine or hydrochloric acid gas.

$$2Al + 3Cl_2\,(dry) \longrightarrow 2AlCl_3$$

$$2Al + 6HCl\,(gas) \longrightarrow 2AlCl_3 + 3H_2$$

The reaction with chlorine is strongly exothermic.

Anhydrous aluminium chloride is also formed when

(*i*) a mixture of aluminium oxide and carbon is strongly heated in dry chlorine gas.

$$Al_2O_3 + 3Cl_2 + 3C \longrightarrow 2AlCl_3 + 3CO$$

(*ii*) a mixture of carbon monoxide and chlorine is passed over heated aluminium oxide.

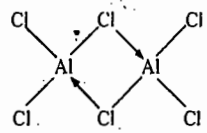
$$Al_2O_3 + 3CO + 3Cl_2 \longrightarrow 2AlCl_3 + 3CO_2$$

Aluminium chloride is white when pure. It sublimes at 183°C. It is extremely hygroscopic and fumes strongly in moist air due to the formation of hydrogen chloride.

$$2AlCl_3 + 6H_2O \longrightarrow 2Al(OH)_3 + 6HCl$$

Structure of $AlCl_3$. The vapour density measurements show that $AlCl_3$ is *monomeric* above 800°C. The structure of the monomer is *planar triangular* and the bonding is predominantly *covalent*. The Al atom utilises three sp^2 hybrid orbitals to accommodate $3 + 3\times1 = 6$ electrons.

However, below 400°C it exists as a *dimer* with each Al atom utilizing four sp^3 hybrid orbitals to accommodate $3 + 3\times1 + 1\times2 = 8$ electrons (one of the chlorine atoms is coordinated to Al and donates two electrons). The structure of the dimer is as shown.



In the solid state also, aluminium chloride exists as a dimer and is non-conducting. Al_2Cl_6 is the species which exists when aluminium chloride is dissolved in non-polar or less polar solvents. Its solution in such solvents is also non-conducting.

However, when aluminium chloride is dissolved in a polar solvent like water, it dissociates into ions in the following manner and its solution becomes conducting :

$$2AlCl_3 + aq \longrightarrow [AlCl_2(H_2O)_4]^+\,(aq) + [AlCl_4(H_2O)_2]^-\,(aq)$$

The crystallisation of $AlCl_3$ from aqueous solution, therefore, yields an *ionic* solid of composition $[AlCl_2(H_2O)_4]^+[AlCl_4(H_2O)_2]^-.xH_2O$. This compound decomposes at about 190°C to give the *non-ionic* dimer Al_2Cl_6 :

$$[AlCl_2(H_2O)_4]^+[AlCl_4(H_2O)_2]^-.xH_2O \xrightarrow[190°C]{Heat} Al_2Cl_6 + \text{water}$$

The thermal decomposition is accompanied by a *large decrease in density*. This is probably due to the fact that while there is considerable electrostatic attraction between the cations and the anions in the hydrated salt resulting in the decrease of interionic distance in the lattice of $[AlCl_2(H_2O)_4]^+[AlCl_4(H_2O)_2].xH_2O$ crystal, there is no such ionic attraction in the neutral Al_2Cl_6 units which, therefore, lie at a comparatively greater distance in the lattice of solid Al_2Cl_6.

Aluminium chloride is a strong Lewis acid and readily forms adducts with Lewis bases. It is, therefore, used as a catalyst in organic chemistry (Friedel-Crafts reaction). It is also used in the manufacture of dyes, drugs and pharmaceuticals.

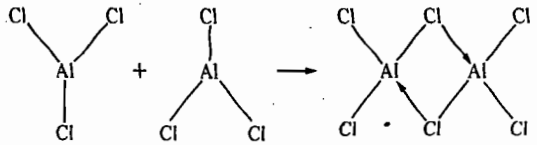
Aluminium tribromide, $AlBr_3$. It is prepared by the direct combination of the elements by passing bromine vapour over heated aluminium. In chemical properties it resembles aluminium chloride. It exists as Al_2Br_6 (*i.e.*, as a dimer) in the crystalline state.

Aluminium triiodide, AlI_3. It is prepared in the same way as aluminium bromide. It reacts with carbon tetrachloride to form aluminium chloride and carbon tetraiodide.

$$4AlI_3 + 3CCl_4 \longrightarrow 4AlCl_3 + 3CI_4$$

It exists as Al_2I_6 (*i.e.*, as a dimer) in the crystalline state.

Characteristic Difference in the Structures of Trihalides of Boron and Aluminium. There is a characteristic difference in the structures of trihalides of boron and aluminium. While the former exist as *monomers*, the latter exist as *dimers*. For example, $AlCl_3$ exists as a dimer, Al_2Cl_6, in non-polar solvents as well as in vapour state between 400 and 800°C. Above 800°C, however, it exists as a monomer. The formation of the dimer is illustrated below :



The arrows indicate donation of electrons to chlorine atoms. The covalency of aluminium increases to 4. The chlorine atoms are arranged tetrahedrally around each aluminium atom.

Such bridge structures are typical of electron-deficient compounds. Boron trihalides, however, do not form dimers. They exist only as *monomers*. This is due to the fact that boron atom is too small to coordinate with four large halide ions such as Cl^-, Br^- and I^-. However, boron atom should be able to coordinate with four fluoride ions which are much smaller in size than other halide ions. Consequently, of the various boron trihalides, the trifluoride at least should exist as a dimer. But actually it is not so. This is because the large amount of energy required for the cleavage of the typical $p\pi - p\pi$ bond in BF_3 to enable dimerisation of BF_3 is not released during the formation of the bridge structure in this case. The boron trifluoride, therefore, exists only as a monomer as do the other halides of boron.

Trihalides of Gallium, Indium and Thallium. The trihalides of gallium, indium and thallium are covalent but the covalent character decreases and ionic character increases on moving from Ga to Tl.

Gallium trichloride ($GaCl_3$) is a white solid, melting at 780°C. The vapours at 500°C consist largely of dimers having the formula Ga_2Cl_6.

Indium trichloride ($InCl_3$), however, does not dimerise. It is relatively more ionic than $GaCl_3$. **Indium triiodide** is, however, dimeric.

Thallium trichloride ($TlCl_3$) also does not dimerise. It is even more ionic than $InCl_3$. It decomposes to TlCl and Cl_2 above 40°C. **TlF_3** is stable upto 500°C. $TlBr_3$ slowly gets converted to $Tl^I[Tl^{III}Br_4]$ at room temperature. TlI_3 is, in fact, an ionic compound of Tl(I) and I_3^-.

Lower Halides of Boron. Several lower halides of boron are known out of which diboron tetrahalides (B_2X_4) are better studied.

When BCl_3 is made to react with mercury, it forms B_2Cl_4.

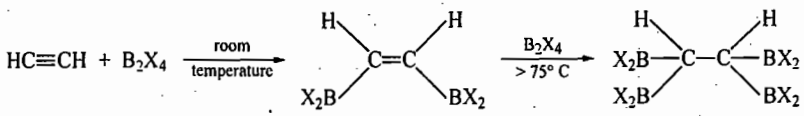
$$2BCl_3 + 2Hg \longrightarrow B_2Cl_4 + Hg_2Cl_2$$

Other diboron tetrahalides are prepared from B_2Cl_4 in the following manner :

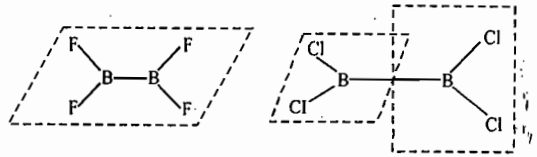
$$B_2Cl_4 \xrightarrow[\text{room temperature}]{SbI_3} B_2F_4 \; ; \; B_2Cl_4 \xrightarrow[-80°C]{BBr_3} B_2Br_4$$

The above diboron tetrahalides burn when brought in contact with air. They react with hydrogen to give BHX_2 and B_2H_6. They are electron-deficient compounds and react with Lewis bases to form stable adducts, $B_2X_4(Base)_2$.

They add to unsaturated hydrocarbons as shown below :



It has been observed that thermal stability of diboron tetrahalides varies with the extent of $p\pi - p\pi$ bonding between B and X. Thus, B_2F_4 which has a planar structure with maximum possibility of $p\pi - p\pi$ bonding is more stable than B_2Cl_4 which has a staggered structure as shown :



Other less studied lower halides of boron are B_4X_4, B_8X_8, B_9X_9, etc. (X = Cl, Br).

Lower Halides of Aluminium, Gallium, Indium and Thallium. All the four elements form monohalides many of which, however, are quite unstable. For instance, AlF, GaF and InF are all unstable gases. AlF, being the most unstable, undergoes quick decomposition into Al and AlF_3

$$3AlF \longrightarrow 2Al + AlF_3$$

Other monofluorides also decompose, though less quickly, in a similar manner.

For a particular element of Group 13, the monohalides of other halogens are more stable than the monofluoride. Thus, gallium(I) chloride, bromide and iodide are thermodynamically more stable than gallium(I) fluoride. The stability of gallium(I) halides, increases with increase in the size of the halide ion. The compound Ga_2Cl_4 is, actually, a mixed halide of Ga(I) and Ga(III) and its correct formula is $[Ga^I[Ga^{III}Cl_4]$. Similarly, indium(I) chloride, bromide and iodide are thermodynamically more stable than indium (I) fluoride. The chloride of indium, In_2Cl_3, appears to have In in the oxidation state of 1·5 but actually it contains both In(I) and In(III) ions and the correct formula of this halide has been shown to be $In_3^I[In^{III}Cl_6]$. Thallium(I) halides are the most stable amongst the monohalides of Group 13 elements. These can be easily prepared by reacting any thallium (I) salt (*e.g.*, $TlClO_4$) with the appropriate alkali halide.

The monohalides, in general, can be prepared by heating the trihalides with the metal.

$$MX_3 + 2M \xrightarrow{Heat} 3MX$$

Indium monohalides can also be prepared by heating indium in a current of the halogen or by heating it with mercuric halide.

$$2In + X_2 \xrightarrow{Heat} 2InX$$

$$2In + 2HgX_2 \xrightarrow{>300°C} Hg_2X_2 + 2InX$$

Several lower halides of thalium are also known (*e.g.*, $TlCl_2$, $TlBr_2$, Tl_2Cl_3, Tl_2Br_3). All these are mixed halides of Tl(I) and Tl(III).

4. Complexes of Group 13 Elements

On account of vacant *p* orbitals, Group 13 elements form a number of complexes. Alkali metal boron hydrides such as $NaBH_4$ and $LiBH_4$ are examples of well known complexes of boron. These contain the complex ion, BH_4^- which is formed by sp^3 hybridisation of the orbitals of boron. It is, therefore, tetrahedral in structure, as shown in Fig. 3.

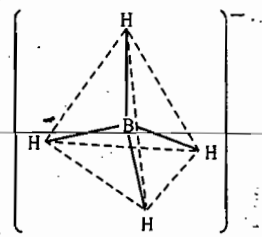


Fig. 3. Tetraheral structure of $[BH_4]^-$ ion.

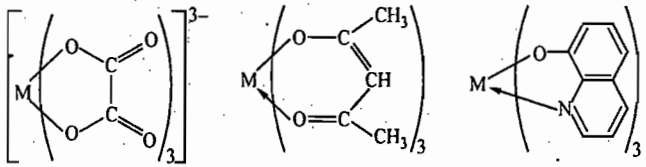
Similar tetrahderal complexes are formed by other elements of Group 13. Well known examples are $Li[AlH_4]$, $NH_4[AlF_4]$, $Na[GaCl_4]$, $Li[TlBr_4]$, etc.

In addition to the above tetrahderal halide and hydride complexes, many octahedral complexes such as $[GaCl_6]^{3-}$, $[InCl_6]^{3-}$, $[TlCl_6]^{3-}$, etc., are also known. The most important octahedral complexes of Group 13 elements are those which are formed with chelate groups such as oxalate, acetyl acetonate,

8-hydroxyquinoline, etc. Their structures are shown below :



oxalate complex acetyl acetone complex 8-hydroxyquinoline complex

II. Some Important Compounds of Group 13 Elements

BORIDES

Compounds of boron with elements (generally transition metals) which are more electropositive than boron itself are known as **borides.** The borides can be prepared by any of the following methods :

1. By heating the metal with boron.

$$Cr + 2B \xrightarrow{1100°C} CrB_2$$

2. By heating the metal or metal oxide with boron carbide.

$$Eu_2O_3 + 3B_4C \xrightarrow{1600°C} 2EuB_6 + 3CO$$

3. By heating the metal oxide with a mixture of B_2O_3 and carbon.

$$V_2O_5 + B_2O_3 + 8C \xrightarrow{1500°C} 2VB + 8CO$$

4. By heating the metal with a mixture of B_2O_3 and B_4C.

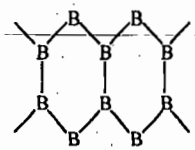
$$7Ti + B_2O_3 + 3B_4C \xrightarrow{2000°C} 7TiB_2 + 3CO$$

5. By electrolysis of a mixture of the metal oxide and B_2O_3 dissolved in a suitable molten salt bath using graphite as the anode and graphite or steel as the cathode. The boride of the metal gets deposited on the cathode.

Structures of Borides. The borides range from metal–rich borides (M_4B, M_5B, etc.) to boron–rich borides (MB_6, MB_{12}, etc.). Some of the salient features of the structures of various categories of borides are discussed below briefly.

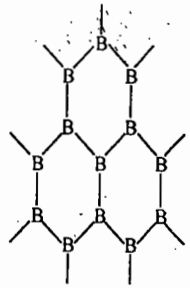
1. Borides having isolated boron atoms. These are metal–rich borides in which the boron atoms occupy the triangular prismatic or square antiprismatic interstices formed by metal atoms. The interstitial boron atoms are not bonded with each other. Examples are Mn_4B, Co_3B, Pd_3B, etc.

2. Borides having chains of boron atoms. As the proportion of boron atoms in borides increases, their tendency to catenate also increases. Thus, in borides M_3B_2 (B : M = 2/3 ; M = V, Nb, Ta), the interstitial boron atoms are present as B_2 units. The borides with the formula MB (B : M = 1 ; M = Ti, Hf, V, Nb, Ta, Cr, Mo, W, Fe, Co, Ni, etc.) have structures with single chains of boron atoms while the borides M_3B_4(B : M = 4 : 3 ; M = V, Nb, Cr, Ta, Mn, etc.) have structures containing double chains of boron atoms, as shown.



3. Borides having extended two-dimensional network. In structures of borides with formula MB_2 (B : M = 2 ; M = Mg, Al, Sc, Y, La, Ti, Zr, Hf, V, Nb, Ta, Cr, Mo, W, etc.), boron atoms further catenate to produce two-dimensional network of boron atoms. This class of borides includes some of the best

electrically conducting, hardest and highest-melting of all the borides. The structure of borides MB_2 consists of alternating layers of close packed metal atoms and two-dimensional sheets of boron atoms made up of interconnecting B_6 rings, as shown.



4. Borides with three-dimensional network. Borides with the formulae MB_4, MB_6, MB_{12}, etc., contain a three-dimensional network of boron atoms. The structure of MB_6 (M = La) is similar to that of CsCl. The B_6 octahedra take the place of Cl^- and the metal M takes the place of Cs^+. The B_6 octahedra are linked with each other along the edges of a cube so that there is an infinite three-dimensional network of boron atoms, as shown.

The borides with the general formula MB_{12} (M = Y) have NaCl type structure in which B_{12} cubo-octahedral units, occupy the place of Cl^- and the metal M takes the place of Na^+. The B_{12} units are linked with each other to produce a three-dimensional network of boron atoms. The structure of borides with the general formula MB_4 (M = La) also contain a three-dimensional network of B_6 octahedra interconnected with B_2 units so that the structure can be said to be a transition between the structures of MB_2 and MB_6.

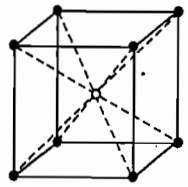
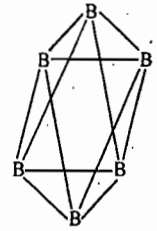
o is metal M



CsCl type structure of MB_6



Structure of B_6 unit

Properties and Uses. Borides possess some unusual properties. They are generally extremely hard, non-volatile refractory substances and are fairly inert chemically. Their electrical and thermal conductivities are many times higher than those of the corresponding pure metals. Their melting points are also much higher than those of the corresponding pure metals.

The borides TiB_2, ZrB_2 and CrB_2, being very hard and very high melting, are used for making turbine blades, combustion chambers and rocket nozzles. The ability of borides to withstand attack by molten metals, slags, salts, etc., makes them useful materials for the fabrication of high temperature reactor vessels, crucibles, etc. The borides are employed as electrodes in high temperature electrolyses due to their inertness to chemical attack at high temperatures and possessing very high electrical conductivity. Since ^{10}B has very high absorption cross-section for thermal neutrons and the products of reaction (n, α) of ^{10}B are stable non-radioactive Li and He, the metal borides are extensively used as neutron shields and control rods in nuclear power plants.

BORON HYDRIDES, BORANES

Boron does not combine directly with hydrogen to form hydrides. Nevertheless, a number of interesting **boron hydrides** are known. These are called **boranes** on analogy with alkanes. These are gaseous substances at ordinary temperatures.

Although it is expected that boron would form the hydride BH_3 yet this compound is unstable at room temperature. However, a large number of higher hydrides of boron are known. These hydrides can be divided into two series depending upon their general formulae which are B_mH_{m+4} and B_mH_{m+6}. Some common compounds belonging to the two series are given below :

B_mH_{m+4}	Series	B_mH_{m+6}	Series
B_2H_6	Diborane (6)	B_4H_{10}	Tetraborane (10)
B_5H_9	Pentaborane (9)	B_5H_{11}	Pentaborane (11)
B_6H_{10}	Hexaborane (10)	B_6H_{12}	Hexaborane (12)
B_8H_{12}	Octaborane (12)	B_8H_{14}	Octaborane (14)
$B_{10}H_{14}$	Decaborane (14)	B_9H_{15}	Enneaborane (15)
		$B_{10}H_{16}$	Decaborane (16)

The numerals in the above names indicate the number of hydrogen atoms present in the borane. The boranes of B_mH_{m+6} series are comparatively less stable.

Several **borane anions** are known which can be assumed to be derived from the three above mentioned series of boranes by the removal of one or two protons. Thus, borane anions can be categorised into $B_mH^-_{m+1}$, $B_mH^{2-}_m$, $B_mH^-_{m+3}$, $B_mH^{2-}_{m+2}$, $B_mH^-_{m+5}$ and $B_mH^{2-}_{m+4}$.

The boranes catch fire spontaneously in air. They are readily hydrolysed yielding boric acid. However, B_9H_{15} and $B_{10}H_{14}$ are quite stable and do not hydrolyse readily. The most important hydride of boron is diborane which has been described below in some details.

Diborane, B_2H_6

Preparation. It is the simplest of the hydrides of boron and can be prepared by the following methods :

1. By the reaction of iodine on sodium borohydride in diglyme.

$$2NaBH_4 + I_2 \xrightarrow{\text{Diglyme}} B_2H_6 + 2NaI + H_2$$

2. By passing silent electric discharge through a mixture of hydrogen and boron trichloride (vapour) at a low pressure.

$$2BCl_3 + 6H_2 \xrightarrow[\text{discharge}]{\text{Electric}} B_2H_6 + 6HCl$$

3. By the reduction of boron trichloride with lithium aluminium hydride.

$$4BCl_3 + 3LiAlH_4 \longrightarrow 2B_2H_6 + 3AlCl_3 + 3LiCl$$

4. By reducing gaseous boron trifluoride with sodium hydride at 180°C.

$$2BF_3 + 6NaH \longrightarrow B_2H_6 + 6NaF$$

Properties. 1. Physical State. Diborane is a colourless gas with a foul smell.

2. Stability. It is stable only at low temperatures. When heated at temperatures between 100°C and 250°C in a closed vessel, it changes to a number of higher hydrides :

$$B_2H_6 \xrightarrow{\text{Heat}} B_4H_{10}, B_5H_9, B_5H_{11}, B_6H_{10}, B_6H_{12}, \text{etc.}$$

The process, evidently, involves a series of decompositions and polymerisations, the first step being decomposition of B_2H_6 into BH_3.

3. Action of oxygen. Diborane and other boranes have attracted the attention of technologists on account of a large amount of energy released during their combustion. For example,

$$B_2H_6 + 3O_2 \longrightarrow B_2O_3 + 3H_2O ; \qquad \Delta H = -2165 \text{ kJ mol}^{-1}$$

4. Hydrolysis. It gets hydrolysed readily yielding boric acid.

$$B_2H_6 + 6H_2O \longrightarrow 2H_3BO_3 + 6H_2$$

5. Action with alkalies. Diborane dissolves in strong alkali solutions giving metaborates and evolving hydrogen.

$$B_2H_6 + 2KOH + 2H_2O \longrightarrow 2KBO_2 + 6H_2$$

6. Action with metals. Diborane reacts slowly with active metals such as Na, K, Ca or their amalgams. However, the reaction becomes fast in the presence of ether.

$$2B_2H_6 + 2Na \longrightarrow NaBH_4 + NaB_3H_8$$

The anion $B_3H_8^-$ formed as above was the first known polyborane anion.

7. Action with carbon monoxide. It reacts with carbon monoxide at 100°C and 20 atm pressure to form the carbonyl H_3BCO.

$$B_2H_6 + 2CO \longrightarrow 2H_3BCO$$

8. Action with halogens. It reacts with halogens under different conditions to form haloboranes and halodiboranes.

$$B_2H_6 + 6Cl_2 \xrightarrow{\text{low temp.}} 2BCl_3 + 6HCl$$

$$2B_2H_6 + 7Br_2 \xrightarrow{\text{low temp.}} B_2H_5Br + 7HBr + 2BBr_3$$

I_2 does not react with B_2H_6.

9. Action with halogen acids. Diborane reacts with halogen acids to give halodiboranes and evolving hydrogen.

$$B_2H_6 + HX \longrightarrow B_2H_5X + H_2$$

10. Action with hydrides. It combines with hydrides of alkali metals to form complex hydrides.

$$B_2H_6 + 2NaH \longrightarrow 2Na[BH_4]$$

11. Addition to alkenes and alkynes. Diborane adds to alkenes and alkynes in ether at room temperature to form organoboranes.

$$6RCH{=}CH_2 + B_2H_6 \longrightarrow \underset{\text{Organoborane}}{2B(CH_2CH_2R)_3}$$

The reaction is known as hydroboration reaction and has been of great synthetic utility in organic chemistry.

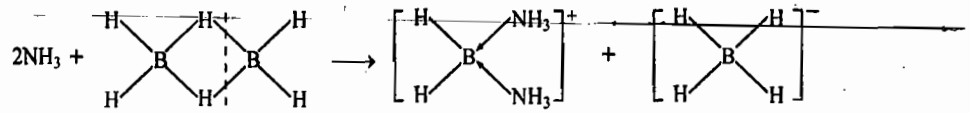
12. Action with ammonia. Diborane reacts with ammonia, the products depending upon the conditions of experiment.

(*i*) $$B_2H_6 + 2NH_3 \xrightarrow{\text{low temp.}} \underset{\text{Diammoniate of diborane}}{B_2H_6.2NH_3}$$

(*ii*) $$nB_2H_6 \xrightarrow[\text{high temp.}]{\text{Excess } NH_3} \underset{\text{Boron nitride}}{(BN)_n}$$

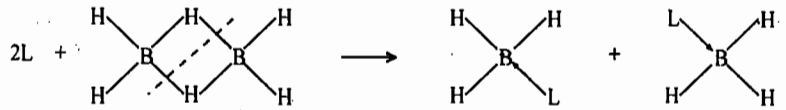
(*iii*) $$3B_2H_6 + 6NH_3 \xrightarrow{200°C} \underset{\text{Borazine}}{2B_3N_3H_6} + 12H_2$$

The compound $B_2H_6.2NH_3$ obtained in reaction (*i*) is ionic and exists as $[H_3N{\rightarrow}BH_2{\leftarrow}NH_3]^+[BH_4]^-$. Its formation can be explained by assuming unsymmetric cleavage of BHB bridges of B_2H_6, as shown below :



$N(CH_3)_3$ reacts with B_2H_6 to give $Me_3N{\rightarrow}BH_3$. Similar compounds are obtained from the reaction of B_2H_6 with PF_3, Me_2S, Et_2S, etc. These reactions can be explained by assuming symmetric cleavage of

BHB bridges of B_2H_6 by the Lewis bases mentioned above, as shown below :



(L stands for Lewis base such as $N(CH_3)_3$, PF_3, Me_2S, Et_2S).

13. Action with boron halides. Diborane reacts with boron halides to produce halodiborane.

$$B_2H_6 + BBr_3 \longrightarrow B_2H_5Br + BHBr_2$$

14. Methylation of diborane. $B(CH_3)_3$ and $Pb(CH_3)_4$ react with B_2H_6 to give methylated products of the composition $(CH_3)_n B_2H_{6-n}$ (n = 1 to 4).

15. Action with methanol. Diborane reacts with methanol to give methoxy products $B(OCH_3)_3$, $BH(OCH_3)_2$ and $BH_2(OCH_3)$.

Structure of Diborane. Boranes provide interesting examples of *electron-deficient compounds*. We may consider the case of diborane, B_2H_6, as an example. Since boron atom in excited state has three half-filled orbitals, it has three electrons available for sharing. Therefore, it can link to itself three hydrogen atoms. Thus, while each boron atom in diborane can link to itself three hydrogen atoms, there are no electrons left to form a bond between the two boron atoms. Spectroscopic studies reveal that the structure of diborane is as shown in Fig. 4.

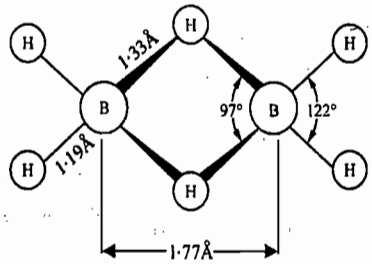


Fig. 4. Structure of diborane molecule.

The various bond distances and angles are as shown.

Four hydrogen atoms, two on the left and two on the right, known as *terminal hydrogens*, are in different environments from the other two hydrogen atoms which are known as the bridging atoms. The two boron atoms and the four terminal hydrogen atoms lie in the same plane while the two boron atoms and the two bridging hydrogen atoms, one above and the other below, lie in a plane perpendicular to this plane.

The **bridge structure** discussed above is supported by the following facts :

1. Heat capacity measurements have shown that the rotation of the two ends of the molecule against each other is very much hindered. This indicates that the bridging hydrogen atoms lie in a plane at right angles to the plane in which the rest of the molecule lies. In a molecule like ethane, in which there are no bridging hydrogen atoms, the hindrance to this type of rotation is very low.

2. Nuclear magnetic resonance and Raman spectra have shown that four hydrogens are of one type and two hydrogens are of another type. In ethane all the six hydrogens are known to be equivalent.

3. Diborane cannot be methylated beyond $(CH_3)_4B_2H_2$. The hydrogens which cannot be methylated, evidently, are in a different environment. These are the bridging hydrogen atoms.

Bonding in Boranes

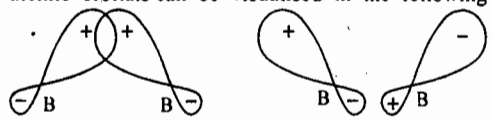
The bonding in boranes may be explained on the basis of an idea of *three centre–two electron* (3c – 2e) types of bonds proposed by Longuet-Higgins in 1949. The idea was later refined by Lipscomb and his coworkers.

Three Centre–two electron Bonds. In molecular orbital theory of covalent bonding, two atomic orbitals of the same symmetry and similar energy linearly combine with each other resulting in the formation of two molecular orbitals by the LCAO method (Chapter 4 on Chemical Bonding).

In a similar manner, if three atomic orbitals of same symmetry and similar energy combine linearly, they would give rise to three molecular orbitals (the number of atomic orbitals which combine linearly is always equal to the number of molecular orbitals formed).

The idea of linear combination of three atomic orbitals can be visualised in the following manner :

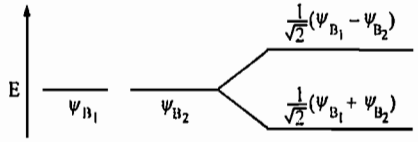
Let ψ_{B_1} be one of the four hybrid orbitals of one boron atom which combines linearly with a hybrid orbital ψ_{B_2} of another boron atom. This results in the formation of two molecular orbitals, *viz.*, $1/\sqrt{2}(\psi_{B_1} + \psi_{B_2})$ and $1/\sqrt{2}(\psi_{B_1} - \psi_{B_2})$. The two linear combinations resulting in the formation of two molecular orbitals are as shown.



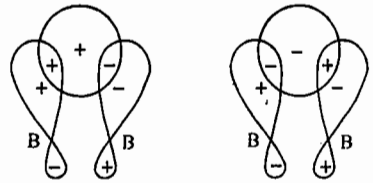
I — $\frac{1}{\sqrt{2}}(\psi_{B_1} + \psi_{B_2})$ Additive combination

II — $\frac{1}{\sqrt{2}}(\psi_{B_1} - \psi_{B_2})$ Subtractive combination

The additive combination I brings the positive lobe of ψ_{B_1} near the positive lobe of ψ_{B_2} making a *positive overlap* possible between ψ_{B_1} and ψ_{B_2}. This results in a decrease of energy of the molecular orbital formed by this combination. The subtractive combination II brings the positive lobe of ψ_{B_1} near the negative lobe of ψ_{B_2} making only *negative overlap* possible between ψ_{B_1} and ψ_{B_2}. This results in an increase in energy of the molecular orbital formed by the combination. The relative energies of the two molecular orbitals are represented as shown.



Let us now combine linearly the atomic orbital of H atom ψ_H with molecular orbital of boron atom which has the same symmetry and similar energy as that of ψ_H. The molecular orbital $1/\sqrt{2}(\psi_{B_1} - \psi_{B_2})$ cannot combine with ψ_H either by addition or by subtraction, as shown.

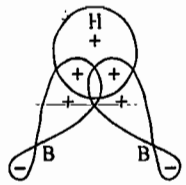


III — Additive combination. Net overlap is zero

IV — Subtractive combination. Net overlap is zero

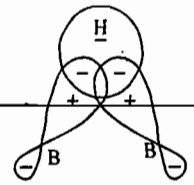
As can be seen, the net overlap in both the cases is zero. Hence, such combinations do not occur.

However, the molecular orbital $1/\sqrt{2}(\psi_{B_1} + \psi_{B_2})$ would easily combine with ψ_H, both by addition as well as subtraction, as illustrated below :



V

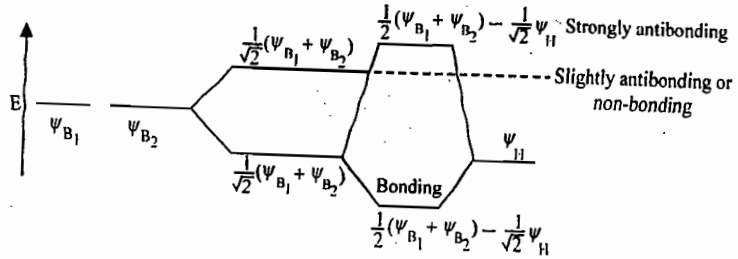
Additive combination of $1/\sqrt{2}(\psi_{B_1} + \psi_{B_2})$ with ψ_H. Net overlap is non-zero and positive. Hence, such a combination is effective and leads to lowering of energy.



VI

Subtractive combination of $1/\sqrt{2}(\psi_{B_1} + \psi_{B_2})$ with ψ_H. Net overlap is non-zero and negative. Hence such a combination is effective in the negative sense and leads to increase in energy.

The normalised linear combination of the *two-centre* molecular orbital $1/\sqrt{2}(\psi_{B_1} + \psi_{B_2})$ with ψ_H to give two 3-centre bonding and antibonding molecular orbitals is shown below :

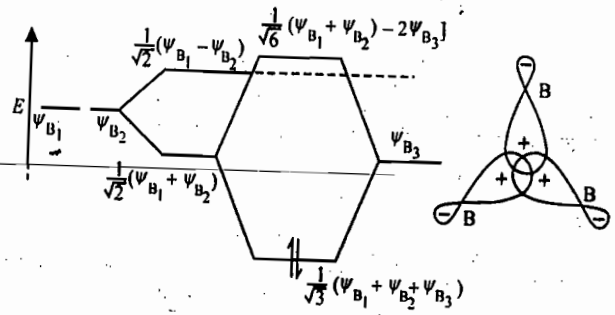


Thus, a linear combination of ψ_{B_1}, ψ_{B_2} and ψ_H results in three molecular orbitals, one of which is *bonding* (V), the other is *slightly antibonding* or *non-bonding* (III or IV) as ψ_H does not affect its energy and the last one is *strongly antibonding* (VI).

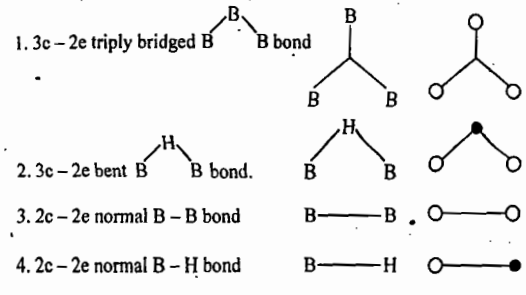
In a molecular orbital wave function obtained by linearly combining a number of atomic orbital wave functions, the square of the coefficient of any atomic orbital wave function gives the contribution of that wave function to the molecular orbital wave function. Since each atomic orbital is completely distributed in the three molecular orbitals, the sum of the squares of the coefficients of the atomic orbital wave functions appearing in the three molecular orbital wave functions is equal to unity. Thus, the contributions of ψ_{B_1} in the bonding, non-bonding and antibonding molecular orbitals are $(1/2)^2$, $(1/\sqrt{2})^2$ and $(1/2)^2$, respectively. The sum of these contributions is, evidently, equal to unity. Also, since each molecular orbital wave function is normalised, the sum of the squares of the coefficients of atomic orbital wave functions in it equals unity. Thus, the sum of the squares of the coefficients of atomic orbital wave functions in the bonding molecular orbital is $(1/2)^2 + (1/2)^2 + (1/\sqrt{2})^2 = 1$. The same is true of the sum of the squares of coefficients of all the atomic orbital wave functions in each of the remaining two molecular orbitals.

The two electrons responsible for the formation of a *three centre-two electron bond* B⟨H⟩B would obviously occupy the bonding molecular orbital.

A similar three centre-two electron bond B⟨B⟩B can be formed by a linear combination of the three hybrid atomic orbitals ψ_{B_1}, ψ_{B_2} and ψ_{B_3} of the three boron atoms of the cluster. The shape of only the resulting bonding molecular orbital in shown below :



The following types of bonds are thus assumed to be involved in bonding in the case of boranes :



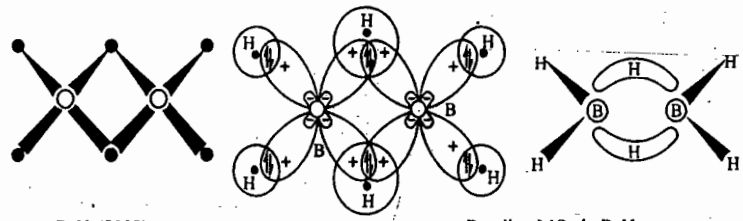
In the above representation and in the ensueing representations of skeletal structures, O denotes B and • denotes H.

The electrons involved in bonding in the framework (skeletal structure) of B_n cluster in boranes are referred to as 'framework electrons'. The B – H – B bonds are considered as part of the B_n framework whereas the terminal B – H bonds are not. Although the framework electrons of B_n cluster are highly delocalised, *i.e.*, they belong to all the boron atoms of the framework, yet the localised 3c – 2e and 2c – 2e molecular orbital approach can explain the main features of the structures of boranes at least qualitatively, as illustrated below.

Each boron atom has three valence electrons of which one electron is used up by each boron atom of the framework in the normal 2c – 2e terminal B – H bond and the remaining two electrons are contributed towards bonding in the B_n framework. However, B atom of each terminal BH_2 group contributes one electron to B_n framework. Thus, overall bonding in boranes is codified as a four digit number, called 'styx' number. The first digit represents the number of 3c – 2e B⟨H⟩B bonds in the structure. The second, third and the fourth digit represents, respectively, the number of the 3c – 2e B⟨B⟩B or B⟨B⟩B bonds, normal 2c – 2e B – B bonds and the terminal BH_2 groups.

Bonding in Boranes. The nature of bonding in some of the boranes is discussed below. The styx number of each borane is also given in brackets.

Bonding in B_2H_6. Valence orbitals of each boron atom in B_2H_6 are sp^3 hybridised. The two terminal BH_2 groups are present in one plane and the bridged B⟨H⟩B part of the molecule is present in a plane perpendicular to the plane containing the two BH_2 groups. Since two valence electrons of each boron atom are used up in BH_2 bonding, the remaining valence electron of each boron atom is used in BHB bonding. Thus, each boron atom contributes one valence electron towards the 3c – 2e BHB bond. The nature of the 3c – 2e BHB bond has already been discussed above in details. The bonding molecular orbitals involved in B_2H_6 and the structure of the molecule are represented below.



B_2H_6(2002) Bonding MOs in B_2H_6

As already mentioned, the B⟨H⟩B bridges are considered as part of the B_n framework. The valence electrons of the two boron atoms can thus be accounted for as follows :

Total number of valence electrons of two boron atoms = 6

Electrons used up in two B⟨H⟩B bridges = 2

Electrons used up in the four terminal B–H bonds = 4

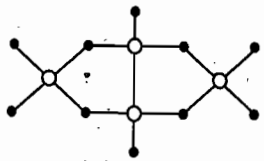
Alternatively,

Total numbers of valence electrons of 2 boron and 6 hydrogen atoms = 6 + 6 = 12

Electrons used up in the two B⟨H⟩B bridges = 4

Electrons used up in the four terminal B – H bonds = 8

Bonding in B_4H_{10}. The boding in B_4H_{10} can be explained more easily by writing the plane projection of its structure, as shown.

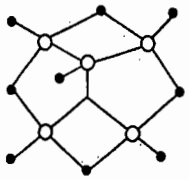


○ B atom ● H atom

Plane projection of the structure of B_4H_{10} (4012)

There are, evidently, four B⟨H⟩B bridges, no B⟨B⟩B or B⟨B⟩B triple bridge, one B – B bond and two terminal BH_2 groups in B_4H_{10}. Hence, out of the 12 valence electrons of 4 boron atoms, 4 electrons are used up in forming the four B⟨H⟩B bridge bonds ; 2 electrons are used up in one B – B bond and the remaining 6 electrons are used up in the six terminal B – H bonds. Alternatively, out of the 22 valence electrons of four boron and ten hydrogen atoms in B_4H_{10}, 8 electrons are used up in the four 3c – 2e B⟨H⟩B bridge bonds, 2 electrons are used up in the single 2c – 2e B – B bond while 12 electrons are used up in the six 2c – 2e B – H bonds.

Bonding in B_5H_9. The bonding in B_5H_9 can be explained conveniently by considering the plane projection of its structure, as shown.

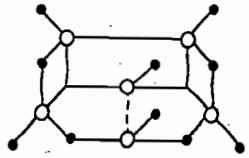


Plane projection of the structure of B_5H_9 (4120).

Out of the 15 valency electrons of five boron atoms, 4 electrons are used up in four B⟨H⟩B bridge bonds, 2 electrons in one B⟨B⟩B triple bridge bond, 4 electrons in the two B – B bonds and the remaining 5 electrons are used up in the terminal five B – H bonds.

Alternatively, out of 24 valence electrons of five boron and nine hydrogen atoms involved in bonding in B_5H_9, 8 electrons are used up in four 3c – 2e B⟨H⟩B bridge bonds, 2 electrons in one 3c – 2e B⟨B⟩B triple bridge bond, 4 electrons in the two 2c – 2e B – B bonds and the remaining 10 electrons in the five 2c – 2e B – H bonds.

Bonding in B_6H_{10}. The bonding in B_6H_{10} can be explained satisfactorily by considering the plane projection of its structure, as shown.

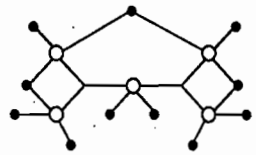


Plane projection of the structure of B_6H_{10} (4220)

Out of the 18 valence electrons of six boron atoms, 4 electrons are used up in four B⟨H⟩B bridge bonds, 4 electrons in two B⟨B⟩B triple bridge bonds, 4 electrons in two B – B bonds and the remaining 6 electrons in the six terminal B – H bonds.

Alternatively, out of a total of 28 valence electrons of six boron and 10 hydrogen atoms in B_6H_{10}, 8 electrons are used up in four 3c – 2e B⟨H⟩B bridge bonds, 4 electrons in two 3c – 2e B⟨B⟩B triple bridge bonds, 4 electrons in two 2c – 2e B – B bonds and the remaining 12 electrons in the six 2c – 2e terminal B–H bonds.

Bonding in B_5H_{11}. The bonding in B_5H_{11} can be explained easily by considering the plane projection of its structure, as shown.

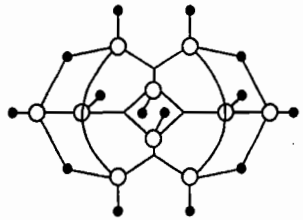


Plane projection of the structure of B_5H_{11} (3203)

There are 15 valence electrons of five boron atoms in B_5H_{11} out of which 3 electrons are used up in three B⟨H⟩B bridge bonds, 4 electrons in two B⟨B⟩B triple bridge bonds and the remaining 8 electrons in the eight terminal B – H bonds.

Alternatively, out of a total of 26 valence electrons of five boron and eleven hydrogen atoms, 6 electrons are used up in three 3c – 2e B⟨H⟩B bridge bonds, 4 electrons in the two 3c — 2e B⟨B⟩B triple bridge bonds and the remaining 16 electrons in the eight terminal B – H bonds.

Bonding in $B_{10}H_{14}$. A plane projection of the structure of $B_{10}H_{14}$ (as shown) explains the bonding in this borane. As can be seen,



Plane projection of the structure of $B_{10}B_{14}$ (4620)

there are four B⟨B⟩B triple bridge bonds and two B⟨B⟩B bent bridge bonds in this structure. Hence, out of the 30 valence electrons of ten boron atoms, 12 electrons are used up in the six B⟨B⟩B bridge bonds, 4 electrons are used up in four B – H bridge bonds and 4 electrons are used in the two B–B bonds. The remaining 10 electrons are used up in the terminal B – H bonds.

Alternatively, out of the 44 valence electrons of ten boron and fourteen hydrogen atoms in $B_{10}H_{14}$, 8 electrons are used up in the four 3c – 2e B⟨H⟩B bridge bonds, 8 electrons in the four 3c – 2e triple bridge B⟨B⟩B bonds, 4 electrons in the two 3c – 2e B⟨B⟩B bent bridge bonds, 4 electrons in the two 2c – 2e B – B bonds and the remaining 20 electrons are used up in the ten terminal 2c – 2e B–H bonds.

Nomenclature. Boranes are named by indicating the number of B atoms with a Latin prefix and the number of H atoms by an arabic numeral in parentheses. Names of anions end in **ate** rather than **ane** and specify the number of H atoms, B atoms and the charge (in that order). The following examples will clarify the nomenclature :

$B_{10}H_{14}$	Nidodecaborane (14)
B_5H_{11}	Arachnopentaborane (11)
$B_{10}H_{10}^{2-}$	Decahydroclosodecaborate (2 –)
$B_{10}H_{14}^{2-}$	Tetradecahydroarachnodecaborate (2 –)

The words closo, nido, arachno indicate a closed skeletal structure, an open skeletal structure and a more open skeletal structure, respectively. The meanings of these words will become more clear to the students when they go through the classification of boranes and carboranes made on the basis of their skeletal structures to be discussed shortly.

Carboranes or Carboboranes

Carboranes or carboboranes are compounds of carbon, boron and hydrogen in which carbon and boron atoms occupy the vertices of a triangular polyhedron. These compounds may be considered to have been derived from boranes by the replacement of BH units by CH units. Carboranes and boranes having the same number of electrons in their bonding frame work, have similar skeletal structures. Three structually different types of carboranes, namely, *closo*, *nido* and *arachno* are known at present (see the next section for this nomenclature). Amongst these the closo carboranes have been studied in greater details. Hence only closo carboranes would be discussed here.

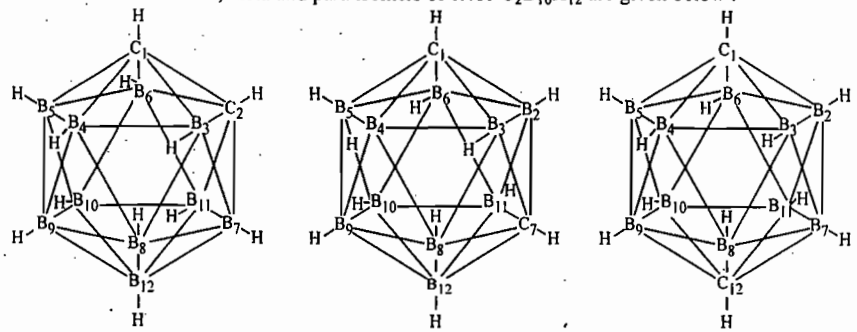
Closo Carboranes. Closo carboranes can be easily prepared from an alkyne and a borane by pyrolysis. Most closo carboranes are stable even upto 400°C. At elevated temperatures they tend to undergo rearrangement to give even more stable isomers.

The most important member of closo carborane family is **dicarbacloso dodecacarborane ($C_2B_{10}H_{12}$)** which has a closed icosachedral structure. The compound occurs in three isomeric forms, *viz.*, ortho, meta and para. All the three isomers are quite stable in air and can be easily prepared as follows :

$$\text{nido } B_{10}H_{14} + 2Et_2S \longrightarrow H_2 + B_{10}H_{12}(SEt_2)_2 \xrightarrow{C_2H_2}$$

$$\underset{\text{(para isomer)}}{\text{Closo } 1,12,\ C_2B_{10}H_{12}} \xleftarrow{700°C} \underset{\text{(meta isomer)}}{\text{Closo } 1,7\ C_2B_{10}H_{12}} \xleftarrow{470°C} \underset{\text{(ortho isomer)}}{\text{Closo } 1,2\ C_2B_{10}H_{12}}$$

The structures of ortho, meta and para isomers of closo $C_2B_{10}H_{12}$ are given below :



(ortho) (meta) (para)

Dicarbacloso dodecacarborane reacts with butyl lithium as shown below :

$$\underset{\text{1, 2 or 1, 7 isomer}}{(CH)_2B_{10}H_{10}} + LiBu \xrightarrow[\text{ether}]{\text{Solvent}} LiC.CHB_{10}H_{10} \xrightarrow[(ii)\ \text{Solvent ether}]{(i)\ LiBu} LiC.CLiB_{10}H_{10}$$

The monolithium and dilithium derivatives can be used for preparing a number of C-substituted derivatives or carboranes as shown.

$$LiC.CLiB_{10}H_{10} \xrightarrow{I_2} (I)_2B_{10}H_{10}$$
$$\xrightarrow{CO_2} (HOOC.C)_2B_{10}H_{10}$$
$$\xrightarrow{NOCl} (C.NO)_2B_{10}H_{10}$$
$$\xrightarrow[H_2O]{HCHO} (C.CH_2OH)_2B_{10}H_{10}$$

Apart from the above derivatives of $(CH)_2B_{10}H_{10}$, a number of polycloso dodecacarboranes have also been synthesised. These derivatives have excellent thermal stability and have important industrial applications.

A number of carborane anions such as $B_9C_2H_{12}^-$, $B_9C_2H_{11}^{2-}$, $B_7C_2H_{11}^{2-}$, are known. These anions form metal complexes with Fe^{2+}, Co^{2+}, Pd^{2+}, etc., which have complicated structures whose discussion is beyond the scope of the book.

Classification of Boranes and Carboranes on the Basis of Their Skeletal Structures. Before we discuss the classification of boranes and carboranes on the basis of their skeletal structures, it would be useful to give Wade's rules for finding out the number of electrons present in the multicentred bonding orbitals of the skeletal structure or framework of a given borane or carborane. Although the concept of localised 3c – 2e and 2c – 2e molecular orbitals satisfactorily explains the bonding in comparatively simple carboranes and boranes, it is not very satisfactory in explaining the bonding in the more complicated boranes and carboranes having highly symmetrical polyhedral structures. In such cases, a molecular orbital description involving completely delocalised molecular orbitals is more useful. Although complete molecular orbital calculations in such cases are tedious, it is possible to give a set of *empirical rules*, called **Wade's rules,** to know the number of electron pairs in the multicentre bonding molecular orbitals of the skeletal structure of a given borane or carborane. These rules are listed below :

Wade's Rules. 1. Each BH unit is assumed to contribute two electrons to the skeletal bonding in a borane or carborane.

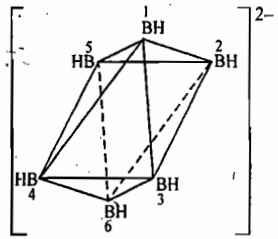
2. The negative charge on a borane or carborane anion is assumed to be used up in skeletal bonding.

3. Each additional H atom in borane or carborane is assumed to contribute one electron to the skeletal bonding.

4. Each CH unit in a carborane is assumed to contribute three electrons to the skeletal bonding.

We shall apply these rules for the classification of boranes and carboranes on the basis of their skeletal structures. On this basis, boranes and carboranes can be classified into the following three types :

A. Closo Boranes and Closo Carboranes. They have a completely closed triangular polyhedral structure in which all the vertices of the triangular polyhedron are occupied by B or C atoms. There are (m+1) electron pairs present in the multicentre bonding orbitals of skeletal structure (or 'cage' or 'framework') of closo boranes and closo carboranes (m is the total number of B and C atoms). The examples are $B_6H_6^{2-}$ and $(CH)_2B_{10}H_{10}$. The structure of $(CH)_2B_{10}H_{10}$ has already been discussed. The structure of closo $B_6H_6^{2-}$ anion is as shown.



In $B_6H_6^{2-}$ anion, m = 6. There are six BH units which according to Wade's rules, contribute 6×2 = 12 electrons to the bonding molecular orbitals of the skeletal structure. The charge of – 2 implies addition of two more electrons to such bonding orbitals. Thus, the total number of electron pairs present in the multicentre bonding orbitals is 6 + 1 = 7 (m + 1 = 7).

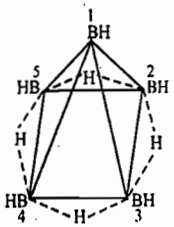
Similarly, in $(CH)_2B_{10}H_{10}$, m is 2+10 = 12. The two CH units, according to Wade's rules, contribute 2×3 = 6 electrons and the ten BH units contribute 10×2 = 20 electrons to the bonding molecular orbitals or the skeletal structure. Thus, there are 13 electron pairs (m + 1 = 13) present in the multicentre bonding orbitals of $(CH_2)B_{10}H_{10}$, commonly written as $C_2B_{10}H_{12}$.

The C and B atoms in the closo structures are numbered in such a manner that the top vertex is given number 1 and the remaining vertices are numbered in a clockwise direction as shown in the structures of $B_6H_6^{2-}$ and $C_2B_{10}H_{12}$.

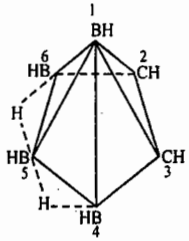
B. Nido Boranes and Nido Carboranes. These boranes and carboranes may be assumed to be derived from the closo triangular polyhedral structure of a closo borane or closo carborane by the removal of one of the vertices of the polyhedron. The resulting ***nido*** (or ***nestlike***) skeletal structure has (m + 2) electron pairs in its multicentre bonding orbitals. The examples are nido B_5H_9 and nido $C_2B_4H_8$ whose structures are given below :

In nido B_5H_9 (m = 5), the five BH units contribute 5×2 = 10 electrons and the four extra hydrogens contribute 4×1 = 4 electrons to the bonding orbitals of the skeletal structure. There are thus 5 + 2 = 7 electron

pairs in the multicentre bonding orbitals of nido B_5H_9. Similarly, in the nido 2, 3, $C_2B_4H_8$ (m = 2 + 4 = 6), the two CH units contribute 2×3 = 6 electrons, the four BH units contribute 4×2 = 8 electrons and the two extra hydrogens contribute 2 electrons to the bonding orbitals of the skeletal structure of nido 2, 3, $C_2B_4H_8$.. Thus, there are 8 electron pairs (m + 2 = 8) in the multicentre bonding orbitals of the skeletal structure of this carborane.

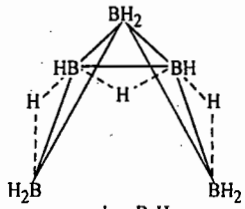


nido B_5H_9



nido 2,3 $C_2B_4H_8$

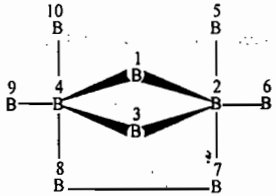
C. Arachno Boranes and Arachno Carboranes. The structures of this type of boranes and carboranes may be assumed to have been derived from nido structures by the removal of the vertices of these structures. There are (m + 3) electron pairs in the multicentre bonding orbitals of boranes and carboranes. The examples are arachno B_5H_{11} and arachno $C_2B_7H_{13}$. The structure of arachno B_5H_{11} is as shown.



arachno B_5H_{11}

It can be seen by applying Wade's rules that arachno B_5H_{11} contains 5 + 3 = 8 electron pairs and arachno $C_2B_7H_{13}$ contains 9 + 3 = 12 electron pairs in the multicentre bonding orbitals of their skeletal structures.

For numbering the B and C atoms in a nido or an arachno structure, the open face is kept upward and their plane projections (showing only B and C atoms) are drawn viewing them from above. First, the interior B and C atoms of the plane projections are numbered in the clockwise direction followed by the numbering of exterior B and C atoms in the clockwise direction. Thus, for nido $B_{10}H_{14}$, the projections and the numbering of B_5H_{11} atoms are as shown :



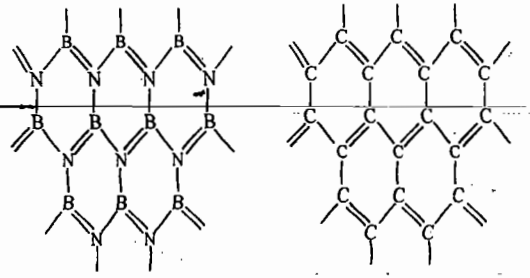
Plane Projection of nido $B_{10}H_{14}$

Compounds of Boron with Nitrogen

Boron forms some interesting compounds with nitrogen, most significant of which are *boron nitride* and *borazine*.

Boron Nitride, BN. As already mentioned, boron nitride is obtained by the interaction of ammonia and diborane. Boron nitride is a white crystalline solid and resembles graphite in its structure, as shown in Fig. 5.

A boron atom bonded together with a nitrogen atom has 8 valence electrons, 3 from boron and 5 from nitrogen. This is the same number of electrons as are present in two adjacent carbon atoms in graphite. The structure of boron nitride, therefore, is very similar to that of graphite shown in Fig. 5(*b*). The B — N bonds in boron nitride are formed by the overlapping of sp^2 hybrid orbitals of boron and nitrogen atoms. The remaining electrons form pi bonds. Unlike graphite, where electrons are *completely delocalised* over all the carbon atoms of the lattice, the electrons in boron nitride are only *partially delocalised* over boron atoms leading to *unequal* B — N *bond lengths*. The layers are arranged in such a manner that boron atoms in one layer are immediately above the nitrogen atoms in the adjacent layer. On heating at 1800°C under a pressure of 85 atm, in the presence



(*a*) Boron nitride (*b*) Graphite

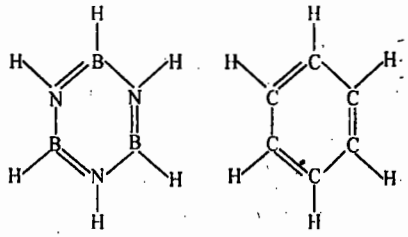
Fig.5. Similarity in the structure of boron nitride and graphite.

of a catalyst, BN gets converted into another modification which, in strcuture, is comparable to diamond.

Borazine or Borazole. Borazine can be prepared by heating together BCl_3 and NH_4Cl. The initial product formed is trichloroborazine which on reducing with $NaBH_4$ yields borazine. It can also be prepared by treating $NaBH_4$ with NH_4Cl.

The **structure** of borazine is similar to that of benzene (Fig. 6).

In this structure, the valence shell orbitals of both boron and nitrogen atoms are sp^2 hybridised. Each nitrogen atom has one lone pair of electrons while each boron atom has an empty *p* orbital. The bonding in borazine is dative and it arises from the sidewise overlapping of fully filled *p* orbitals of nitrogen and empty *p* orbitals of boron. Because of the similarity of the structures of borazine and benzene, borazine is also known as **'inorganic benzene.**



Borazine Benzene

Fig.6. Similarity in the structure of borazine and benzene.

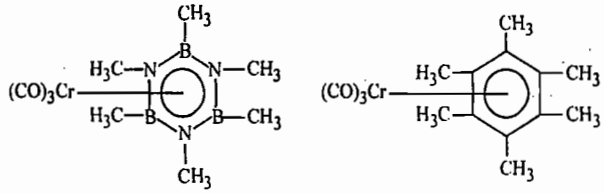
Molecular orbital calculations indicate that the electrons in borazine are only *partially delocalised* unlike benzene in which there is *complete delocalisation*. In fact, complete delocalisation in B_3N_3 ring is not expected either since N-π orbitals are of lower energy than the B-π orbitals. MO calculations indicate that the π electron-drift from N to B is less than the σ electron-drift from B to N due to greater electronegativity of N. These are thus the N atoms which are relatively more electronegative than B atoms in borazine. The π bonding stabilises the planar structure of borazine ring.

The retention of negative charge by nitrogen implies that chemically borazine would be different from benzene. It is thus much more reactive than benzene and readily undergoes addition reactions as, for example,

$$B_3N_3H_6 + 3HX \longrightarrow (H_2N-BHX)_3\ ;\quad X = Cl, OH, OR$$

Borazine undergoes hydrolysis at high temperature to yield NH_3 and $B(OH)_3$. It decomposes slowly on storage.

Borazine resembles benzene in forming similar metal complexes, as illustrated below :



Borazine metal complex Benzene metal complex

Oxo-Compounds of Boron

Ortho Boric Acid, H_3BO_3. Boron forms a number of acids of which ortho boric acid, commonly known as boric acid, is the most important.

Preparation. Boric acid can be prepared by the following methods.

1. From colemanite. A large proportion of the world's supply of boric acid is made from *colemanite*, *viz.*, calcium borate ($Ca_2B_6O_{11}.5H_2O$), occurring in California (U.S.A.) and South America. The mineral is powdered and mixed with boiling water. Sulphur dioxide is passed through the mixture when boric acid and calcium sulphite are formed.

$$Ca_2B_6O_{11} + 2SO_2 + 9H_2O \longrightarrow 2CaSO_3 + 6H_3BO_3$$

On cooling, boric acid crystallises out.

2. From borax. Boric acid is obtained on a large scale from borax. A hot concentrated solution of borax is treated with a calculated quantity of hydrochloric acid or sulphuric acid.

$$Na_2B_4O_7 + 2HCl + 5H_2O \longrightarrow 4H_3BO_3 + 2NaCl$$

Properties. 1. It forms soft pearly-white needle-like crystals having a greasy feel.

2. *It is moderately soluble in water. The dissolution is accompanied by absorption of heat which is consistent with the fact that its solubility increases with rise in temperature.*

3. Boric acid is a very weak acid and ionises mainly as a monobasic acid and that, too, to a very limited extent. The dissociation constant of the acid is of the order of $1{\cdot}0\times10^{-9}$. It is not a proton donor but behaves as a Lewis acid, *i.e.*, as an acceptor of a pair of electrons from an $.OH^-$ ion.

As the concentration of aqueous solution increases beyond 0·025 M, the acidity increases. This anomaly has been explained as due to the formation of a polymeric species.

$$3B(OH)_3 \longrightarrow B_3O_3(OH)_4^- + 2H_2O + H^+$$

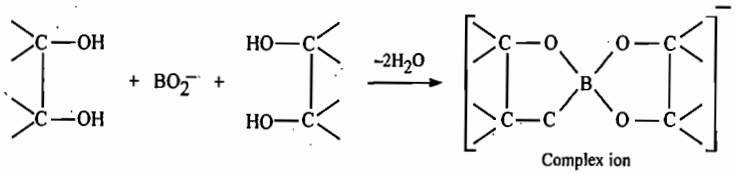
With strong alkalies, it forms salts known as metaborates.

$$B(OH)_3 + NaOH \longrightarrow B(OH)_4^- + Na^+ \longrightarrow \underset{\text{Sod. metaborate}}{Na^+BO_2^-} + 2H_2O$$

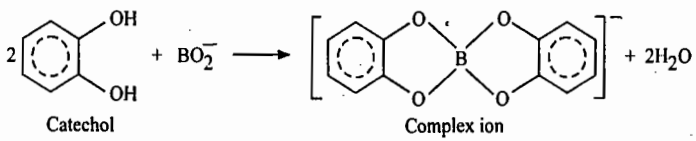
The end point in the titration of boric acid against sodium hydroxide is not sharp on account of excessive hydrolysis of sodium metaborate formed during titration.

$$NaBO_2 + H_2O \rightleftharpoons H_3BO_3 + NaOH$$

However, the addition of certain polyhydroxy compounds such as catechol, mannitol, glycerol or sugars to the titration solution checks the hydrolytic reaction and makes boric acid behave as a strong monobasic acid and the end point can thus be easily detected. The polyhydroxy compounds combine with the metaborate ion to form complex compounds, as illustrated below :



With catechol and mannitol, for instance, the complexation occurs as follows :



$$\underset{\text{Mannitol}}{C_6H_8(OH)_6} + BO_2^- \longrightarrow [C_6H_8(OH)_4BO_4] + 2H^+$$

The elimination of BO_2^- ion in the form of its complexes means no hydrolysis of the end product of the neutralisation reaction. As a result, boric acid ionises freely during titration against a strong alkali thus behaving as a strong acid.

4. On heating at 1000°C or a little above, orthoboric acid loses water to yield metaboric acid.

$$H_3BO_3 \longrightarrow HBO_2 + H_2O$$

When metaboric acid is heated at 160°C, tetraboric acid results.

$$4HBO_2 \longrightarrow H_2B_4O_7 + H_2O$$

At still higher temperatures it swells up giving a frothy mass and finally forms a glass of boron trioxide.

$$H_2B_4O_7 \longrightarrow 2B_2O_3 + H_2O$$

5. Boric acid when heated with CaF_2 and concentrated H_2SO_4, *yields boron trifluoride.*

$$3CaF_2 + 3H_2SO_4 + 2H_3BO_3 \longrightarrow 3CaSO_4 + 2BF_3 + 6H_2O$$

6. On heating boric acid with ethyl alcohol, ethyl borate is formed whose vapours burn with green edged flame.

$$H_3BO_3 + 3C_2H_5OH \longrightarrow \underset{\text{Ethyl borate}}{(B(OC_2H_5)_3} + 3H_2O$$

7. $B(OH)_3$ acts as a strong acid in anhydrous H_2SO_4.

$$B(OH)_3 + 6H_2SO_4 \longrightarrow 3H_3O^+ + 2HSO_4^- + [B(HSO_4)_4]^-$$

Uses. 1. Boric acid is used in making enamels, pottery glazes and glass. 2. It is also used in medicines as an eye-wash (eye lotion). 3. It is used as a food preservative.

Structure of boric acid. In order to understand the structure of boric acid let us consider boron atom in ground state as well as in the excited state. It is evident that 3 singly occupied orbitals become available in the excited state which form bonds with three oxygen atoms. This, is, evidently, a case of sp^2 hybridisation.

Since only one electron from each oxygen atom enters into bond formation, the resulting unit is a trivalent ion, BO_3^{3-}, in which each boron atom is bonded to three oxygen atoms arranged at the corners of an equilateral triangle with boron atom lying in the centre.

The triangular BO_3^{3-} units are bonded together through hydrogen bonds into two-dimensional sheets, as shown in Fig. 7.

It is evident that each boron atom remains bonded to three oxygen atoms and each oxygen atom is bonded to a hydrogen atom. Thus, each unit now consists of H_3BO_3. The hydrogens provide the limbs (or bridges) between the oxygen atoms of different BO_3 units, as shown.

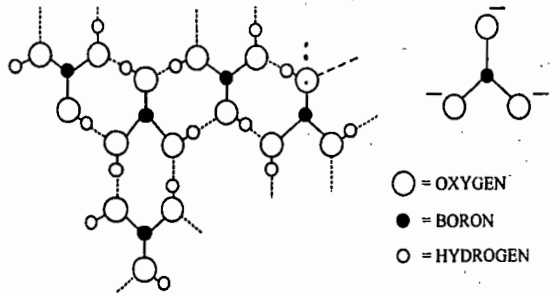


Fig.7. Two-dimensional sl eet structure of boric acid. Dotted lines represent hydrogen bonds.

Lithium Aluminium Hydride, $LiAlH_4$

Preparation. $LiAlH_4$ is prepared by reacting lithium hydride with anhydrous aluminium chloride in ether.

$$4LiH + \underset{\text{anhydrous}}{AlCl_3} \xrightarrow{\text{ether}} LiAlH_4 + 3LiCl$$

On industrial scale, it is prepared by direct combination of the constituent elements under high pressure in the presence of ether.

$$Li + Al + 2H_2 \xrightarrow[\text{140°C, 350 atm}]{\text{ether}} LiAlH_4$$

Alternatively and preferably, $NaAlH_4$ is first prepared by direct synthesis which is then converted

into $LiAlH_4$ by treatment with LiCl.

$$Na + Al + 2H_2 \xrightarrow[140°C,\ 350\ atm]{ether} NaAlH_4$$

$$NaAlH_4 + LiCl \xrightarrow{ether} NaCl\ (s) + LiAlH_4$$

Properties. Lithium aluminium hydride is a white, non-volatile, crystalline solid which is freely soluble in ether and various glymes. It is stable below 120°C.

It is readily attacked by water and ethanol giving hydrogen gas.

$$LiAlH_4 + 4H_2O \longrightarrow LiOH + Al(OH)_3 + 2H_2$$

$$LiAlH_4 + 3C_2H_5OH \longrightarrow Li(AlH(OC_2H_5)_3] + 3H_2$$

It reacts with ethylene, ammonia, phosphine, arsine as well as primary and tertiary amines.

$$LiAlH_4 + 3C_2H_4 \longrightarrow Li[AlH(CH=CH_2)_3] + 3H_2$$

$$LiAlH_4 + 4NH_3 \longrightarrow Li[(Al(NH_2)_4] + 4H_2$$

$$LiAlH_4 + 4PH_3 \longrightarrow Li(Al(PH_2)]_4 + 4H_2$$

$$LiAlH_4 + 4RNH_2 \longrightarrow LiAl(NHR)_4] + 4H_2$$

$$LiAlH_4 + (CH_3)_3N \longrightarrow (CH_3)_3NAlH_3 + LiH$$

Uses. Lithium aluminium hydride is extensively used in organic as well as inorganic chemistry as a versatile reducing agent.

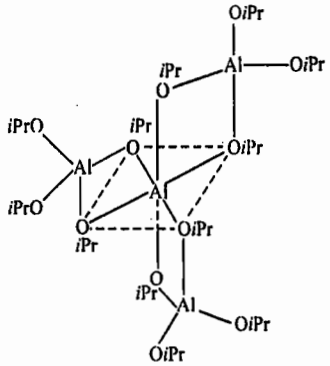
Aluminium Alkoxides, $Al(OR)_3$

These compounds, which are widely used as reducing agents in organic synthesis, can be prepared by the action of aluminium metal on alcohols in the presence of $HgCl_2$ as catalyst or by reacting $AlCl_3$ with sodium alkoxide.

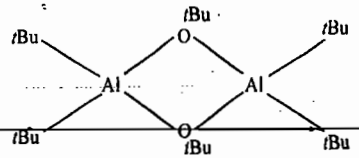
$$Al + 3ROH \xrightarrow{HgCl_2} Al(OR)_3 + 3/2\ H_2$$

$$AlCl_3 + 3RONa \xrightarrow{warm} 3NaCl + Al(OR)_3$$

Actually these alkoxides are complex compounds in which Al has a coordination number 4 and/or 6.



The most widely used aluminium alkoxides for reducing purposes are aluminium isopropoxide and aluminium tertiary butoxide. The former is a tetramer at room temperature whereas the latter is a dimer, as shown below:



Ultramarine. Ultramarine is a complex silicate of aluminium and sodium associated with about 12 per cent of sulphur. It has a fine blue colour and occurs rarely as a mineral. It can be prepared artificially by heating a mixture of kaolin, soda ash, sulphur and charcoal to bright red heat. At first a white mass is formed which in the presence of air changes to green. It is powdered and heated with more sulphur when the *blue* ultramarine, having the composition $Na_5Al_2Si_2S_3O_{12}$ is obtained.

If this product is heated in a stream of chlorine, a *violet* coloured variety of ultramarine is obtained. However, the blue variety is the most popular and is used in laundry for blueing purposes. It is also used in calico printing and in blue paints.

Organometallic Compounds of Group 13 Elements

These have been discussed in details in Chapter 34 on Organometallic Compounds.

QUESTIONS

1. (*a*) Give the electronic configurations of the elements of Group 13.
   (*b*) Why does boron differ from the rest of its family members ? Discuss the main points of difference.
   (*c*) "While Al, Ga, In and Tl form both covalent and electrovalent compounds, boron mostly forms covalent compounds." How would you explain this behaviour ?
2. (*a*) What is meant by diagonal relationship in periodic classification ? Discuss the diagonal relationship of boron with silicon.
   (*b*) $B(OH)_3$ is acidic, $Al(OH)_3$ is amphoteric while $Tl(OH)_3$ is distinctly basic in character. How would you account for this ?
3. (*a*) Account for the trivalency and monovalency of Group 13 elements.
   (*b*) Why is BBr_3 a better Lewis acid than BF_3 ?
   (*c*) How does boric acid ionise in water ? Why is its acidity increased by the addition of catechol?
4. Give the preparation and properties of boron halides. Why are these subtances called Lewis acids ?
5. (*a*) Give an account of the hydrides of boron with special reference to diborane.
   (*b*) Discuss in details the bridge structure of diborane. Bring out clearly the nature of bonds in hydrogen bridges.
   (*c*) Discuss in details the nature of bonding involved in B_2H_6, B_4H_{10}, B_6H_{10}, B_5H_{11} and $B_{10}H_{14}$.
6. Give reasons for the following :
   (*a*) Boron trichloride is monomeric while aluminimum trichloride is dimeric.
   (*b*) BF_3 is a weaker Lewis acid than BCl_3 and BBr_3.
7. (*a*) Discuss the gradation in properties of elements of Group 13 with respect to
   (*i*) oxidation state (*ii*) electron affinity
   (*iii*) metallic character (*iv*) electronegativity.
   (*b*) What is meant by back bonding ? On the basis of back bonding, explain why BF_3 is a weaker Lewis acid than BCl_3.
8. Explain the following :
   (*a*) Aluminium forms $[Al(OH)_6]^{3-}$ but $[B(OH)_6]^{3-}$ is not known.
   (*b*) The +1 oxidation state becomes progressively more stable from boron to thallium.
   (*c*) The B – X (X = F, Cl, Br, I) distance is shorter than what is expected theoretically in BX_3 molecules.
   (*d*) BF_3 is a weaker electron acceptor than BCl_3.
9. (*a*) Normally the ionization energy should decrease regularly as we move along a group. However, the ionisation energies (kJ mol^{-1}) of Group 13 elements are as follows :

B	Al	Ga	In	Tl
800	577	579	558	589

   How much you account for this anomalous behaviour ?
   (*b*) How does the structure of boron nitride differ from that of graphite ?
10. (*a*) How does boron occur in nature ? Describe briefly the extraction of boron.
    (*b*) How does boron react with
    (*i*) nitric acid (*ii*) sodium hydroxide (*iii*) magnesium (*iv*) nitrogen ?
11. (*a*) How is boric acid obtained from *colemanite* ? Discuss in details the structure of the acid.
    (*b*) How does boric acid react with (*i*) ethyl alcohol (*ii*) calcium fluoride in the presence of H_2SO_4 ?
    (*c*) What is the action of heat on boric acid ?
12. What are carboranes ? How are boranes and carboranes classified ?
13. What are Wades' rules ? Discuss the application of these rules in classifying carboranes into closo, nido and arachno carboranes. Discuss briefly how closo carbonanes are prepared.

16 THE ELEMENTS OF GROUP 14

Group 14 contains five elements, namely, **carbon, silicon, germanium, tin** and **lead.** Carbon is an essential constituent of all organic matter. Silicon is an important constituent of inorganic matter. Carbon and silicon are typical non-metals. Germanium has intermediate character while tin and lead are distinctly metals. Carbon occurs hardly upto 0·1 per cent in the earth's crust. However, combined with oxygen and hydrogen it occurs in all living tissues belonging to plant or animal kingdom It occurs as carbon dioxide in the atmosphere and as carbonates in rocks and minerals such as limestone, dolomite, etc. In free state, it occurs as coal, diamond and graphite.

Silicon occurs most abundantly, next only to oxygen, upto about 26 per cent in the earth's crust, as silica and silicates.

Germanium occurs rather sparsely. Tin occurs chiefly as SnO_2 in its ore known as *tin stone* while lead occurs as PbS in its ore known as *galena*.

Electronic Configurations. The electronic configurations of elements of Group 14 are shown in Table 1.

Thus, the general outer electronic configuration of the elements of this group may be written as $\mathbf{ns^2p^2}$.

TABLE 1

Electronic Configurations of Elements of Group 14

Element	At. No.	Electronic Configurations
Carbon, C	6	[He] $2s^2p^2$
Silicon, Si	14	[Ne] $3s^2p^2$
Germanium, Ge	32	[Ar] $3d^{10}4s^2p^2$
Tin, Sn	50	[Kr] $4d^{10}5s^2p^2$
Lead, Pb	82	[Xe] $4f^{14}5d^{10}6s^2p^2$

Carbon and silicon have 8 electrons in the penultimate shell (noble gas kernel) while the rest of the elements have 18 electrons in the penultimate shell. Carbon and silicon contain only *s* and *p* electrons while the rest of the elements also contain fully paired *d* electrons in the penultimate shells.

GENERAL CHARACTERISTICS OF GROUP 14 ELEMENTS

Important physical properties and other physical constants of the elements of Group 14 are shown in Table 2.

TABLE 2

Physical Properties of Elements of Group 14

Property	Carbon	Silicon	Germanium	Tin	Lead
Atomic number	6	14	32	50	82
Molar mass (g mol^{-1})	12·00	28·08	72·59	118·89	207·19
Density (g cm^{-3})	3·52	2·49	5·35	7·30	11·34
Atomic radius (Å)	0·77	1·11	1·22	1·41	1·47
Molar volume (cm^3 mol^{-1})	3·4	11·4	13·6	16·3	18·27
Melting point (°C)	3727	1410	937·5	231·8	327·4
Boiling point (°C) (Pauling's values)	4833	2680	2830	2270	1725
Electronegativity	2·5	1·9	2·0	1·8*	1·8*
Ionization energy (kJmol^{-1})	1086	786	761	708	716
Oxidation states (stable)	+ 4	+ 4	+ 2, + 4	+ 2, + 4	2, + 4

1. Molar volume and atomic radius. Molar volumes and atomic radii, as expected, increase with increase in atomic number.

2. Melting points and boiling points. The melting point as well as the boiling point of carbon, the first element, are exceedingly high. The values decrease as we move from carbon to lead. The melting points of tin and lead are relatively low.

3. Ionization energy. Ionization energy of carbon, the first element, is quite high, being 1086 kJ mol^{-1}. This is understandable in view of the small size of the carbon atom. There is a sharp decrease in the ionization energy as we move from carbon to the next element silicon. This is due to an appreciable increase in the size of the Si atom. There is, however, a very small decrease in ionization energy as we move from Si to Sn. This is because the *d* electrons which are now present in the inner configuration of Ge and Sn, shield the nuclear charge less effectively than is done by the *s* and *p* electrons. The outer electrons are, therefore, held strongly by the nucleus and hence, in spite of a sizeable increase in atomic radius, there is only a small decrease in ionization energy as we move from Si to Sn. In the last element, Pb, there are *f* electrons in the inner configuration which shield the nuclear charge less effectively even than the *d* electrons. Also there is only a marginal increase (of 0·03 Å) in the atomic radius as we move from Sn to Pb. Because of these two factors, the ionization energy of Pb, instead of decreasing, shows a marginal increase.

4. Oxidation states. All the elements have, in common, the oxidation state of + 4. The + 4 state is of much greater importance in carbon and silicon and + 2 state becomes increasingly important for germanium, tin and lead.

5. Metallic and non-metallic character. The change from non-metallic to metallic character with increase in atomic number in the same group, is best illustrated in this group, as already mentioned. The first two elements, carbon and silicon, are distinctly non-metals even though electrical properties of silicon are like those of a semi-metal. The third element, germanium, is partly non-metal and partly metal (*i.e.,* it is a semi-metal) while the last two elements, tin and lead, are distinctly metals in their physical and chemical properties.

6. Electronegativity. Carbon is the most electronegative element of this group. The electronegativity decreases on moving down the group but not after silicon (Table 2). This appears to be due to filling of the *d* orbitals in the case of germanium and tin and also the *f* orbitals in the case of lead.

7. Nature of bonds in their compounds. The elements of Group 14, on account of their high ionisation energies, do not form stable M^{4+} ions. Their electronegativities are also sufficiently low to permit the formation of stable anions. All the same, carbon does have a tendency to form C_2^{2-} ions, as in certain carbides. Thus, calcium carbide is an ionic compound which may be represented as $Ca^{2+}C_2^{2-}$. All the elements, and carbon and silicon in particular, show a covalency of 4.

The last three elements (Ge, Sn and Pb) have a tendency to form M^{2+} ions as well as M^{4+} ions. However, Sn and Pb prefer to form M^{2+} ions. The reason for showing reluctance to exhibit higher oxidation states by the heavier elements of the group have already been discussed in details in Chapter 12. Thus, $Sn^{2+}$and Pb^{2+} exist as stable ions and are much more common than Sn^{4+} and Pb^{4+} ions.

Sn(IV) and Pb(IV) compounds are more covalent than electrovalent in nature. This is to be expected from Fajan's rule according to which the smaller the ion, the greater is its tendency towards covalency. Sn^{4+} and Pb^{4+} ions have much smaller radii than Sn^{2+} and Pb^{2+} ions.

8. Formation of complexes. The tendency of an element to form complexes is favoured by (*a*) small size of its atom or ion, (*b*) high charge and (*c*) availability of vacant orbitals of appropriate energy. Except for the first element carbon, the succeeding elements in this family have vacant *d* orbitals which permit formation of coordinate bonds with other atoms or ions having lone pairs of electrons. For

example, silicon tetrafluoride which is a tetracovalent compound, can form complexes such as $[SiF_6]^{2-}$.

$$2HF + SiF_4 \longrightarrow H_2[SiF_6]$$

Since Si orbitals in $[SiF_6]^{2-}$ undergo sp^3d^2 hybridisation, the complex ion has an octahedral structure. The covalency of silicon thus rises to 6 in this complex ion.

Similarly, other elements of the group can also have a covalency of six due to availability of *d* orbitals, as in $[SnCl_6]^{2-}$ and $[PbCl_6]^{2-}$.

9. Tendency to form chains. Catenation. Carbon exhibits the remarkable property of **catenation**, *i.e., to form chains of identical atoms.* Silicon has much smaller tendency to form chains. Germanium has still smaller tendency while tin and lead have hardly any tendency to do so. Thus, in Group 14 elements, tendency to catenate decreases in the order C > Si > Ge > Sn > Pb.

As a result of catenation, carbon atoms can link together to form linear chains, branched chains and even rings of different sizes. The tendency of an element to form chains depends upon the strength of the element–element bond (bond energy) which is maximum in the case of carbon. The bond energies of C – C, Si – Si, Ge – Ge and Sn – Sn bonds are 354, 222, 167 and 155 kJ mol^{-1}, respectively.

10. Allotropy. Most of the elements of Group 14 show allotropy. Thus, carbon exists in two well-defined crystalline forms known as *diamond* and *graphite*. Besides these, there are microcrystalline forms which were previously regarded as amorphous. These are *coal, coke, charcoal, carbon black*, etc. All these have finely divided graphite structures. Silicon is known to exist in *crystalline* and *amorphous forms*. Germanium also exists in *two crystalline forms*. Likewise, tin exists in three solid forms : *grey tin, white tin* and *rhombic tin*. Grey tin is stable below 18°C, white tin above 18°C and rhombic tin above 161°C. *Grey tin* exists usually in powder form and is a poor conductor of electricity. It, therefore, lacks metallic properties. Its density is 5·75 g cm^{-3}. *White tin*, on the other hand, is soft, ductile and good conductor of electricity. It has, therefore, metallic character. It has also the usual metallic lustre. Being stable at room temperature, it is the most common form of tin. Its density is 7·30 g cm^{-3}.

Unique Character of Carbon. Carbon with smallest atomic radius and lowest molar volume is most compact of all the elements in this group. It has highest melting and boiling points. It has the highest ionisation energy and is the most electronegative element in this group. Also because of the absence of *d* orbitals, it has least tendency to form complex compounds. Its maximum covalency remains 4.

Carbon can form multiple bonds, *i.e.*, double bonds and triple bonds, in a number of its compounds. The most remarkable property of carbon, however, lies in its property of catenation as a result of which it forms thousands of compounds in which carbon atoms are bonded to one another through covalent bonds.

Comparison of Carbon with Silicon. Carbon and silicon, the first two elements of this group, have a number of properties in common. Due to similar electronic configurations, they form similar hydrides (*e.g.*, CH_4, SiH_4 and C_2H_6 and Si_2H_6), similar halides (*e.g.*, CCl_4, $SiCl_4$), similar oxides (*e.g.*, CO_2, SiO_2) and similar oxyacids (*e.g.*, H_2CO_3, H_2SiO_3), etc. In spite of these similarities, the two elements and their compounds differ appreciably from one another in several respects. Most of these differences, though not all, arise from the following factors : 1. Difference in sizes of carbon and silicon atoms, carbon atom being much smaller than silicon atom. 2. Non-availability of *d* orbitals in carbon atom. 3. Carbon having high capacity for catenation, as pointed out above.

Some of the important differences between the two elements are summed up below :

1. Carbon is harder and has higher melting and boiling points than silicon.

2. Carbon in the form of graphite is a good conductor of electricity while silicon is a pair conductor of electricity.

3. Carbon, due to its small atomic size, can form pi bonds with oxygen involving *p* orbitals while silicon due to its large atomic size cannot do so.

4. Due to its high capacity for catenation, carbon forms thousands of compounds. Silicon has much lower capacity for catenation. The number of its compounds is, therefore, limited.

5. Carbon is an essential constituent of living organisms belonging to animal or vegetable kingdom. Silicon is an essential constituent of most of the non-living materials including rocks, hills, clays, soils, ores, etc.

The **compounds of carbon and silicon** also differ in several respects as illustrated below.

1. Hydrides. The hydrides of carbon are numerous (*e.g.*, CH_4, C_2H_6, C_2H_4, C_2H_2, C_6H_6, $C_6H_5CH_3$ and a host of others). Many of these are highly stable. Silicon hydrides (SiH_4, Si_2H_6, etc.) are only a few in number and are not as stable.

2. Oxides. Carbon forms two similar oxides, CO and CO_2, both being *gases* at ordinary temperatures. Silicon forms only one oxide, SiO_2, which is a *solid* with high melting and boiling points. The reason why CO_2 is a gas while SiO_2 is a highly stable solid has been discussed in details in a subsequent section in this chapter dealing with the **structure of silica**.

3. Halides. Carbon tetrachloride does not undergo hydrolysis in water. It also does not form addition compounds. Silicon tetrachloride, however, gets hydrolysed in water and forms addition compounds with ammonia. This is due to the presence of *d* orbitals in silicon. Carbon does not form dihalides while silicon does.

4. Silicones. Silicon is capable of forming cross-linked silicones through hydrolysis of its halides. These compounds are used as lubricants, water repellents and insulators, etc. No such compounds are formed by carbon.

EXTRACTION OF ELEMENTS OF GROUP 14

Recovery of Carbon. Carbon is one of the most widely distributed elements. It occurs naturally in pure forms as diamond and graphite and more abundantly in a contaminated form as coal. The purest form of coal is anthracite which contains about 95 percent carbon. Other varieties of coal are steam coal, bituminous coal, lignite and peat in which the carbon content is respectively, 93, 88, 67 and 60 per cent.

All the naturally occurring forms are recovered as such from their respective mines. Graphite and diamond, are, however, prepared artificially also, as described below.

Artificial diamonds. Artificial diamonds are prepared by Moissan's method. In this method, pure sugar charcoal and iron are heated in a graphite crucible to a temperature of about 3000°C in an electric arc furnace. At this temperature, the iron dissolves an appreciable amount of carbon. The graphite crucible containing the molten mass is *cooled rapidly* by placing it in a bath of molten lead (temperature 327°C). As a result of the solidification of the external surface of the iron, an enormous pressure is exerted on the interior mass (cast iron expands on solidification). Under these conditions, the carbon is thrown out in the form of *minute diamonds*. The mass is cooled and treated with hydrochloric acid to dissolve the iron. The residual carbon is found to contain a number of small diamonds (not more than 0·8 mm in diameter), some transparent and some black.

Artificial graphite. Large amounts of graphite are prepared artificially by Acheson process. A mixture of sand and powdered anthracite (or coke) is heated strongly to about 2500°C in an electric furnace consisting of two carbon electrodes connected by a thin carbon rod. An alternating current is passed and heating continued for 24 – 30 hours. Silicon carbide first formed decomposes into graphite and silicon, the latter volatilises off leaving behind the graphite.

$$SiO_2 + \underset{\text{Coke}}{3C} \longrightarrow 2CO + SiC$$

$$SiC \longrightarrow Si + \underset{\text{graphite}}{C}$$

Extraction of Silicon. Silicon occurs abundantly (26%) in the earth's crust, next only to oxygen (50%). But unlike carbon it does not occur free in nature. As oxide, SiO_2, it is found in sand, quartz of various forms, flint, opal, etc. It is also found as silicates, *e.g., feldspar* ($KAlSi_2O_8$), *mica* [$KH_2Al(SiO)_3$], in rocks and clays.

In laboratory, silicon may be prepared by heating dry powdered silica with magnesium or aluminium.

$$SiO_2 + 2Mg \longrightarrow Si + 2MgO$$

Magnesium oxide and any unreacted silica are removed by treatment with hydrofluoric acid in polythene vessel. Silicon left behind is a *brown amorphous powder.*

On a commercial scale, it is prepared by heating a mixture of finely powdered sand or quartz and carbon in an electric furnace.

$$SiO_2 + 2C \longrightarrow Si + 2CO$$

Silicon formed in this way is *crystalline* in structure and grey in colour. A small amount of iron is added usually to avoid the formation of silicon carbide (carborundum). In this way, an alloy of iron and silicon, called ferrosilicon, is obtained.

Extraction of Tin. Tin does not occur free in nature. Its chief source is the ore *casseterite*, SnO_2, also known as *tin stone.*

The ore is freed of silicious impurities by froth floation and gravity processes. The magnetic impurity *wolfrom* is removed by electromagnetic means (Chapter 10).

The purified ore is roasted in a rotary furnace. It is then mixed with anthracite and smelted in a reverberatory furnace, using lime as flux. The metal obtained is purified by liquation process.

Extraction of Lead. Small quantities of lead occur native in Sweden. However, its chief ore is *galena*, lead sulphide, which contains about 6 – 8% lead. Galena also contains small quantities of silver (upto 0·1%).

If the ore is rich in lead, it is heated in a reverberatory furnace in a limited supply of air when PbS is partly converted to PbO and partly to $PbSO_4$. The supply of air is then reduced, some more of the ore is added and temperature of the furnace is raised when PbO & PbS and PbS & $PbSO_4$ interact to give lead. If, however, the ore is poor in lead, it is roasted in a free supply of air to convert PbS into PbO which is then reduced on heating with carbon in a blast furnace using lime as flux.

Extraction of Germanium. Germanium occurs rarely. The only relatively rich ore of germanium is *germanite*, GeO_2, which contains nearly 6 per cent of the metal. The ore is strongly heated with hydrochloric acid when the chloride $GeCl_4$ distils off. This is hydrolysed to give pure dioxide, GeO_2, which is dried and then reduced by hydrogen or carbon to give the element.

PROPERTIES OF ELEMENTS OF GROUP 14

Properties of Carbon. Physical Properties. Carbon exists in various allotropic forms, of which *diamond* and *graphite* are crystalline while *coal, wood charcoal, animal charcoal, lamp black, coke* and *gas carbon* are amorphous. The X-ray analysis has revealed, however, that the so-called amorphous carbons are in reality crystalline in structure. However, they consist of extremely fine crystals. These carbons are, therefore, termed as **microcrystalline carbons.** Diamond and graphite are, however, structurally very much different from each other. While diamond has a *three- dimensional tetrahedral structure*, graphite has a *two-dimensional layer structure,* as discussed below.

Structure of diamond. Diamond is a big *three-dimensional polymer* comprising of a large number of carbon atoms arranged *tetrahedrally* by utilising their sp^3 hybrid orbitals. The structure is shown in

Fig. 1. The C – C bond distance is 1·54 Å. It will be seen that each carbon atom lies at the centre of a regular tetrahedron and is linked to four surrounding carbon atoms lying at the corners of the tetrahedron by strong covalent bonds through sharing of their valency electrons. The result is a very big, three-dimensional polymer. Due to high strength of covalent bonds holding numerous carbon atoms together, diamond is very hard and has high density. Since melting of diamond requires breaking of the strong covalent bonds, the melting point of diamond is unusually high, being close to 3500°C. Diamond is the purest form of carbon and is the hardest substance known. It has a very high refractive index (2·417) and a very high density (3·51 g cm^{-3} at 25°C). It is transparent to X-rays and is a bad conductor of heat and electricity.

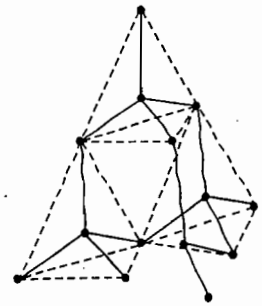


Fig. 1. Structure of diamond.

Structure of graphite. Graphite, unlike diamond, has a *two-dimensional* structure. In this case, only three of the four valency electrons of each carbon atom are involved in bonding. Thus, each carbon atom makes use of its three sp^2 hybrid orbitals forming three covalent bonds with three other carbon atoms in the same plane (unlike the structure of diamond in which each carbon atom is linked to four other carbon atoms through sp^3 hybrid bonds). Thus, the structure of graphite is two-dimensional sheet-like consisting of a number of benzene rings fused together (Fig. 2*a*), unlike that of diamond which is three-dimensional. The sheets or layers are held together by relatively weak van der Waals forces. The C – C covalent bond distance is 1·42 Å. The distance between the two successive layers is 3·36 Å (Fig. 2*b*). This large distance rules out the possibility of covalent bonding between carbon atoms in different layers. Hence, the fourth valency of each carbon atom remains unsatisfied, *i.e.,* the fourth valency electron remains unpaired or free. This free electron can easily move from one carbon atom to another under the influence of applied potential. This permits the passage of electricity through graphite and makes graphite a good conductor of electricity.

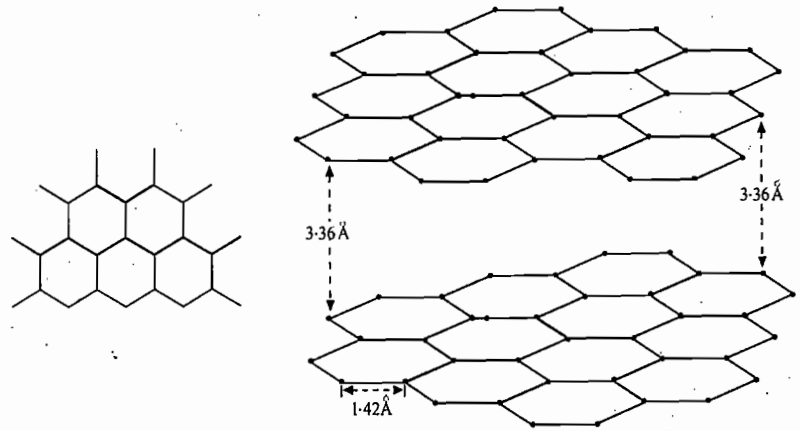

Fig. 2. (*a*) Hexagonal-layer structure of graphite (*b*) Bonding in graphite.

The above layer structure of graphite is less compact than that of diamond. Further, since the bonding between the layers involving only van der Waals forces is weak, these layers can slide over each other. This gives softness, greasiness and lubricating character to graphite.

Graphene. Very recently, Andre Geim and Konstatin Novoselov, Russian scientists working at the University of Manchester (U.K.), succeeded in peeling with an ordinary piece of Scotch tape, the successive two-dimensional layers of carbon from a small chunk of graphite eventually obtaining a layer a single carbon atom thick. They named it **graphene.** Most surprisingly, graphene is 100 times stronger than steel and conducts heat and electricity better than copper.

This remarkable discovery for which the two scientists have been awarded the 2010 Nobel Prize in physics, holds promise for a host of applications, the most significant of which include replacement of carbon fibres in composite materials for the fabrication of lighter air craft and satellites and replacement of silicon in transistors to produce faster electronic devices. The discovery is likely to revolutionize the electronics industry.

The physical characteristics of the various allotropic forms of carbon are shown in Table 3.

TABLE 3

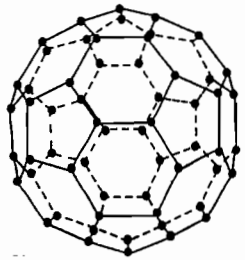
Physical Characteristics of Various Allotropic Forms of Carbon

	Crystalline forms		Microcrystalline forms			
Property	**Diamond**	**Graphite**	**Coal**	**Charcoal**	**Animal charcoal**	**Lamp black**
1. Colour	Colourless transparent	Grey	Black	Black	Black	Black
2. Carbon content	100%	95 – 97%	60 – 90%	68 – 85%	8 – 10%	98 – 99%
3. Density ($g\ cm^{-3}$)	3·51	2·25	–	1·4 – 1·7	–	–
4. Hardness	Hardest substance	Soft, marks the paper	Hard mass	Soft	Soft	Soft
5. Electrical conductivity	Bad conductor	Good conductor	Bad conductor	Bad conductor	Bad conductor	Bad conductor

Fullerenes

Fullerenes are allotropes of carbon having the general formula C_{2n} (n = 30 – 48). These are prepared by passing high voltage current through graphite rods in the inert atmosphere of helium. The graphite of the rods sublimes producing a fluffy mass called 'fullerene soot.' This soot is then dissolved in organic solvents such as benzene and chromatographed when the solutions of pure C_{60} (about 79%) and C_{70} (about 20%) separate out as major fractions. Minor amounts (about 1%) of higher fullerenes comprising of C_{76}, C_{78}, C_{80}, etc., also separate out in the process. The solutions of pure fullerenes, when concentrated, yield crystals containing solvent molecules trapped in the interstices. The sublimation of these crystals in vacuum yields solvent-free fullerene crystals.

The most common of these fullerenes, C_{60}, contains 20 hexagons and 12 pentagons of carbon atoms fused with one another resulting in a spherical **football-like geometry,** as shown.



Spherical foot-ball like geometry of fullerene

There are two types of C – C bonds in the structure of C_{60} one of which is 1·48 Å and the other is 1·38 Å in length. Although the fullerene C_{60} is one of the most strained molecules known so far yet it shows high kinetic stability. Nevertheless, its thermal stability is less than that of graphite and diamond. It starts decomposing at about 700°C.

In the fullerene C_{70}, there are eight distinct types of C – C bonds with lengths varying between 1·39 Å and 1·54 Å. This fullerene has also spherical, football-like structure containing several hexagons and pentagons of carbon atoms fused together. Higher fullerenes have similar football-like structures.

Chemical Properties of Carbon. Of all the allotropic forms, charcoal is the most reactive. It readily burns in air to give carbon dioxide. It reacts with concentrated sulphuric acid and concentrated nitric acid and reduces them readily to SO_2 and NO_2, respectively. It combines with many metals to give carbides, *e.g.*, CaC_2 and Al_4C_3. When heated with sulphur, it forms carbon disulphide.

Chemically, diamond is resistant towards almost all chemical reagents. It burns in air when heated at 900°C giving carbon dioxide. It is slowly oxidised to carbon dioxide by a mixture of potassium dichromate and sulphuric acid at 200°C. It is stable in vacuum up to 1500°C but changes into graphite at 1800°C and more rapidly at 2000°C.

Graphite, like diamond, is not attacked by dilute acids. It is slowly oxidised to CO_2 by chromic acid. It is oxidised by concentrated nitric acid to give graphitic acid, $C_{11}H_4O_5$, which is an insoluble yellowish green substance. With alkaline potassium permanganate, it is oxidised to oxalic acid and mellitic acid, $C_6(COOH)_6$.

Uses. ***Coal*** is used extensively as a fuel in boilers, engines, furnaces, etc. It is also used in the manufacture of coal gas, producer gas, water gas and synthetic petrol. ***Anthracite*** is used as a reducing agent in metallurgical processes and for the manufacture of graphite.

Charcoal (activated) is used as an excellent adsorbent in gas masks and for removing offensive odour from the air used in air-conditioning processes. It is also used for removing fusel oil, in decolourising sugar syrup and for refining of oils, fats, glycerine, etc. It is also used in the treatment of drinking water after chlorination to adsorb the excess of chlorine.

Lamp black is used in making printing inks, paints, shoe polish and as black pigment. The main application, at present, is as a *filler* in making rubber tyres.

Graphite, being a good conductor of electricity, is used in making electrodes and carbon rods and in covering moulds for electrodeposition of copper. It is also used as a solid lubricant. The so-called lead pencils actually contain graphite mixed with a little clay.

Properties of Silicon. Physical Properties. It is a hard and brittle solid with a high melting point (1410°C). It has the same appearance as graphite. Its electrical conductivity is very low compared to that of graphite. It shows allotropy as it exists in two well-defined forms, namely, a *brown amorphous powder* and *a grey crystalline mass*. The amorphous brown powder and crystalline grey varieties differ in particle size and content of impurities. The amorphous variety fuses on strong heating and solidifies on cooling to give the crystalline form.

Chemical Properties. *Amorphous silicon* is chemically more active than the crystalline variety. It unites spontaneously with fluorine at ordinary temperature forming the flouride, SiF_4. When heated in chlorine it burns forming silicon tetrachloride, $SiCl_4$. It also combines with oxygen, bromine, sulphur, nitrogen and carbon at progressively increasing temperatures. It is insoluble in water as well as in acids but a mixture of nitric and hydrochloric acids attacks it. It is also slowly attacked by steam when heated to redness.

$$Si + 2H_2O \longrightarrow SiO_2 + 2H_2$$

It dissolves in hot concentrated alkalies to form silicates.

$$Si + 2KOH + H_2O \longrightarrow K_2SiO_3 + 2H_2$$

It also dissolves in fused sodium carbonate displacing carbon.

$$Na_2CO_3 + Si \longrightarrow Na_2SiO_3 + C$$

It combines with certain metals forming silicides.

$$2Mg + Si \longrightarrow Mg_2Si$$

The *crystalline variety* reacts with halogens and alkalies but not with oxygen even when strongly heated.

Uses. 1. Silicon is added to steel as such or, more usually, in the form of *ferrosilicon* to increase its resistance to attack by acids.

2. Its alloys, such as *silicon bronze* and *manganese-silicon bronze*, possess strength and hardness even greater than steel.

3. Pure silicon is used in the fabrication of transistors.

Properties of Tin. Physical Properties. 1. Tin has a silvery-white lustre which does not tarnish on exposure to air.

2. It exists in three allotropic forms : *grey, white* and *rhombic*. The transition temperatures are as follow :

$$\text{Grey} \overset{18°C}{\rightleftharpoons} \text{White} \overset{161°C}{\rightleftharpoons} \text{Rhombic}$$

The densities of the three forms are 5·74, 7·32 and 6·55 gram per c.c., respectively. White tin is not only the heaviest but also the most stable variety.

The conversion of white tin into grey tin takes place very slowly at 18°C, which is the transition temperature. However, if the temperature is as low as –50°C and a small amount of grey tin is already present, the conversion becomes very rapid. This conversion is known as **tin pest** or **tin disease**.

3. White tin is malleable but not ductile. It becomes brittle when heated to 200°C.

4. When bent, the metal produces a cracking noise which is called **tin cry.** This is due to rubbing of metal crystals over one another.

5. Tin melts at a relatively low temperature of 232°C but boils at a relatively high temperature of 2270°C.

Chemical Properties. 1. Action of air. Air has no action on tin at ordinary temperatures but when heated to whiteness (1500 – 1600°C) in the presence of oxygen it burns with a bright flame giving stannic oxide.

2. Action of halogens and sulphur. If the metal is heated in an atmosphere of chlorine or sulphur vapour, it readily combines to form stannic chloride and stannic sulphide, respectively.

3. Action of acids. Tin is slowly attacked by dilute hydrochloric acid but the reaction becomes rapid on heating with concentrated hydrochloric acid forming stannous chloride and evolving hydrogen.

Dilute sulphuric acid has no action but hot concentrated acid dissolves the metal forming stannous sulphate and evolving sulphur dioxide.

Dilute nitric acid attacks the metal forming stannous nitrate and ammonium nitrate.

$$4Sn + 10HNO_3 \longrightarrow 4Sn(NO_3)_2 + NH_4NO_3 + 3H_2O$$

Hot concentrated acid produces copious fumes of nitrogen dioxide and meta stannic acid.

$$Sn + 4HNO_3 \longrightarrow H_2SnO_3 + 4NO_2 + H_2O$$

Organic acids have no action.

4. Action of alkalies. When the metal is heated with alkali solutions it reacts to evolve hydrogen.

$$Sn + 2NaOH + H_2O \longrightarrow \underset{\text{Sodium stannate}}{Na_2SnO_3} + 2H_2$$

Uses. 1. Tin is used in the preparation of a number of alloys such as solder, britannia metal, white metal, etc. The names, compositions and uses of some important tin alloys are given in Table 4.

TABLE 4
Some Important Tin Alloys

Name	Percentage Composition	Uses
Solder	Sn 50% Pb 50%	In soldering
Pewter	Sn 75% Pb 25%	In making cups, mugs and other utensils
Babbit metal	Sn 90% Sb 7% Cu 3%	For making bearings for machinery
Britannia metal	Sn 90% Sb 8% Cu 2%	For making table ware
White metal	Sn 82% Sb 12% Cu 6%	For making table ware
Bell metal	Sn 25% Cu 75%	For making bells, gongs, etc.
Rose metal	Sn 28% Pb 22% Bi 50%	For electric fuses

2. It is used in the preparation of collapsible tubes for tooth pastes and various ointments. 3. The metal is extensively used in **tinning** brass utensils. 4. It is largely used in forming a protective coating over iron. The process is known as **tin plating.** It consists in dipping the clean sheets of iron or steel in a bath of molten tin and passing through hot pairs of rollers. A thin coherent film of tin is deposited. Tin coated plates are used in the manufacture of tin cans, kerosene oil containers and other similar articles. 5. Tin amalgam is used in making mirrors. 6. Tin foil is used for wrapping cigarettes and other articles.

Properties of Lead. Physical Properties. Lead is a bluish grey metal and possesses, when freshly cut, a bright metallic lustre which, however, becomes dull on exposure to air due to the formation of a thin layer of the oxide on the surface. It is so soft that it can be cut with a knife and scratched with the finger-nail. It marks paper. It is malleable but not very ductile. The presence of other metals makes it hard and brittle. Its specific gravity is 11·34. It melts as 327·4°C and boils at 1725°C.

Chemical Properties. 1. Action of air. It is not attacked by dry air but gets tarnished in moist air due to the formation of a thin film of the insoluble basic carbonate which prevents it from further action.

2. Action of air and heat. When heated in air or oxygen, lead is oxidised to litharge (PbO) and red lead (Pb_3O_4).

3. Action of water. Lead is not attacked by pure air-free water (except at the boiling point). It slowly decomposes steam at high temperatures. It is readily corroded by water containing dissolved air forming lead hydroxide which is appreciably soluble in water. The solvent action of water, known as 'plumbo solvency' is greater when water contains nitrates, organic acids and ammonium salts. The reaction is, however, retarded by certain salts such as phosphates, carbonates and sulphates since they form a coating of insoluble lead salts on the surface of the metal which protects it from further action. Thus, hard water has no solvent action on lead.

4. Action of acids. Lead is only slightly attacked by dilute hydrochloric acid or dilute sulphuric acid in the cold because a film of insoluble lead chloride or lead sulphate is formed on the surface which prevents further action. Powdered lead is readily dissolved by boiling hydrochloric acid due to formation of the soluble complex, $H_2[PbCl_4]$.

$$Pb + 2HCl \longrightarrow PbCl_2 + H_2$$
$$PbCl_2 + 2HCl \longrightarrow \underset{\text{Chloroplumbous acid}}{H_2[PbCl_4]}$$

Concentrated sulphuric acid dissolves lead readily at 230 – 240°C with the evolution of sulphur dioxide but the action is retarded by the formation of insoluble layer (crust) of lead sulphate on the metal surface.

With cold dilute nitric acid, lead forms lead nitrate and nitric oxide.

With concentrated nitric acid it evolves brown fumes of nitrogen dioxide.

Lead readily dissolves in acetic acid in the presence of oxygen, forming lead acetate.

$$Pb + 2CH_3COOH + 1/2\ O_2 \longrightarrow (CH_3COO)_2Pb + H_2O$$

5. Action of alkalies. It is slowly attacked by caustic alkalies with the evolution of hydrogen.

$$Pb + 2NaOH \longrightarrow \underset{\text{Sodium plumbite}}{Na_2PbO_2} + H_2$$

6. Action of chlorine and sulphur. Lead directly combines with chlorine and sulphur to form lead tetrachloride and lead sulphide, respectively.

Uses. Lead is used 1. For making lead pipes for carrying water. 2. For making telegraph and telephone wires which are to be burried in earth. 3. In fine arts on account of the ease with which it can be worked out, cut and soldered and due to its resistance to water and many acids 4. In making bullets and lead accumulators. 5. In making pigments like chrome yellow, chrome red, red lead, white

lead, etc. 6. In making lead alloys. Some of the important alloys are : *Type metal* (82% Pb, 15% Sb, 3% Sn), used for making printing type ; *Solder* (50% Pb, 50% Sn), used for soldering ; *Pewter* (20% Pb, 80% Sn) used for making utensils.

Wooden tanks lined with lead are frequently used for several chemical operations on a large scale.

Properties of Germanium. Germanium is silvery-white, hard and brittle. It has no allotrope. It is more reactive than silicon. Like silicon, it is used in the fabrication of transistors.

COMPOUNDS OF GROUP 14 ELEMENTS

I. A Comparative Study

1. Hydrides. All the elements of this group form covalent hydrides although the number of the stable hydrides and the ease with which these are formed decreases as we move from carbon to lead.

A brief description of the hydrides of the various elements is given below.

Hydrides of Carbon. Carbon forms a number of hydrides, known as *alkanes* (general formula C_nH_{2n+2}), *alkenes* (general formula C_nH_{2n}), *alkynes* (general formula C_nH_{2n-2}) and a number of aromatic compounds (*e.g.*, benzene, toluene, xylene), etc. The methods of their preparation and properties are discussed fully in organic chemistry books.

Hydrides of Silicon. These compounds are similar to hydrides of carbon but they are much less stable. The number of silicon hydrides is also much less than the number of hydrides of carbon. These are called **silanes** and have the general formula Si_nH_{2n+2}, where n stands for the number of silicon atoms. Silanes with n upto 8 are known. The individual members are known as *silane* (SiH_4), *disilane* (SiH_6), *trisilane*, (Si_3H_8), *tetrasilane*, (Si_4H_{10}), etc. The first two members are colourless gases while the third and subsequent members are liquids. The freezing points and boiling points of these compounds are given below :

	Monosilane (SiH_4)	*Disilane* (Si_2H_6)	*Trisilane* (Si_3H_8)	*Tetrasilane* (Si_4H_{10})
F.P. (°C)	– 185	– 132	– 117	– 89
B.P. (°C)	– 112	– 14	53	107

SiH_4 is stable at room temperature. Thermal stability decreases with increasing chain length.

Silanes are produced by the action of acids on metallic silicides, *e.g.*,

$$Mg_2Si + 4HCl \longrightarrow 2MgCl_2 + SiH_4$$

Actually a mixture of silanes is obtained, the composition of the mixture being : SiH_4 (40%), Si_2H_6 (30%), Si_3H_8 (12%), Si_4H_{10} (10%) and others (8%). Monosilane can be separated by fractionating in vacuum.

Pure monosilane is prepared by reacting silicon tetrachloride with lithium aluminium hydride in ether at low temperature.

$$SiH_4 + LiAlH_4 \longrightarrow SiH_4 + LiCl + AlCl_3$$

The structures of silanes are analogous to those of alkanes.

The silanes are much less stable than the corresponding alkanes. The lower silanes decompose more readily than the higher ones. Thus, monosilane, SiH_4, decomposes spontaneously on coming into contact with air.

$$SiCl_4 + 2O_2 \longrightarrow SiO_2 + 2H_2O$$

In fact, all the silanes are spontaneously inflammable and explosive in air.

If the gas is bubbled through water, then, as soon as it comes in contact with air, each bubble ignites giving vortex ring of finely divided silica.

They decompose slowly when brought in contact with water.

$$SiH_4 + 3H_2O \longrightarrow H_2SiO_3 + 4H_2$$

Silanes are soluble in strong alkali solutions in the presence of air and evolve hydrogen.

$$SiH_4 + 2NaOH + 1/2\,O_2 \longrightarrow Na_2SiO_3 + 3H_2$$

Silanes, therefore, have *strong reducing properties*. They reduce permanganate to Mn (II) ; mercury (II) to mercury(I) or even mercury(0) ; iron(III) to iron(II) and copper(II) to copper hydride.

They react with chlorine and bromine with explosive violence even at ordinary temperatures. But treatment of SiH_4 with HCl or HBr at 100°C in the presence of aluminium chloride as a catalyst results in the substitution of hydrogen atoms by chlorine or bromine

$$SiH_4 + HCl \xrightarrow{Al_2Cl_6} SiH_3Cl + H_2$$

Halosilanes can also be obtained by reacting silane with solid AgX in a heated flow reactor.

$$SiH_4 + 2AgCl \xrightarrow{260°C} SiH_3Cl + HCl + 2Ag$$

Hydrides of Germanium. The hydrides of germanium (called *germanes*) have the general formula Ge_nH_{2n+2} (n upto 5). Three hydrides of germanium are more commonly known. These are *monogermane*, GeH_4, *digermane*, Ge_2H_6 and *trigermane*, G_3H_8.

These are prepared in the same way as silanes. Thus, treatment of magnesium germanide with dilute hydrochloric acid yields a mixture of mono, di and trigermanes. The individual germanes can be separated by fractional distillation.

Monogermane *alone* can be prepared by the reduction of germanium tetrachloride with lithium aluminium hydride.

The first two compounds are colourless gases while the higher germanes are liquids. Their freezing and boiling points are given below :

	GeH_4	Ge_2H_6	Ge_3H_8	Ge_4H_{10}	Ge_5H_{12}
F.P.(°C)	– 165	– 109	– 106	–	–
B.P. (°C)	– 88	22	110·5	177	234

Germanes are less volatile and less reactive than the corresponding silanes. For example, in comparison to SiH_4, GeH_4 does not ignite when brought in contact with air. Also, unlike silanes, these are not attacked by water. Monogermane, unlike monosilane, is not attacked by alkali (30 per cent NaOH or KOH). Digermane, however, evolves hydrogen under these conditions. At higher temperatures, they decompose to give germanium and hydrogen.

Hydrides of Tin and Lead. Two hydrides of tin, *monostannane* (SnH_4) and *distannane* (Sn_2H_6) are known. SnH_4 is obtained as a gas by reducing tin (IV) chloride with ethereal lithium aluminium hydride. It is also formed by the action of atomic hydrogen on metallic tin or by the action of $SnCl_2$ with aqueous $NaBH_4$.

The freezing and boiling points of monostannane are –146°C and –52°C, respectively. It is not stable and decomposes slowly even at room temperature into tin and hydrogen. It decomposes readily above 145°C. It is resistant to attack by dilute aqueous acids or alkalies. Distannane, Sn_2H_6, is much less stable. Higher homologues are not known.

There is some doubt about the existence of lead hydride although it is claimed that it is formed in minute quantities as a gas when a lead-magnesium alloy is dissolved in dilute acids.

In general, it may be concluded that the stability of the hydrides of elements of Group 14 decreases as we move down the group. Since thermal stability decreases, their tendency to act as reducing agents increases as we move down the group.

2. Halides

Tetrahalides. All the elements of this group form tetrahalides which are mostly covalent.

Amongst the simple tetrahalides, the tetrafluorides of C, Si and Ge (*i.e.*, CF_4, SiF_4 and GeF_4) are gases while the tetrafluorides of Sn and Pb (*i.e.*, SnF_4 and PbF_4) are solids. The last two are more ionic in character than the first three.

Carbon tetrabromide, CBr_4, is a solid while tetrabromides of silicon, germanium and tin (*i.e.*, $SiBr_4$, $GeBr_4$ and $SnBr_4$) are liquids. The tetraiodides of the first four elements (*i.e.*, CI_4, SiI_4, GeI_4 and SnI_4) are solids. $PbBr_4$ and PbI_4 are unknown.

Important tetrahalides of carbon are discussed below.

Carbon tetrafluoride is prepared on a laboratory scale by reacting fluorine and silicon carbide or by fluorinating CO or CO_2 by SF_4. It is a highly stable gas with melting point (–183·5°C) quite close to that of CH_4 (–182·5 °C).

Carbon tetrachloride is prepared on a large scale by passing chlorine into carbon disulphide in the presence of a small amount of iodine.

$$CS_2 + 3Cl_2 \longrightarrow S_2Cl_2 + CCl_4$$

Carbon tetrachloride boiling at 76·7°C can be easily separated by fractional distillation as S_2Cl_2 boils at a higher temperature, *i.e.*, 138°C.

It is a colourless liquid with high density (1·58 g cm^{-3}). It is non-polar and is, therefore, miscible with non-polar solvents. It is a common laboratory and industrial solvent for non-polar materials. It is non- combustible and is used as fire-extinguisher.

It is also used for preparing **freons** such as $CFCl_3$, CF_2Cl_2 and CF_3Cl which are used in refrigeration.

CCl_4 resists hydrolysis. However, CCl_4 does react with water at 300°C to form $COCl_2$

$$CCl_4 + H_2O \xrightarrow{300°C} COCl_2 + 2HCl$$

Moist iron reduces CCl_4 to $CHCl_3$.

$$CCl_4 + 2H \xrightarrow[\text{moisture}]{Fe} CHCl_3 + HCl$$

HF reacts in the catalytic presence of $SbFCl_4$, as follows :

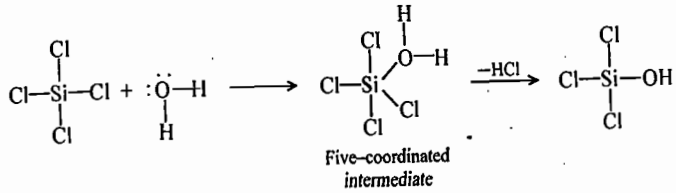
$$CCl_4 + HF \xrightarrow{SbFCl_4} CFCl_3 + HCl$$

$$CCl_4 + HF \xrightarrow{SbFCl_4} CF_2Cl_2 + HCl$$

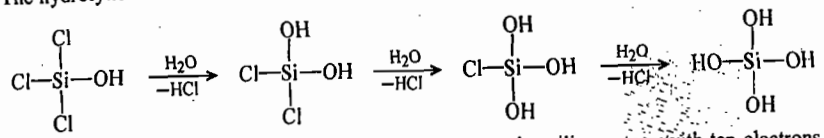
The catalyst $SbFCl_4$ used in the above reactions is obtained by the action of HF on $SbCl_5$.

Differences Between Tetrahalides of Carbon and Tetrahalides of Other Elements of Group 14. The tetrahalides of carbon differ from the tetrahalides of other elements of this group in two respects.

1. Hydrolysis. While tetrahalides of carbon are not hydrolysed by water under normal conditions, the tetrahalides of other elements *are readily hydrolysed*. The hydrolysis of tetrahalides of silicon and other elements is due to the availability of empty *d* orbitals in the valency shells of their central atoms. The *mechanism of hydrolysis of $SiCl_4$* is illustrated below. It involves the nucleophilic attack by water molecule to form a five-coordinated intermediate $SiCl_4(H_2O)$ which then dissociates with the elimination of HCl giving $SiCl_3OH$.



The hydrolytic attack continues till all the chlorine atoms are replaced by *OH* groups.



It can be seen that the five-coordinated intermediate contains silicon atom with ten electrons in its outermost shell. The availability of empty 3*d* orbitals in the outermost shell of silicon permits donation of electrons by oxygen atoms of water molecules to silicon atom to form hydrated intermediate, $SnCl_4.H_2O$. On the other hand, carbon has only *s* and *p* orbitals in its outermost shell and *three are no vacant d orbitals for bond formation*. As a result, it cannot form five-coordinated intermediate and, therefore, the *tetrahalides of carbon are not hydrolysed.*

Hydrolysis of silicon tetrafluoride yields silica and fluosilicic acid.

$$3SiF_4 + 2H_2O \longrightarrow SiO_2 + 2H_2SiF_6$$

Fluosilicic acid is known only in solution. It is a strong acid and exists largely in the ionised state.

$$H_2SiF_6 + 2H_2O \longrightarrow 2H_3O^+ + [SiF_6]^{2-}$$

The formation of $[SiF_6]^{2-}$ ion involves sp^3d^2 hybridisation of orbitals of Si and has *octahedral structure.*

Stannic chloride on hydrolysis produces the complex compound $H_2[SnCl_3(OH)_3]$.

$$SnCl_4 + 3H_2O \longrightarrow H_2[SnCl_3(OH)_3] + HCl$$

GeF_4 hydrolyses in the same way as SiF_4

$$3GeF_4 + 2H_2O \longrightarrow 2H_2GeF_6 + GeO_2$$

2. Formation of Complexes. Carbon tetrahalides do not form complexes because carbon has no *d* orbitals in the outer shell and cannot increase its coordination number. The tetrahalides of the rest of the elements, however, do form complexes since due to the availability of vacant *d* orbitals in the valency shell, these elements can increase their coordination number from *four* to *six*. The common examples are : $[SiF_6]^{2-}$, $[GeF_6]^{2-}$, $[SnCl_6]^{2-}$

Trihalides. Carbon, silicon and germanium give trihalides of the type $MHCl_3$, *e.g.*, $CHCl_3$, $SiHCl_3$, $GeHCl_3$. Lead and tin do not form such compounds.

Dihalides. Carbon does not form dihalides. Silicon differs from carbon and resembles germanium, tin and lead in forming dihalides.

Silicon dichloride is formed on heating silicon tetrachloride with silicon at temperatures above 1100°C.

$$SiCl_4 + Si \longrightarrow 2SiCl_2$$

Germanium dihalides are formed by passing the tetrahalide vapour over the heated metal.

$$GeX_4 + Ge \longrightarrow 2GeX_2$$

These dihalides are strong reducing agents.

Anhydrous stannous chloride is prepared by heating stannic chloride and tin together.

$$SnCl_4 + Sn \longrightarrow 2SnCl_2$$

Lead dihalides are all sparingly soluble in cold water and are obtained as precipitates by reaction of the type

$$Pb(NO_3)_2 + 2HF \longrightarrow PbF_2 + 2HNO_3$$

The dihalides of germanium, tin and lead are more ionic than covalent in character.

3. Oxides

The elements of this group form two types of oxides, namely, **monoxides** of the formula MO (*e.g.*, CO, SiO, GeO, SnO and PbO) and **dioxides** of the formula MO_2 (*e.g.*, CO_2, SiO_2, GeO_2, SnO_2 and PbO_2). Lead also forms an oxide, Pb_3O_4 which, in fact, is a mixed oxide of PbO and PbO_2, *viz.*, $2PbO.PbO_2$.

Monoxides. Carbon monoxide is obtained by burning carbon in a limited supply of oxygen.

Pure CO can be obtained by heating formic acid with sulphuric acid, the latter acting as a dehydrating agent.

It is a colourless, odourless toxic gas. Its toxic nature is due to its ability to form a complex with haemoglobin in the blood. Carbon monoxide is an essential constituent of gaseous fuels like water gas, producer gas, etc.

The bonding in carbon monoxide may be represented as

$$:C:::O: \quad \text{or} \quad C{\equiv}O:$$

Two pairs of electrons are considered to be shared between carbon and oxygen resulting in a double bond. The oxygen may then be considered to be donating its lone pair of electrons to carbon giving a coordinate bond. The properties of CO can be explained satisfactorily if it is maintained that carbon monoxide is a resonance hybrid of three structures, as shown below :

$$:C::\ddot{O}: \longleftrightarrow :\overset{-}{C}:::\overset{+}{O}: \longleftrightarrow :\overset{+}{C}:\overset{-}{\ddot{O}}:$$

The molecular orbital structure of CO has already been discussed in Chapter 4.

SiO can be obtained by heating silicon dioxide with silicon at about 1300°C in vacuum.

$$SiO_2 + Si \longrightarrow 2SiO$$

Stannous chloride when reacted with weak alkali solutions forms a white precipitate of stannous hydroxide, $Sn(OH)_2$, which on dehydration in the absence of air gives stannous oxide, SnO.

$$Sn(OH)_2 \xrightarrow{-H_2O} SnO$$

GeO can be obtained by dehydrating $Ge(OH)_2$ or by heating Ge and GeO_2 at about 1000°C.

$$Ge(OH)_2 \longrightarrow GeO + H_2O$$

$$GeO_2 + Ge \longrightarrow 2GeO$$

When heated to 700°C and above, GeO undergoes disproportionation to give GeO_2 and Ge.

PbO is obtained by reacting molten lead with air or oxygen above 600°C.

Among the monoxides, CO is *neutral*, GeO is *basic* while SnO and PbO are *amphoteric*.

Dioxides. Carbon dioxide is obtained on burning carbon in excess of air.

In the laboratory, it can be prepared by the action of cold, dilute hydrochloric acid on marble ($CaCO_3$).

It is a colourless gas with a faint pungent odour and slight acidic taste. It dissolves in water to a small extent giving carbonic acid.

$$CO_2 + H_2O \rightleftharpoons H_2CO_3$$

It, therefore, behaves as a *weak acid*. It dissolves in alkalies to form salts.

$$CO_2 + 2NaOH \longrightarrow Na_2CO_3 + H_2O$$

Solid carbon dioxide, commonly known as **dry ice**, is a soft, white, snow-like substance with specific gravity 1·53 and melting point – 56·6°C at 5·2 atm pressure. It is manufactured by evaporating liquid carbon dioxide at 20°C and 70 atm pressure to a pressure of less than 5·2 atm. Solid carbon dioxide is used as a refrigerant under the commercial name drikold. It is highly suitable for this purpose as it leaves no residue. It is used as a substitute of ice in cold drinks and in the preparation of ice-cream. Mixed with ether or acetone it provides freezing mixtures with exceedingly low temperatures. It is extensively used in the transport of perishable food-stuffs. It provides cold as well as an inert atmosphere (devoid of oxygen). Both these factors help in killing the undesirable bacteria which otherwise spoil the food.

It is also used in hospitals for surgical operations of sores.

Artificial rain-making has also been accomplished by spraying small pellets of dry ice from aeroplanes over clouds to produce condensation.

The bonding in carbon dioxide is represented as

$$:\ddot{O}::C::\ddot{O}: \quad \text{or} \quad :\ddot{O}{=}C{=}\ddot{O}:$$

However, carbon–oxygen bond length in carbon dioxide is 1·15 Å while the value to be expected for a double bond, C=O, is about 1·20 Å and for a triple bond, C≡O, is 1·10 Å. This shows that the simple double bond formula is inadequate.

It is now maintained that resonance occurs between the three possible structures given below :

$$:\overset{-}{\ddot{O}}{-}C{\equiv}\overset{+}{O}: \longleftrightarrow :\ddot{O}{=}C{=}\ddot{O}: \longleftrightarrow :\overset{+}{O}{\equiv}C{-}\overset{-}{\ddot{O}}:$$

Silicon dioxide, frequently referred to as **silica,** is obtained by heating silicon in oxygen.

$$Si + O_2 \longrightarrow SiO_2$$

Pure silica (amorphous form) can be prepared as a white powder by the action of silicon tetrachloride or tetrafluoride with water.

$$SiCl_4 + 2H_2O \longrightarrow SiO_2 + 4HCl$$

It is insoluble in water and in all acids except HF with which it reacts to form silicon tetrafluoride.

$$SiO_4 + 4HF \longrightarrow SiF_4 + 2H_2O$$

It is acidic and dissolves in hot concentrated alkalies to form sodium silicate.

$$SiO_2 + 2NaOH \longrightarrow Na_2SiO_3 + H_2O$$

Structure of SiO_2.. The study of its crystal structure by X-rays has shown that silica forms 'giant molecules' by linking together of a number of SiO_4 tetrahedra in each of which a silicon atom is linked to four oxygen atoms. This structure, though extending three-dimensionally, may be represented, in a simplified form as shown in Fig. 3.

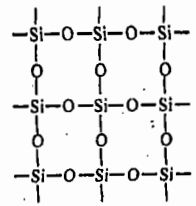


Fig. 3. Structure of SiO_2.

It is to be noted that while CO_2 is a *gas*, SiO_2 is a hard *solid* with a very high melting point. This characteristic difference may be explained as follows : The carbon atom has a small radius (0·77 Å). The positively charged nucleus, therefore, attracts outer electrons very strongly and does not permit the oxygen to combine with another carbon atom. In silica, however, the size of silicon atom (1·17 Å) is fairly large as compared to that of carbon. As a result, the positively charged nucleus cannot attract the outer electrons so strongly and hence the oxygen atom can be shared between two different silicon atoms. This leads to the formation of a giant SiO_2 molecule as shown.

In terms of atomic orbital theory, the formation of double bond between C and O atoms requires the lateral overlapping of $2p$ orbitals of carbon atom with the $2p$ orbitals of oxygen atom. Since the size and energy of the $2p$ orbitals of carbon and $2p$ orbitals oxygen atoms are nearly of the same level, they overlap effectively to form pi bonds between C and O atoms. This permits the formation of monomeric O=C=O molecule.

The formation of double bond between Si and O atoms requires the lateral overlapping of $3p$ orbitals of silicon with $2p$ orbitals of oxygen atom. Due to appreciable differences in the size and energy of these orbitals, $3p$ and $2p$ orbitals cannot overlap effectively to form pi bonds between Si and O atoms. This hinders the formation of Si=O bond in SiO_2 molecule. The tetravalency of silicon is acquired by forming four Si – O bonds. Thus, SiO_2 molecule comprises of a tetrahedron which contains one Si atom surrounded by four oxygen atoms (see central silicon atom in Fig. 3). These tetrahedra are linked together by sharing of the oxygen atoms between the two adjacent tetrahedra.

The crystal structure in silica is highly stable and, therefore, a considerable amount of energy is needed to break it. This explains the hardness and high melting point of silica.

Germanium and **tin dioxides** are obtained by heating germanium and tin with oxygen or air.

$$Ge + O_2 \longrightarrow GeO_2$$

$$Sn + O_2 \longrightarrow SnO_2$$

Lead dioxide is formed by electrolytic oxidation of lead.

The dioxides GeO_2 and SnO_2 are amphoteric. For example, SnO_2 reacts with acids as well as alkalies.

$$SnO_2 + 4HCl \longrightarrow SnCl_4 + 2H_2O$$

$$SnO_2 + 2NaOH \longrightarrow Na_2SnO_3 + H_2O$$

It is evident from the above discussion that the acidic character of dioxides decreases and basic character increases as move down the group.

II. Important Compounds of Elements of Group 14

COMPOUNDS OF CARBON

***Metal Carbonyls**

Carbon atom of carbon monoxide has a lone pair of electrons which can be donated to transition metals to form complex compounds called metal carbonyls Thus, **metal carbonyls** *are complex compounds of transition metals with carbon monoxide.* The number of carbon monoxide molecules which get chemically bonded to a metal through coordinate bonds vary with the nature of the metal. For example, the number of CO molecules bonded to nickel in nickel carbonyl, $Ni(CO)_4$, is 4 while in chromium carbonyl, $Cr(CO)_6$, it is 6.

Carbonyls are formed readily with transition metals since they have vacant d orbitals which can accept the donated electron pairs. The number of coordinate bonds that can be formed in this manner depends largely on the number of vacant orbitals. Generally, the number of ligands attached is such that the metal atom appears to possess the same number of electrons as the next noble gas. For example, the atomic number of nickel is 28, *i.e.*, it has 28 electrons. According to the valence bond concept of metal–ligand bonding in coordination complexes, each CO molecule donates one lone pair of electrons to the metal ion to form Ni←CO bond. Four CO molecules donate 8 electrons in all raising the number of electrons in the central atom to 36 which is equal to the number of electrons contained in the next noble gas, krypton. This number is called effective atomic number. *The total number of electrons*

*For a detailed discussion of metal carbonyls, refer to Chapter 32 on Mononuclear Complexes of Pi Acceptor Ligands.

present in the atom of the metal forming the complex, including those gained by sharing in the formation of the complex, is called the **effective atomic number** *of the metal.*

The structure of nickel carbonyl, $NiCO_4$, is represented in Fig. 4.

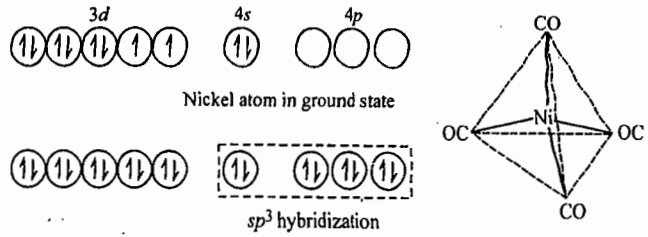

Fig. 4. Tetrahedral structure of nickel carbonyl, $Ni(CO)_4$.

Since the energy of $3d$ and $4s$ electrons is not very much different, the $4s$ electrons can easily go to fill the $3d$ orbitals, *vacating thereby the* $4s$ orbital. Thus, four orbitals (one $4s$ and three $4p$) become available for chemical bonding with four CO molecules to form the complex, $Ni(CO)_4$. Since all the four bonds are known to be exactly identical, it follows that s and p orbitals hybridise to give four sp^3 hybrid orbitals of the same energy. The molecule, $Ni(CO)_4$, has, therefore, a **tetrahedral structure**, as shown.

Some other important carbonyls are $Fe(CO)_5$, $V(CO)_6$, $Cr(CO)_6$, $Mo(CO)_6$, etc. These are called **mononuclear carbonyls** since there is only one metal atom in them. A large number of **polynuclear carbonyls** which contain more than one metal atom are also known. The common examples are $Co_2(CO)_8$, $Mn_2(CO)_{10}$, $Fe_2(CO)_9$, $Fe_3(CO)_{12}$, etc. The binuclear carbonyl $Fe_2(CO)_9$ has a *bridged structure* in which bonding between metal atoms occurs through the CO group. The binuclear carbonyl $Co_2(CO)_8$ has a *non-bridged structure* in which the metal atoms are linked directly, *i.e.*, as Co – Co. Trinuclear carbonyls are known to have cyclic structures.

Preparation of Carbonyls. The metal carbonyls can be prepared by the following general methods:

1. By direct interaction of carbon monoxide with finely divided transition metals under suitable conditions of temperature and pressure. For example,

$$Ni + 4CO \xrightarrow[1\,atm]{30°C} Ni(CO)_4$$

$$Fe + 5CO \xrightarrow[200\,atm]{200°C} Fe(CO)_5$$

2. By the action of carbon monoxide on a metal oxide or halide in the presence of a reducing agent (generally excess of CO itself). For example,

$$OsO_4 + 9CO \xrightarrow[350\,atm]{250°C} Os(CO)_5 + 4CO_2$$

$$2CrCl_3 + 12CO \xrightarrow[LiAlH_4,\ ether]{115°C,\ 70\,atm} 2Cr(CO)_6 + 3Cl_2$$

3. Metal carbonyls can also be prepared as follows :

$$2CoCO_3 + 2H_2 + 8CO \xrightarrow[120–200°C]{250–300\,atm} Co_2(CO)_8 + 2CO_2 + 2H_2O$$

$$VCl_3 + 6CO + 3Na \xrightarrow[\text{high pressure}]{120°C} V(CO)_6 + 3NaCl$$

4. Polynuclear carbonyls are generally prepared by thermal or photochemical decomposition of simple carbonyls.

$$2Fe(CO)_5 \xrightarrow{h\nu} Fe_2(CO)_9 + CO$$

$$2Co_2(CO)_8 \xrightarrow{70°C} Co_4(CO)_{12} + 4CO$$

Properties of Carbonyls. The simple carbonyls, having only one metal atom, *viz.*, $M(CO)_n$, are generally *colourless* liquids, or solids with low melting points. The well known examples are $V(CO)_5$ which is a *black* solid and $Fe(CO)_5$ which is a *yellow* liquid.

Chemical properties of carbonyls are quite varied. Some of the most important ones are discussed below.

1. The alkaline hydrolysis of $Fe(CO)_5$ gives yellow alkali carbonyl hydride.

$$Fe(CO)_5 + 3NaOH \longrightarrow Na[HFe(CO)_4] + Na_2CO_3 + H_2O$$

2. Reduction of carbonyls by suitable reductants gives carbonylates. For example,

$$CO_2(CO)_8 + 2Na \xrightarrow{\text{Tetrahydrofuran}} 2Na[Co(CO)_4]$$

$$Mn_2(CO)_{10} + 2Li \longrightarrow 2Li[Mn(CO)_5]$$

3. Carbonyls react with the halogens to form the corresponding halides.

$$Mn_2(CO)_{10} + Br_2 \xrightarrow{40°C} 2Mn(CO)_5Br$$

$$Fe(CO)_5 + I_2 \longrightarrow [Fe(CO)_4I_2] + CO$$

4. The CO group can be displaced by other groups such as PF_3, PCl_3, etc. Thus,

$$Ni(CO)_4 + 2PF_3 \longrightarrow Ni(CO)_2(PF_3)_2 + 2CO$$

In addition to the above reactions, each carbonyl gives a number of specific reactions, the discussion of which is, however, beyond the scope of the book.

Metal Cyanides

Metal cyanides may be classified into *ionic, covalent* and *complex cyanides*. A brief description of each type is given below.

1. Ionic Cyanides. Ionic cyanides are generally prepared by neutralising HCN with appropriate alkali.

NaCN can also be prepared by any one of the following high-temperature reactions :

$$2Na + 2C + 2NH_3 + 3/2\ O_2 \xrightarrow{\text{heat}} 2NaCN + 3H_2O$$

$$NaNH_2 + C \xrightarrow{\text{heat}} NaCN + H_2$$

$$Na_2CO_3 + 4C + N_2 \xrightarrow{\text{heat}} 2NaCN + 3CO$$

The bond between the metal and the cyanide group is predominantly *ionic*. The radius of CN^- ion. (1·91 Å) falls in between the radii of Cl^- and Br^- ions (1·81 Å and 1·96 Å, respectively). The crystal structure of the ionic cyanides is similar to that of the alkali metal halides. Sodium, potassium and rubidium cyanides have NaCl-type structure whereas cesium and thallium(I) cyanides have CsCl-type structure. At room temperature, the freely rotating CN^- groups occupy the Cl^- lattice sites. At lower temperatures, the free rotation of CN^- groups ceases and all of them become parallel at their respective lattice sites.

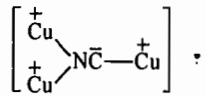
Lithium cyanide has a loosely packed 4-coordinate geometry. That is why LiCN has low density (1·02 g cm^{-3}) and low melting point (157°C)

2. Covalent Cyanides. Metals such as silver, gold, platinum, palladium, nickel and copper form *covalent cyanides*. Examples are : AgCN, $Ni(CN)_2$, $Pd(CN)_2$, etc. X-ray studies on silver cyanide reveal that the compound has a chain-like structure which may be represented as

$$Ag-C\equiv N\cdots\cdots Ag-C\equiv N\cdots\cdots Ag-C\equiv N\cdots\cdots$$

The structure shows the linking of Ag atoms through cyanide bridges. Similar bridges are believed to be present in gold cyanide as well as in some other cyanides.

A cyanide group is mostly bonded to the metal M through the carbon atom. However, the metal cyanide MCN has a tendency to coordinate with another metal atom through N atom as well. An example where a cyanide group is linked to three metal atoms is provided by a cyano complex $[Cu_3CN]^{2+}$ of Cu(I) which has the cyano bridge of the type shown :



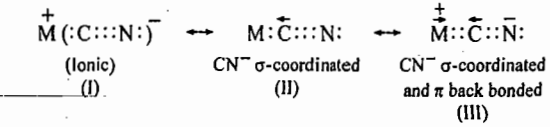
The lines in this structure do not represent exact bond order.

The cyanide group is isoelectronic with CO and has unfilled $\overset{*}{\pi}$ orbitals which may form π bonds with the filled $d\pi$ orbitals of the metal so that the bond order in metal–carbon bond may be greater than one.

3. Complex Cyanides. Cyanides containing discrete groups of the type $[M(CN)_n]^{x-n}$ are called complex cyanides. The metal ion which has been shown to be in $+x$ oxidation state, generally belongs to the transition series or immediately follows the transition series. These complex cyanides have properties quite different from the simple cations from which these are derived. The metal ions in these cyanides sometimes have unusual oxidation states. The coordination number of the metal ion may be 2 as in $[Cu(CN)_2]^-$, 4 as in $[Ni(CN)_4]^{2-}$, 6 as in $[Fe(CN)_6]^{4-}$ or 8 as in $[Mo(CN)_8]^{4-}$.

The bonding in complex cyanides occurs mostly between metal M and C of cyanide group. As already stated, cyanide group is isoelectronic with CO containing two $\overset{*}{\pi}$ orbitals capable of overlapping with $d\pi$ orbitals of the metal. Thus, there is a possibility of $d\pi - \overset{*}{\pi}$ bond formation apart from a normal sigma bond formation between M and C so that the bond order of M – C bond is greater than one.

According to the valence bond approach, the actual structure of M – CN is a resonance hybrid of the following structures :



It may be noted that in resonating structure III, the additional electron pair between M and C is contributed by M through pi back bonding.

Hydrogen Cyanide, HCN

Preparation. 1. Hydrogen cyanide can be prepared by reacting NaCN or KCN with any acid. For example,

$$NaCN + H_2SO_4 \longrightarrow Na_2SO_4 + HCN$$

2. On a large scale, it is prepared from methane.

$$CH_4 + NH_3 + 3/2\ O_2 \xrightarrow[1200\text{–}1300°C]{\text{Pt–Rh, 2 atm}} HCN + 3H_2O \text{ (Andrusson process)}$$

$$CH_4 + NH_3 + 3/2\ O_2 \xrightarrow[1000\text{–}200°C]{\text{Pt}} HCN + 3H_2O \text{ (Degusso process)}$$

Physical Properties. *HCN is a colourless substance which melts at* –134°C and boils at 25·6°C. It is highly poisonous. It has a very high dielectric constant (~ 115 at 20°C). This high value is due to the association of HCN molecules through hydrogen bonding. It is miscible with water, ethanol, ether, etc.

Chemical Properties. 1. HCN has predominantly a covalent character with some ionic contribution in bonding. That is why its aqueous solution is weakly acidic and is neutralised by alkalies. Thus,

$$HCN + NaOH \rightleftharpoons NaCN + H_2O$$

2. HCN is easily oxidised to cyanogen (C_2N_2) or cyanate ion.

$$HCN \rightleftharpoons 1/2\ (C_2N_2) + H^+ + e^-$$

$$HCN + H_2O \rightleftharpoons [CNO]^- + 3H^+ + 2e^-$$

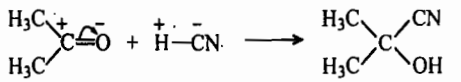
3. It is easily reduced to CH_3NH_2.

$$HCN + 2H_2 \xrightarrow[140°C]{\text{Pd}} CH_3NH_2$$

4. HCN is readily hydrolysed to give HCOOH.

$$HCN \xrightarrow[H_2O]{H^+} \underset{\text{Formamide}}{HCONH_2} \xrightarrow[H_2O]{H^+} HCOONH_4 \longrightarrow HCOOH + NH_3$$

5. It reacts with carbonyl compounds to give cyanohydrins. For example,



Acetone Acetone cyanohydrin

Uses. HCN is used in the manufacture of acrylonitrile, metal cyanides, methyl methacrylate and many other organic compounds. It is also used in the manufacture of insecticides and pesticides.

Metal Carbides

Metal carbides can be divided into the following categories :

1. Salt-like Carbides 2. Covalent Carbides 3. Interstitial Carbides

1. Salt-like Carbides. Carbides of this type are simple compounds of carbon with more electropositive elements, *i.e.*, with metals of Groups 1, 2 and 13. The metal, its oxide or hydride is heated strongly in an electric arc with carbon to get the required carbide. For example,

Be_2C is obtained by heating BeO and C at 1900–2000°C.

$$2BeO + 3C \xrightarrow{1900\text{–}2000°C} Be_2C + 2CO$$

Calcium carbide is obtained by heating lime and coke at 2200–2250°C.

$$CaO + 3C \longrightarrow CaC_2 + CO$$

Aluminium carbide is prepared by heating Al and C in an electric furnace.

$$4Al + 3C \longrightarrow Al_4C_3$$

In general, these compounds exist as transparent crystals and in the solid state they are non-conductors of electricity.

They are readily hydrolysed in water yielding different hydrocarbons. The salt-like carbides are further classified according to the hydrocarbon which they produce on hydrolysis, as illustrated below.

1. *Acetylides.* The carbides which yield **acetylene** on hydrolysis are known as **acetylides**. The examples are MgC_2, BeC_2 and CaC_2.

$$CaC_2 + 2H_2O \longrightarrow Ca(OH)_2 + C_2H_2$$

They contain C_2^{2-}, *i.e.*, $(C \equiv C)^{2-}$ ions. Some other carbides having similar structures are Cu_2C_2, Ag_2C_2, etc. These, however, are *not* hydrolysed yielding acetylene and are, therefore, *not* regarded as true acetylides.

2. *Methanides.* The carbides such as aluminium and beryllium carbides, Al_4C_3 and Be_2C, which give **methane** on hydrolysis, are known as **methanides**. For example,

$$Al_4C_3 + 12H_2O \longrightarrow 4Al(OH)_3 + 3CH_4$$

These carbides contain C^{4-} ions.

3. *Allylides.* Magnesium carbide, Mg_2C_3, is the only carbide which yields **allylene** on hydrolysis.

$$Mg_2C_3 + 4H_2O \longrightarrow 2Mg(OH)_2 + \underset{\text{Allylene}}{CH_3C \equiv CH}$$

This carbide is, therefore, classified as an **allylide**.

4. A few carbides, as of thorium and lanthanides, of formula MC_2, yield, on hydrolysis, a mixture of several hydrocarbons including acetylene, olefins and hydrogen.

2. Covalent Carbides. These carbides contain carbon covalently bonded with elements which have the same electronegativity as carbon or a higher value, such as hydrogen, sulphur and chlorine. The covalent carbides can be divided into two categories depending upon their volatility.

(*i*). The first category consists of covalent carbides which contain small discrete molecules. These are formed by combination of carbon with hydrogen or the elements of Groups 16 and 17. The examples are CH_4, CS_2 and CCl_4. These carbides are either gases or volatile liquids and are not thermally stable. In fact, these compounds are not included amongst carbides at all. These are generally included amongst hydrides, sulphides and halides of carbon, respectively.

(*ii*). The second category consists of giant molecules formed by linking together of a large number of simpler units. The common examples are boron carbide, B_4C and silicon carbide, SiC. These are thermally stable, hard and chemically inert solids.

3. Interstitial Carbides. These carbides are prepared, as usual, by the direct combination of metal and carbon or by the reduction of metal oxide with carbon at high temperature close to 2000°C. Transition metals like Ti, Zr, Hf, V, Nb, Ta and Mo form these carbides. The metals retain their close-packed lattice strcutures and *incorporate carbon atoms in their octahedral interstices* to give MC and M_2C type carbides. The common examples are WC, TaC, V_2C, Nb_2C, Ta_2C, W_2C. These carbides melt at very high temperatures. They are extremely hard refractory materials and have melting points in the range of 3000–4000°C. Since carbon atoms occupy octahedral interstices in close packed lattice of metal atoms, the size of metal atoms must be large enough to form octahedral sites of sufficient size to accommodate C atoms. The limiting radius for metal atoms has been found to be 1·35 Å. Interestitial carbides are very hard and brittle. They are good conductors of electricity and are chemically inert. Due to their extensive hardness and chemical inertness, WC and TaC are used for the manufacture of high speed cutting tools.

Metals with atomic radius below 1·3 Å, as, for example, iron (1·26 Å), chromium (1·27 Å) and manganese (1·27 Å), form carbides which have properties in between those of the salt-like and the interstitial carbides. The carbon atoms in these carbides are located inside the trigonal prisms formed by the metal atoms. These carbides are relatively less stable and are easily decomposed by acids and water.

Applications of Carbides in Industry. The properties of carbides of each type have been described above. Some of these compounds find many applications in industry.

1. Silicon carbide, for example, is used as an *abrasive* under the name *carborundum* and also as a *refractory material*. At high temperatures it has thermal conductivity higher than that of any other refractory material and is, therefore, superior to all of them. It is also very resistant to abrasion and corrosion. It also finds applications in *nuclear reactors* as it provides a good material for making containers for nuclear fuels at high temperatures.

2. Boron carbide, B_4C, which is even harder than silicon carbide, is being used now increasingly as an abrasive. It is also used as a shield against radioactive radiations.

3. Tungsten carbide, WC, is used in making tools and dies.

Carbon Disulphide, CS_2

Preparation. 1. Carbon disulphide is prepared by directly heating sulphur and coke in iron retorts at 750°C – 1000°C.

$$C + 2S \xrightarrow[750\text{–}1000°C]{\text{heat}} CS_2$$

2. It is also prepared from natural gas as follows :

$$CH_4 + 4S \xrightarrow[\text{or } Al_2O_3]{SiO_2 \text{ gel}} CS_2 + 2H_2S$$

Physical Properties. Pure carbon disulphide is a colourless, volatile liquid boiling at 46·2°C. It freezes at – 111·6°C and has a flash point of – 30°C. Its vapour are toxic and have an adverse effect on the nervous system.

Chemical Properties. 1. CS_2 is highly inflammable and burns in air to give CO_2 and SO_2.

$$CS_2 + 3O_2 \longrightarrow CO_2 + 2SO_2$$

2. It combines with metal sulphides to give thiocarbonates.

$$MS + CS_2 \longrightarrow MCS_3$$

where M is a divalent metal.

3. It reacts with aqueous NaOH to give a mixture of Na_2CO_3 and Na_2CS_3 (sodium thiocarbonate).

$$3CS_2 + 6NaOH \longrightarrow Na_2CO_3 + 2Na_2CS_3 + 3H_2O$$

4. It reacts with ammonia and primary and secondary amines to give dithiocarbamates.

$$2NH_3 + CS_2 \longrightarrow \underset{\text{Amm. dithiocarbamate}}{NH_4(H_2NCS_2)}$$

$$(C_2H_5)_2NH + CS_2 \xrightarrow{NaOH} \underset{\text{Sodium salt of N, N diethyl dithiocarbamate}}{(H_5C_2)_2N{-}C(=S)S^-\,Na^+}$$

5. Water reacts with CS_2 slowly to give COS and H_2S at 200°C and CO_2 and H_2S at higher temperatures.

$$CS_2 + H_2O \longrightarrow \underset{\text{Thiocarbon dioxide}}{COS} + H_2S$$

$$COS + H_2O \longrightarrow CO_2 + H_2S$$

6. MgO, SO_3, HSO_3Cl convert CS_2 to COS in a similar manner. For example,

$$MgO + CS_2 \longrightarrow COS + MgS$$

$$COS + MgO \longrightarrow CO_2 + MgS$$

7. CS_2 reacts with ethanol in the presence of alkalies to give sodium ethyl dithiocarbonate, also known as *sodium xanthate*.

$$CS_2 + NaOH + C_2H_5OH \longrightarrow \underset{\text{(Sodium ethyl dithiocarbonate)}}{S{=}C(OC_2H_5)(SNa)} + H_2O$$

If, in the above reaction, ethanol is replaced by cellulose, the resulting product is cellulose xanthate which dissolves in aqueous alkali solution to give a viscous solution named as *viscose*. The viscose is treated with an acid to yield *viscose rayon* and *cellophane*. During this treatment, cellulose is regenerated.

8. CS_2 reacts with Cl_2 to give CCl_4, as described earlier.

9. Fluorine reacts with CS_2 to form a variety of fluorinated products such as SF_4, SF_6, S_2F_{10}, etc. The exact nature of the product depends upon the reaction conditions.

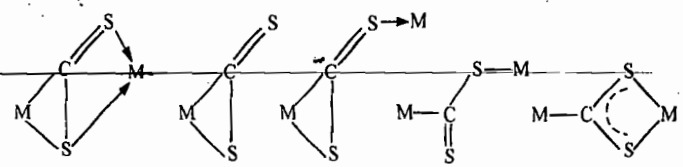
10. It readily undergoes 'insertion reactions' introducing thereby a $-S-\overset{S}{\overset{\|}{C}}-$ group in between a metal–nitrogen bond as also in some other bonds. For example,

$$Ti[N(C_2H_5)_2]_4 + CS_2 \longrightarrow \underset{\text{Tetrakis diethyl-dithiocarbamatotitanium}}{Ti\left[\begin{matrix}-S\\-S\end{matrix}\!\!>C-N<\begin{matrix}C_2H_5\\C_2H_5\end{matrix}\right]_4}$$

11. CS_2 is an efficient complexing agent. This is evidenced by the following reaction :

$$Pt(PPh_3)_2X_2 + CS_2 \longrightarrow \begin{matrix}Ph_3P\\Ph_3P\end{matrix}\!\!>Pt<\begin{matrix}C{=}S\\S\end{matrix} + X_2$$

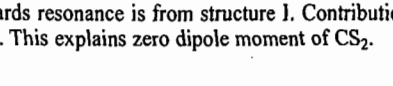
Many complexes of CS_2 with the following types of CS_2 linkages are known :



Uses. Carbon disulphide is used in the manufacture of viscose rayon and cellophane. It is also used in the vulcanization of rubber and for manufacturing insecticides.

Structure of CS_2. Electron diffraction studies show that CS_2 molecule in gaseous phase is *linear* like CO_2. The dipole moment of CS_2 is also zero like that of CO_2. The CS bond distance in CS_2 is found to be 1·54 Å which is quite close to C = S distance. The C – S single bond distance is known to

be 1·8 Å which is obviously far greater than the observed C = S distance in CS_2. Actual structure of CS_2 is maintained to be a resonance hybrid of the following resonance structures :

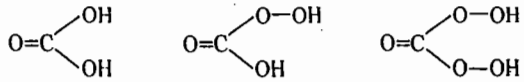


(I) (II) (III)

Major contribution towards resonance is from structure I. Contributions of structures II and III are minor but equal and opposite. This explains zero dipole moment of CS_2.

Percarbonates

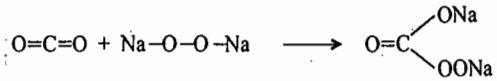
Percarbonates are supposed to be derived from percarbonic acids known as *permonocarbonic acid* and *perdicabonic acid*. The formulae and structures of these acids in relation to carbonic acid are represented as



Carbonic acid Permonocarbonic acid Perdicarbonic acid

These acids have not been isolated so far but their salts, *permonocarbonates* and *perdicarbonates* are known. However, they are not very stable.

Permonocarbonates. Permonocarbonates of sodium and potassium can be prepared by passing carbon dioxide through a solution of the corresponding alkali peroxide. Thus,



These can also be prepared by the action of hydrogen peroxide on the corresponding alkali carbonate. Thus,

$$Na_2CO_3 + H_2O_2 \longrightarrow Na_2CO_4 + H_2O$$

The permonocarbonates when freshly prepared contain water of crystallisation. They are soluble in water, the solution behaving as if it is a mixture of simple carbonate and hydrogen peroxide. The salts, therefore, may be regarded as simple hydrated carbonates containing also hydrogen peroxide as a molecule of crystallisation, the composition of the sodium salt being represented as

$$Na_2CO_3.H_2O_2.H_2O$$

This formula is supported by the fact that the compound slowly liberates iodine from a solution of potassium iodide and that hydrogen peroxide can be extracted by shaking the aqueous solution with ether.

Perdicarbonates. Sodium and potassium perdicarbonate can be prepared by the electrolysis of a concentrated aqueous solution of the corresponding carbonate at a temperature of – 110°. The electrolytic reaction may be represented as

$$K_2CO_3 \longrightarrow K^+ + KCO_3^-$$

$$H_2O \rightleftharpoons H^+ + OH^-$$

At cathode : *At anode* :

$$2H^+ + 2e^- \longrightarrow 2H \longrightarrow H_2 \qquad 2KCO_3^- \longrightarrow K_2C_2O_6 + 2e^-$$

Potassium perdicarbonate appears as a bluish precipitate. It is washed with cold water, alcohol and ether and finally dried. It is stable at ordinary temperatures in the absence of moisture. In water it decomposes to give potassium carbonate.

$$2K_2C_2O_6 \longrightarrow 2K_2CO_3 + 2CO_2 + O_2$$

It also decomposes on heating. It acts as an oxidising agent and liberates iodine from potassium iodide.

$$K_2C_2O_6 + 2KI \longrightarrow 2K_2CO_3 + I_2$$

It can also oxidise lead sulphide to lead sulphate.

$$PbS + 4K_2C_2O_6 \longrightarrow PbSO_4 + 4K_2CO_3 + 4CO_2$$

Intercalation Compounds of Graphite

Intercalation means the *insertion of layers of atoms, ions or molecules of a chemical species between the layers of a host material to form 'sandwich' type of compounds.*

In graphite, the interlayer distance (3·36 Å) is considerably greater than the normal C–C covalent bond distance (1·42 Å). The adjacent layers in graphite are, therefore, held together by weak van der Waals forces. It is thus possible for a number of substances to intercalate (*i.e.*, get inserted) between the layers of graphite to give **intercalation compounds** of variable composition depending upon the nature of the species which are inserted between the layers. Some typical types of intercalation compounds of graphite are described below.

1. Intercalation Compounds of Alkali Metals. When graphite is reacted with potassium metal at 300°C, it gives an intercalation compound of composition C_8K.

$$8C\,(\text{graphite}) + K \xrightarrow{300°C} C_8K$$

Rubidium and cesium react in a similar manner to give the intercalation compounds, C_8Rb and C_8Cs, respectively.

Intercalation is difficult with lithium and sodium. However, extra pure sample of graphite reacts with lithium at 500°C to give brass coloured C_6Li and copper coloured $C_{12}Li$. Sodium also reacts with graphite under strictly controlled conditions to form $C_{64}Na$.

The intercalation compound C_8M (where M is K, Rb or Cs) is formed through a number of stages. The compound formed first is $C_{60}M$ (called *fifth stage* intercalation compound) which, in the presence of the alkali metal, gets gradually converted into $C_{48}K$ (called *fourth stage* intercalation compound) and then into $C_{36}M$ (called *third stage* intercalation compound), further into $C_{24}M$ (called *second stage* intercalation compound) and *finally* into C_8M (called **first stage intercalation compound**). Compounds with higher content of alkali metal than that in C_8M are *unstable* probably because of *electrostatic repulsion of intralayers of alkali metal cations.* C_8M is known to have an ionic structure, *viz.*, $C_8^-M^+$.

If the intercalation compound is heated under reduced pressure, the reaction occurs in the reverse direction accompanied by the gradual loss of the alkali metal. Thus, the intercalation compound C_8K changes, on heating, to $C_{24}K$, $C_{36}K$, $C_{48}K$ and finally to $C_{60}K$.

$$C_8K \xrightarrow{heat} C_{24}K \xrightarrow{heat} C_{36}K \xrightarrow{heat} C_{48}K \xrightarrow{heat} C_{60}K$$

1st stage compound (copper coloured) 2nd stage compound (steel blue) 3rd stage compound (dark blue) 4th stage compound (black) 5th stage compound (black)

Structure and Properties. The crystal structure of the *first stage* intercalation compound C_8K contains planar layer of K metal in between two layers of graphite, as shown in Fig. 5. The spacing between K atoms within a layer is twice the spacing between the centres of graphite hexagons in the graphite layers. The C – C distance within a layer of graphite is the same as in pure graphite but the spacing between two graphite layers in C_8K (5·4 Å) is larger than in pure graphite (3·36 Å). This is due to the entry of K atoms in between the two graphite layers. The structures of other intercalation compounds, *viz.*, C_8Rb and C_8Cs are similar to that of C_8K.

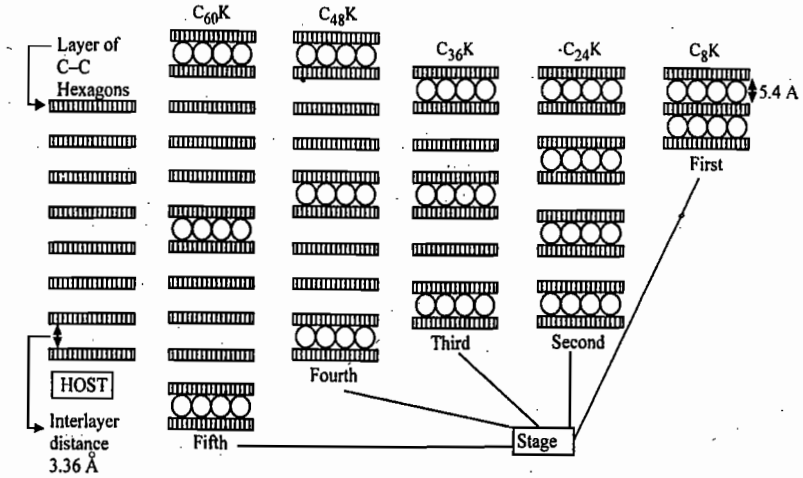


Fig. 5. Structures of intercalation compounds of graphite formed with potassium metal (shown as O) at different stages of intercalation (qualitative).

The structures of compounds formed at other stages of intercalation are arrived at by varying the frequency of occurrence of the intercalated layers containing alkali metal atoms in the host lattice. The structures of *fifth stage* compound $C_{60}K$, *fourth stage* compound $C_{48}K$, *third stage* compound $C_{36}K$, *second stage* compound $C_{24}K$ and first stage compound C_8K are represented in Fig. 5.

The intercalation alkali metal compounds are more conducting than graphite. They are paramagnetic while graphite is diamagnetic. Their electrical conductance decreases with increase in temperature as in metals. These properties indicate that in intercalation compounds bonding occurs through the transfer of electrons from alkali metal atoms to the conduction band of the host element (*i.e.*, graphite) so that the structure of these compounds can be written as $C_n^-M^+$. This very well explains why intercalation compounds are mostly formed by electropositive metals, *i.e.*, alkali metals.

Intercalation compounds of alkali metals are highly reactive. They readily react with water to produce alkali metal hydroxide and hydrogen gas.

$$C_nM + H_2O \longrightarrow MOH + 1/2\,H_2 + \underset{\text{(graphite)}}{nC}$$

2. Intercalation Compounds of Oxoacids and Metal Halides. Besides alkali metals, intercalation compounds are also formed by several oxoacids and metal halides.

Intercalation compounds of oxoacids are formed by reacting graphite with concentrated oxoacids under oxidising conditions, *i.e.*, in the presence of air or oxygen. *These compounds are called lamellar graphite salts.* The formation of these salts is reversible. The formation of the first stage intercalation compound with concentrated H_2SO_4 is as follows :

$$24C + 3H_2SO_4 + 1/2\,O_2 \longrightarrow \underset{\substack{\text{First stage compound}\\ \text{(Blue)}}}{C_{24}^+HSO_4^-.2H_2SO_4} + 1/2\,H_2O$$

The overall stoichiometry is close to the formula $C_8H_2SO_4$ as in C_8M.

A series of graphite nitrates such as $C_{24}^+NO_3^-.2HNO_3$ (blue), $C_{48}^+NO_3^-.3HNO_3$ (black), etc., can also be prepared in a similar manner. Besides HNO_3 and H_2SO_4, several other oxoacids are also known to form intercalation compounds with graphite. The extent of intercalation depends on the strength of the acid and its concentration. The formation of intercalation compounds with oxoacids leads to the swelling and crumbling of graphite electrodes in electrochemical processes conducted in acid media. The graphite electrodes thus need frequent replacement.

Electrical conductivity of intercalated graphite salts is higher than that of the pure graphite.

A non-conducting pale lemon coloured product of variable composition called **graphite oxide** is obtained by treating graphite with fuming nitric acid or concentrated nitric acid containing $KClO_3$ or with a mixture of concentrated nitric acid, concentrated sulphuric acid and $KClO_4$.

Graphite oxide decomposes between 70° – 200°C to CO_2, CO, H_2O and soot. Its structure consists of hexagonal network of C_6 rings in the chair form. It also contains some bridging O atoms, C=O and C – OH groups. The approximate formula of graphite oxide can be written as $C_6O_{1\cdot1-1\cdot7}(OH)_{1\cdot7-2\cdot5}$

Intercalation compounds with metal halides are prepared by reacting metal halides in the presence of the free halogens with graphite. The intercalated halides are all Lewis acids. For example, the first stage intercalated compound of $FeCl_3$ is $C_{6-7}FeCl_3$; second stage compound is $C_{12}FeCl_3$ and third stage compound is $C_{24-30}FeCl_3$.

In the intercalated graphite compounds of oxoacids and metal halides, there appears to be a transfer of electrons from the host (graphite) to the guest species which leads to the formation of intercalation species of the type , $C_{24}^+HSO_4^-.2H_2SO_4$, $C_{24}^+NO_3^-.2HNO_3$ (formed in the presence of oxygen) and $C_{10}^+Cl^-.FeCl_2.5FeCl_3$ and $C_{27}^+AlCl_4^-.2AlCl_3$ (formed in the presence of free chlorine). The formation of positive 'holes' near the top of the valence band of graphite explains the enhanced conductivity of these compounds.

3. Intercalation Compounds of Oxides and Sulphides. A number of oxides and sulphides also intercalate into graphite. Thus, oxides such as SO_3, N_2O_5, Cl_2O_7, CrO_3 and MoO_3 readily intercalate into graphite as do several sulphides such as V_2S_3, Cr_2S_3, WS_2, PdS and Sb_2S_3.

4. Intercalation Compounds of the Halogens. Graphite reacts with fluorine at 400° – 500°C to give **graphite monofluoride** which has a variable composition CF_n, n varying from 0·7 to about 1. The colour of CF_n depends upon the fluorine content and ranges from black ($n \sim 0{\cdot}7$) to transparent white ($n \sim 1$). The intercalation compound $CF_{\sim 1}$ is chemically inert. However, it gradually liberates fluorocarbons when heated to about 800°C. Since all the double bonds in graphite open up to add fluroine atoms during the formation of $CF_{\sim 1}$, it is non-conducting.

When a mixture of fluorine and hydrogen fluoride reacts with powdered graphite at room temperature, a bluish black intercalation compound is predominantly formed whose composition approaches, C_4F. The structure of C_4F comprises of graphite sheets with regularly spaced fluorine atoms above and below each graphite layer. Some C_2F is also formed during the above reaction.

Chlorine and bromine also form intercalated compounds with approximate compositions C_8Cl, C_8Br, $C_{12}Br$, $C_{16}Br$ and $C_{20}Br$.

Several interhalogens such as ClF_3, BrF_3, IF_5, also form a number of intercalation compounds with graphite.

COMPOUNDS OF SILICON

Silicides. These compounds are prepared either by the direct combination of the metal with silicon or by the reduction of SiO_2 with a mixture of the metal and carbon. The melting points of silicides are lower than those of the corrosponding carbides and borides. Several metals, both representative and transition, form silicides. Of these, the silicides of elements of Groups 1 and 2 are quite reactive. They hydrolyse readily to give products which depend upon the stoichiometry of the reacting silicide. Thus, whereas the hydrolysis of Ca_2Si produces $Ca(OH)_2$, SiO_2 and H_2, the hydrolysis of CaSi yields silanes alongwith polysilene and that of $CaSi_2$ gives H_2 and polysilene. The silicides of transition metals are less reactive compared to those of metals of Groups 1 and 2.

Like borides and carbides, the composition of metal silicides cannot be explained by the simple concept of valence. Since boron and silicon are closely related to each other, the silicides are structurally closely related to borides. Some metal-rich silicides M_3Si (M = V, Cr, Mo, Mn) have metal-like structures and like metals, they have good electrical conductivity. However, some other metal-rich silicides M_2Si (M = Mg, Ge, Sn, Pb, Ca, Ru, Ce, Rh, Ni) have non-metallic structures and are non-conductors of electricity. In silicon-rich silicides, atoms have a tendency to catenate into isolated Si_2 units (as in U_3Si_2), Si tetrahedra (as in K_4Si_4), Si chains (as in α USi_2, $ThSi_2$, $TiSi_2$), two-dimensional hexagonal Si nets (as in β USi_2) and three-dimensional Si frame work (as in $SrSi_2$). Many of the metal silicides have typical metallic lustre and hence are used in artificial jewellery.

Silicon Hydrides. These compounds are similar to hydrocarbons but are much less stable. The number of silicon hydrides is also much less than the number of hydrocarbons. These are called **silanes** and have the general formula Si_nH_{2n+2} where *n* stands for the number of silicon atoms. The individual members are known as *silane*, SiH_4, *disilane*, Si_2H_6, *trisilane*, Si_3H_8, etc. The first two members are colourless gases while the third and subsequent members are liquids.

These are produced by the action of acids on metallic silicides, *e.g.*,

$$Mg_2Si + 4HCl \longrightarrow 2MgCl_2 + SiH_4$$

Actually a mixture of silanes is obtained. Monosilane can be separated by fractionating in vaccum, as in the case of boron hydrides.

Pure monosilane is prepared by reacting silicon tetrachloride with lithium aluminium hydride in ether.

$$SiCl_4 + LiAlH_4 \xrightarrow{\text{ether}} SiH_4 + LiCl + AlCl_3$$

Monosilane is unstable, decomposing spontaneously on coming in contact with air.

$$SiH_4 + 2O_2 \longrightarrow SiO_2 + 2H_2O$$

If the gas is bubbled through water then, as soon as it comes in contact with air, each bubble ignites giving vortex ring of finely divided silica (cf. phosphine). It decomposes slowly when brought in contact with water.

$$SiH_4 + 3H_2O \longrightarrow H_2SiO_3 + 4H_2$$

Monosilane is soluble in strong alkali solutions in the presence of air.

$$SiH_4 + 2NaOH + 1/2\ O_2 \longrightarrow Na_2SiO_3 + 3H_2$$

Thus, monosilane differs from methane in its reactions with water and sodium hydroxide. However, as in methane, the hydrogen atoms can be substituted by chlorine atoms giving SiH_3Cl (silyl chloride) SiH_2Cl_2 (dichlorosilane), $SiHCl_3$ (silicon chloroform) and $SiCl_4$ (silicon tetrachloride). The trisilylamine, $(SiH_3)_3N$, is not basic, unlike trimethylamine $(CH_3)_3N$.

Silicon Dioxide or Silica, SiO_2. Silica occurs in nature in several amorphous and crystalline forms. The three important crystalline forms are *quartz, tridymite* and *cristobalite*.

Quartz is the most common form. Its specific gravity is 2·648 and it melts in an electric furnace at 1740°C. It can be shaped into vessels such as flasks and beakers, like glass. These vessels have certain advantages over glass as the material is much less soluble in acids or alkalies and its coefficient of expansion is very small and the chances of breakage on sudden heating and cooling are small. Sometimes it occurs as clear colourless hexagonal crystals and is used for optical apparatus. More often it occurs in opaque or coloured masses. Certain coloured varieties are used as gems, *e.g., amethyst* (purple), *jaspar* (red) and *opal* (white).

Quartz is more transparent to ultraviolet light than is glass. It is, therefore, used in all apparatuses where ultraviolet light is to be used. *Sand* is also a crystalline form of quartz which is formed as a result of 'weathering' or disintegration of rocks and further breaking down by violent movements of water.

Quartz is stable below 870°C above which it changes into *tridymite*. Tridymite is stable between 870°C and 1470°C above which it changes into *cristobalite*. Cristobalite melts when heated to 1740°C.

Amorphous forms of silica are *agate, jaspar* and *onyx*.

Silica is also found in certain plants and animals. For example, the hard portions of straw and bamboo contain silica. The skeletons of certain marine organisms (*e.g.*, sponges) consist largely of silica. Claws of animals and finger nails also contain silica.

Pure silica (amorphous form) can be prepared as a white powder by the action of silicon tetrachloride or tetrafluoride with water.

$$SiCl_4.2H_2O \longrightarrow 4HCl + \underset{\text{Silica gel}}{SiO_2}$$

The silica gel is dehydrated by heating.

It is insoluble in water and in all acids, except hydrofluoric acid with which it reacts to form silicon tetrafluoride.

$$SiO_2 + 4HF \longrightarrow SiF_4 + 2H_2O$$

It dissolves in hot concentrated alkalies to form sodium silicate.

$$SiO_2 + 2NaOH \longrightarrow 2Na_2SiO_3 + H_2O$$

The addition of hydrochloric acid to this mixture reprecipitates the hydrated gelatinous silica.

$$Na_2SiO_3 + 2HCl \longrightarrow 2NaCl + H_2O + SiO_2$$

Silica, being a non-volatile substance, displaces volatile acids from their salts on heating to a high temperature, *e.g.*,

$$Na_2SO_4 + SiO_2 \longrightarrow Na_2SiO_3 + SO_3$$

$$Ca_3(PO_4)_2 + 3SiO_2 \longrightarrow 3CaSiO_3 + P_2O_5$$

Apart from the few reactions given above, silica is an inert substance.

Uses. The important uses of the various natural forms of silica may be summarised as follows : 1. Quartz, when transparent, is used in making optical instruments and lenses. 2. The coloured varieties of quartz are used as gems, *e.g.*, amethyst, jaspar and opal. 3. The opaque quartz is used in making vessels which are acid and alkali resistant and can stand sudden changes of temperature and are, therefore, superior to glass vessels 4. Sand is used in the manufacture of glass, mortar and porcelain. It forms an important construction material when mixed with lime or cement. 5. A transluscent variety of glass, known as vitreosil, is obtained by fritting sand with an electrically heated carbon rod or plate. 6. Silica is used in making refractory bricks for furnace linings. 7. Sand (finely ground) is used in the extraction of phosphorus from phosphates.

Silicic Acids. When a dilute solution of sodium silicate, Na_2SiO_3, is poured gradually into a vessel containing excess of dilute hydrochloric acid, the following reaction takes place.

$$Na_2SiO_3 + 2HCl \longrightarrow 2NaCl + SiO_2 + H_2O$$

However, no visible precipitate (of silica) is observed although the conductivity of the mixture falls appreciably indicating that the reaction as represented by the above equation has definitely taken place. If the liquid is placed in a dialyser, sodium chloride is seen to diffuse out completely leaving behind a colloidal solution of *silicic acid*, known as **silicic acid hydrosol**. This can be concentrated by evaporation, either by gentle heating or by keeping over concentrated sulphuric acid. The sol is readily coagulated on the addition of a small amount of sodium carbonate or phosphate to give a transparent jelly, known as *silica gel*.

Silicic acid has not been isolated. However, silicates of different compositions are known and may be considered to be derived from different hypothetical silicic acids, the more important of which are *orthosilicic acid*, H_4SiO_4 and *metasilicic acid*, H_2SiO_3. The latter may be considered to be derived from

the former by the loss of one molecule of water.

$$H_4SiO_4 \xrightarrow{-H_2O} H_2SiO_3$$

The other hypothetical acids are disilicic acid and trisilicic acid which contain 2 and 3 silicon atoms per molecule, respectively. Their formation from orthosilicic acid may be represented by the following equations.

$$2H_4SiO_4 \xrightarrow{-2H_2O} \underset{\text{Disilicic acid}}{H_2Si_2O_6} \quad \text{or} \quad 2SiO_2.2H_2O$$

$$3H_4SiO_4 \xrightarrow{-2H_2O} \underset{\text{Trisilicic acid}}{H_6Si_3O_9} \quad \text{or} \quad 3SiO_2.3H_2O$$

Silica Gel. Silica gel may be prepared by hydrolysing silicon tetrachloride or tetrafluoride or by adding a mineral acid such as hydrochloric acid to a fairly concentrated solution of sodium silicate or by adding, gradually, a solution of ammonium sulphate to that of sodium silicate.

$$Na_2SiO_3 + 2HCl \longrightarrow 2NaCl + H_2O + SiO_2$$

$$Na_2SiO_3 + (NH_4)_2SO_4 \longrightarrow Na_2SO_4 + 2NH_3 + H_2O + SiO_2$$

In each case, silica separates out as a gel (also called a hydrogel), that is, a colloidal system in which water is dispersed in a solid. The gel is filtered and washed to remove the soluble impurities. It is then dried by heating at 110°C in an air-oven.

Uses. 1. When exposed to moist atmosphere it adsorbs moisture. Hence, dry silica gel is used as an excellent drying agent because it can take up a large amount of water vapour and, at the same time, is chemically inert. Every time, after drying, it can be used over again. 2. It can also adsorb sulphur compounds and is used in removing them from petroleum. 3. When silica gel is heated to fusion and cooled, it changes into a transparent solid known as *silica glass*. It is superior to ordinary glass since it softens at a lower temperature and can be more easily shaped into vessels such as crucibles, dishes, etc. It has low coefficient of expansion and, therefore, an article made of silica glass can withstand sudden changes in temperature. 4. It is also used in making certain types of optical lenses as it transmits ultraviolet light better than ordinary glass.

GLASS

The name **glass** is given to any amorphous and transparent solid which is produced on the solidification of a liquid. The word is generally used for the transparent substance obtained when white sand is fused with oxides and carbonates of alkali and alkaline earth metals and the molten mixture is cooled.

Glass is a mixture of a number of silicates. When it is heated it does not melt at a fixed temperature. On the other hand, it gradually softens and can be moulded into any desired shape. It is this property of glass which makes it a useful material since a number of articles of different shapes and forms can be made out of it. It completely melts into a liquid at a very high temperature.

Manufacture of Glass

Raw Materials. The raw materials required for the preparation of glass are

(*i*) *Silica* (in the form of sand).

(*ii*) *Compounds of alkali metals*, such as Na_2CO_3, Na_2SO_4, $NaNO_3$, K_2CO_3 and KNO_3.

(*iii*) *Compounds of alkaline earth metals*, such as $CaCO_3$, CaO, $BaCO_3$. These are required when glass of high refractive index is needed.

(*iv*) *Oxides of heavy metals*, such as PbO, Pb_3O_4. These are added for getting glass of higher refracting power.

(*v*) *Calcium phosphate*, $Ca_3(PO_4)_2$. This is required when it is desired to produce *opalescent glass*. Arsenic and antimony are also added in such cases, in the form of their oxides.

(*vi*) *Colouring materials*. Certain metallic oxides are added to fused silicates during the manufacture of glass to prepare glass of *different colours*. For example, ferric oxide is added to get yellow colour, chromic oxide to get green colour, manganese oxide to get purple colour and CoO to get blue colour in glass.

Manufacture of Ordinary Glass. The ordinary glass (soda glass), also known as window glass, has approximately the composition : $Na_2O.CaO.6SiO_2$. It is obtained by fusing together in proper proportions sodium carbonate, calcium carbonate and sand or quartz (silica, SiO_2). Each constituent is finely powdered and then mixed intimately with one another. A small amount of 'scrap glass' from a previous run is also added. This acts as a flux. The mixture is then fused in a tank furnace heated by producer gas on the regenerative principle of heat economy. The following reactions take place :

$$Na_2CO_3 + SiO_2 \longrightarrow Na_2SiO_3 + CO_2$$

$$CaCO_3 + SiO_2 \longrightarrow CaSiO_3 + CO_2$$

In the early stages, considerable frothing occurs on account of the formation of carbon dioxide. On continued heating the entire amount of carbon dioxide is driven out and a clear viscous fused mass is obtained. This consists of a mixture of Na_2SiO_3 and $CaSiO_3$. It is then poured into moulds or stamped with dies to produce different articles such as bottles, flasks, etc. The articlcs are allowed *to cool gradually* (annealing).

Annealing. The glass if cooled rapidly becomes brittle and fragile and if cooled very slowly it devitrifies and becomes opaque. Therefore, the articles should be cooled neither very slowly nor very quickly. For this purpose, they are made to pass through a long tunnel-like furnace which is very hot at the mouth-end and very cold at the tail-end so that the articles are cooled gradually during their passage through the tunnel. This process is known as **annealing** and takes several days for completion.

Varieties of Glass. 1. Soda glass. The ordinary glass prepared in the above manner is known as **soda glass** or **soft glass**. Its approximate composition is : SiO_2 75%, sodium oxide 15%, calcium oxide 8%, aluminium oxide 2% (as an impurity). This is also called soft glass as it softens at a comparatively lower temperature and can be easily shaped into different forms. It is used in making cheap window panes, bottles, dishes, etc.

2. Potash glass (Hard glass). If sodium carbonate is replaced by potassium carbonate in the above process, a hard glass, which has a higher melting point and can withstand higher temperature, is obtained.

3. Flint glass. If calcium carbonate is replaced in sufficient quantity by lead carbonate or lead oxide (litharge), and sodium carbonate is replaced partly by potassium carbonate, a glass of higher refracting power, known as flint glass, is obtained. Its approximate composition is : silica 45%, sodium oxide 4%, potassium oxide 4%, calcium oxide 3%, lead oxide 44%. It has a higher density and transparency than ordinary glass and is used for making optical instruments as well as for ornamental purposes. It is prepared by fusing litharge, potassium carbonate and silica in proper proportions.

4. Crown glass. A partial replacement of silica by phosphorus pentoxide gives crown glass.

5. Pyrex glass. Addition of certain amounts of boron and aluminium oxides produces a glass with a very low coefficient of expansion, known as *pyrex glass*. This can withstand sudden alterations of temperature very well and is highly suitable for laboratory glass-ware such as flasks, beakers, etc., which are to be heated to high temperatures. Its approximate composition is : silica 80%, sodium oxide 4%, calcium oxide 0·5%, potassium oxide 0·5%, B_2O_3 12%, Al_2O_3 3%.

6. Jena glass. It is obtained by decreasing the alkali content and increasing the alumina content in ordinary soda glass. It also contains barium and zinc oxides and boron trioxide in place of some silica. This glass is stronger than the ordinary glass. At the same time, it is more resistant to the action of acids and alkalies.

7. Crooke's glass. This is a special type of glass used for optical purposes and contains cerium oxide.

8. Bottle glass. It is ordinary soda-lime glass containing MgO to the extent of 3·5 per cent and $Al_2O_3.Fe_2O_3$ to the extent of 0·5 per cent.

9. Ground glass. It is prepared by grinding ordinary soda (soft) glass by emery and turpentine oil or by *sand blasting*.

10. Safety glass. It is used in making wind screens of automobiles, aeroplanes, railway trains, etc. It is prepared by placing a layer of *transparent plastic* (usually a sheet of *vinyl acetate resin*) between two layers of glass by means of a suitable adhesive. The three layers are joined together tightly by the action of heat and pressure.

This glass does not break easily under ordinary impact. This is the reason for the name "safety glass" or "unbreakable glass" given to it. However, it does break under heavy impact. But the particles of glass do not shatter because they are held by the plastic.

Thermoplastics. The main disadvantage of using glass is that it is brittle and fragile. In recent years, it has been replaced, for a variety of purposes, by *transparent plastics*. A plastic consists of highly polymerised substances. It softens on heating and can be given any shape just like glass and is, therefore, sometimes called *thermoplastic*. The interlinking of the molecules in the polymerised materials gives it hardness as well as insolubility.

SILICATES

Silicates occur in earth's crust in abundance in the form of *silicate minerals* and *aluminosilicate clays*. Sodium silicate, Na_2SiO_3, is the only common silicate which is soluble in water. It is prepared by fusing sodium carbonate with silica (SiO_2) at 1500°C. Most of the silicates are insoluble in water. This is due to the great strength of the Si – O bond. This bond can be broken only on treatment with strong reagents like hydrofluoric acid.

The electronegativity of oxygen is 3·5 and that of silicon is 1·9. The electronegativity difference of 1·6 suggests that Si – O bond, though covalent, has an appreciable degree of ionic character.

All silicates comprise of $(SiO_4)^{4-}$ units which are formed by sp^3 hybridisation of Si orbitals. The outer electronic configuration of silicon atom in the excited state is $3s^1p_x^1p_y^1p_z^1$. Thus, it forms four bonds with oxygen atoms by utilising its sp^3 hybrid orbitals and yielding $(SiO_4)^{4-}$ units. The oxygen atoms pick up one electron each from some metal in order to complete their octets. As expected, $(SiO_4)^{4-}$ unit has a **tetrahedral structure,** as shown in Fig. 6. The plane circles represent oxygen atoms and the small dots represents the silicon atoms. As already mentioned, all silicates contain the tetrahedral $(SiO_4)^{4-}$ units. They differ from one another only in the manner in which these units are linked together.

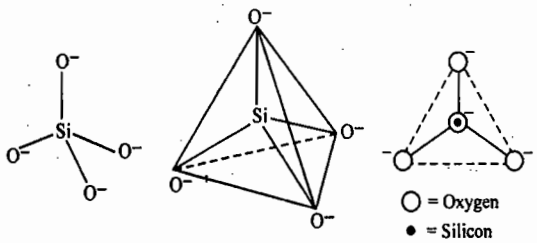

Fig. 6. Tetrahedral structure of $(SiO_4)^{-4}$ ion.

In some cases, several $(SiO_4)^{4-}$ tetrahedral units are bridged together through oxygen atoms of the units. The bridging oxygen atom is covalently bonded to the two Si atoms of the bridging $(SiO_4)^{4-}$ units. The number of oxygen atoms of an $(SiO_4)^{4-}$ unit which form bridges with other $(SiO_4)^{4-}$ units may be one, two, three or all the four. In this way, a number of complex silicates can be formed. The resulting silicate chains are negatively charged anions because any oxygen atom which is not a bridging atom carries a unit negative charge. This negative charge is balanced by a metal cation. Thus, metal

cations such as Li^+, K^+, Ca^{2+}, Al^{3+} are present in silicate minerals. These serve to hold the solid together by ionic attraction.

The structure of silicates has been understood recently with the development of X-ray diffraction techniques.

Different Types of Silicates

Depending upon the linkage of $(SiO_4)^{4-}$ tetrahedral units, the silicates may be classified into the following types.

1. Ortho silicates. These contain discrete $(SiO_4)^{4-}$ units. The common examples are *zircon* ($ZrSiO_4$), *willemite* (Zn_2SiO_4), *phenacite* (Be_2SiO_4). Another important group of orthosilicates is the *garnets* having the general formula $[M_3^{II}M_2^{III}(SiO_4)_3]$, where M^{II} can be Ca^{2+}, Mg^{2+} or Fe^{2+} and M^{III} can be Al^{3+}, Fe^{3+} or Cr^{3+}.

2. Pyrosilicates. These contain disilicate anion, $(S_2O_7)^{6-}$ units. The $(Si_2O_7)^{6-}$ units are formed by joining two tetrahedral $(SiO_4)^{4-}$ units through one oxygen atom, as shown in Fig. 7.

It may be noted that any oxygen atom which does not form a bridge has to pick up an electron from some metal to complete its octet and thus acquire a negative charge. In the present case, there are 6 oxygen atoms which do not form bridges, as shown. Consequently, the Si_2O_7 unit is an anion carrying 6 negative charges and is written as $(Si_2O_7)^{6-}$. The metal atoms from which the electrons are picked up by the oxygen atoms are present in the silicate structure as cations. The number of cations is such that they balance the negative charge on the silicate anion. The most important pyrosilicate is of scandium known as *thortveitite* having the formula $Sc_2(Si_2O_7)$. The 6 negative charges on $(Si_2O_7)^{6-}$ anion are balanced by the same number of positive charges on the two Sc^{3+} ions. The other example of pyrosilicates is *hemimorphite* $[Zn_4(OH)_2Si_2O_7]$.

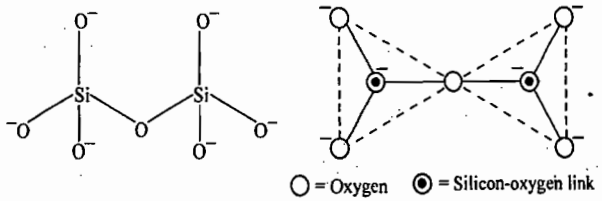

Fig. 7. Structure of $(S_2O_7)^{6-}$ ion in pyrosilicates.

3. Chain Silicates. If there are two bridging oxygens per silicon atom, *i.e.*, there is sharing of two oxygen atoms by each SiO_4 tetrahedron, a simple chain structure, as shown in Fig. 8, results. The remaining two oxygens per silicon atom do not form bridges. The resulting silicate, therefore, is an anion carrying 2 negative charges per silicon atom. The structure given below, for example, contains 5 silicon atoms and, therefore, the silicate ion is an anion carrying 10 negative charges.

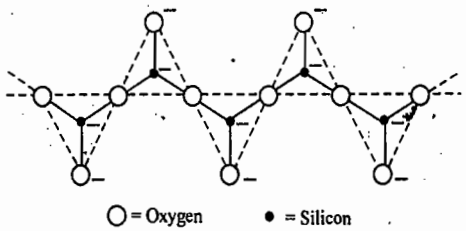

Fig. 8. Structure of chain silicates. The primary unit is $(SiO_3)^{2-}$.

It is eviden from the above structure that there is a total of 3 oxygen atoms per silicon atom. Therefore, the chain silicates contain $(SiO_3)^{2-}$ as the primary units and the general formula of this type of silicates is $[SiO_3)_n^{2-}$. These chains are found in minerals called *pyroxenes*. The common examples are *enstatite*, $MgSiO_3$, *diopside*, $CaMg(SiO_3)_2$ and *spodumene*, $LiAl(SiO_3)_2$.

In certain minerals, double chain structures have been observed. These are formed by further

sharing of oxygen atoms of SiO_4 tetrahedra by half the silicon atoms. The double chain structures (Fig. 9) have the basic unit $(Si_4O_{11})^{6-}$ and are represented by a class of minerals called *amphiboles*. Typical examples of this class are *tremolite*, $Ca_2Mg_5(Si_4O_{11})_2(OH)_2$, *amosite*, $(MgFe)_7Si_8O_{22}(OH)_2$ and *crocidolite* $Na_2Fe_3^{II}Fe_2^{III}Si_8O_{22}(OH)_2$.

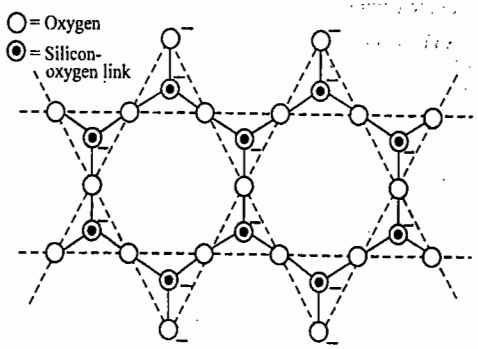

Fig. 9. Structure of double chain silicates. The basic unit is $(Si_4O_{11})^{6-}$.

4. Cyclic Silicates. These are formed by sharing of two oxygens per silicon atom resulting in the formation of a cyclic structure, as shown in Fig. 10. The primary unit in this case also is $(SiO_3)^{2-}$.

The cyclic ion, $(Si_3O_9)^{6-}$, shown in Fig. 10 (*a*), occurs in *wollastonite* $(Ca_2Si_3O_9)$ and *bentonite* $(BaTiSi_3O_9)$ while the cyclic ion $(Si_6O_{18})^{12-}$, shown in Fig. 10 (*b*), occurs in *beryl* $(Be_3Al_2Si_6O_{18})$.

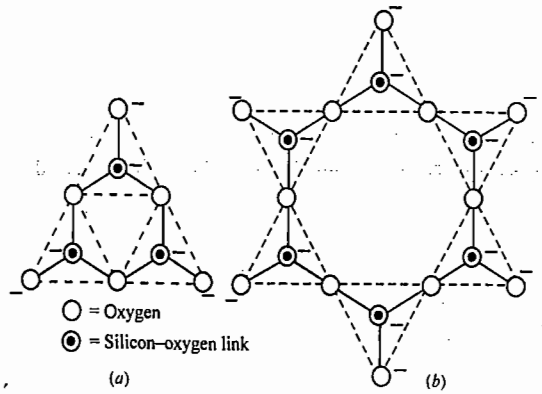

Fig. 10. Structure of cyclic silicates.

5. Sheet Silicates. These are formed by sharing of three bridging oxygens per silicon atom and result in the formation of infinite *two-dimensional sheets*. Each SiO_4 tetrahedron shares three corner oxygen atoms with other tetrahedra, as shown in Fig. 11. The oxygen atom shown around the silicon atom is the one that does not form the bridge and hence carries a negative charge. Actually, this oxygen lies below the plane of the paper. There is one negative charge per silicon atom in such structures. The negative charge on the sheets is neutralised by the positive charge of the 'binding' cations lying in between such sheets. Such substances cleave readily into thin sheets as in micas which are silicates or aluminosilicates of this type.

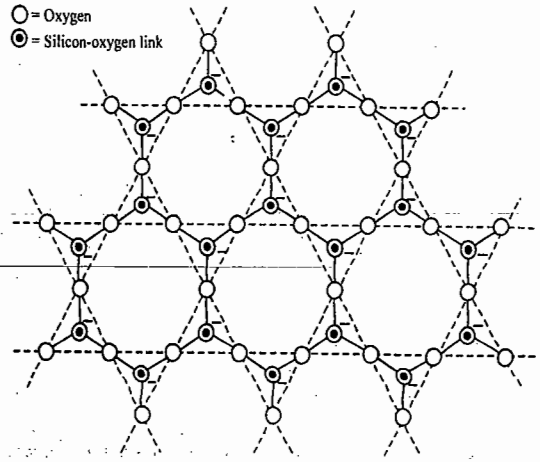

Fig. 11. Two-dimensional structure of sheet silicates.

Some common examples of sheet silicate are *kaolinite*, $Al(OH)_4SiO_5$ and *talc*, $Mg_3(OH)_3Si_4O_{16}$.

Sometimes in these silicates, silicon atoms are partially replaced by aluminium atoms. Examples are : *biotite* $K(MgFe)_3(OH)_3(AlSi_3O_{10})$ and *miscovite*, $KAl_2(OH)_2(AlSi_3O_{10})$

6. Three-Dimensional Silicates. Lastly, there is the extreme case in which four oxygens per silicon atom are bridging atoms. In other words, all the four oxygens of the SiO_4 tetrahedron act as bridge atoms. This results in a *three-dimensional* structure. Since all the oxygens are the bridge atoms, the silicate is neutral. There are no metal cations in this structure. This silicate structure will have the general formula $(SiO_2)_n$, *e.g.*, *quartz, tridymite, cristobalite.*

However, sometimes, $(SiO_4)^{4-}$ unit is replaced by $(AlO_4)^{5-}$ unit in tetrahedral positions in the SiO_2 lattice. In such cases, the presence of an additional monovalent cation is necessary to maintain electrical neutrality. Such replacement results in minerals like *feldspar* $(KAlSi_2O_8)$, *zeolite* $(NaAlSi_2O_6.H_2O)$ etc.

When feldspar is acted upon by carbon dioxide and water of the atmosphere at room temperature it slowly forms potassium carbonate and the clay, *kaolin* $[Al_2O_3.2SiO_2.2H_2O]$. The potassium carbonate, being soluble, becomes available in soil as plant food while kaolin is carried away by water streams to lower levels and is used in making pottery.

Replacement of $(SiO_4)^{4-}$ units with $(AlO_4)^{5-}$ units. Structure of aluminosilicates. The radius ratio rAl^{3+}/rO_2^- is about 0·43. This is close to the limiting radius ratio for coordination numbers 4 to 6. Accordingly, Al^{3+} ion would either fit into the space lattice of tetrahedral $(AlO_4)^{5-}$ ion or an octahedral $(AlO_6)^{9-}$ ion. The $(AlO_4)^{5-}$ ion has roughly the same size as the $(SiO_4)^{4-}$ ion and can thus replace the latter from silicates provided the electrical neutrality is maintained by the adjustment of positive charge elsewhere in the structure.

It is to be kept in mind that Al^{3+} ion can either be a part of $(AlO_4)^{5-}$ unit (in which its coordination number would always remain 4) or it can be present as cation used for binding the chains and sheets in the silicate structure by neutralising the negative charge of the chains or sheets. In the latter role, the coordination number of Al^{3+} cation is generally 6. Such a binding Al^{3+} cation can be replaced by other cations provided the principle of electroneutrality is maintained.

Some of the important **aluminosilicates** are described below.

Micas. Micas are *amphiboles* which are made up of *sheets* of $(SiO_4)^{4-}$ tetrahedra in which some of the $(SiO_4)^{4-}$ tetrahedra are replaced by $(AlO_4)^{5-}$ tetrahedra. In *muscovite*, the sheet composition is $(Si_3AlO_{10})^{5-}$. Two such sheets with their tetrahedral vertices inward are linked by the binding Al^{3+} ions whose octahedral coordination is completed by OH^- ions. The double sheets which have, in consequence, the composition $[Al_2Si_3O_{10}(OH)_2]^-$ are stacked one upon another with sufficient number of K^+ ions between two such double sheets to maintain electrical neutrality. The cleavage of mica is due to the weakness along these layers of K^+ ions. A wide variety of replacement is possible. Thus, the binding Al^{3+} ions may be replaced by Mg^{2+} ions and the 'sandwiched' K^+ ions by Na^+ ions. Micas are tough, elastic and transparent.

They are chemically inert and thermally stable. They also have a high dielectric constant. Due to these characteristic properties micas are used in furnace windows and electrical appliances. The powdered mica is used as a filler for rubbers, plastics and in insulation boards.

Clay. Clays are produced by weathering and decomposition of igneous rocks. They are generally composed of very fine particles. China clay, *i.e.*, *kaoline*, with formula $Al_2O_3.2SiO_2.2H_2O$, more correctly written as $Al_2(OH)_4Si_2O_5$, has a sheet structure in which the sheets are held together by the OH bridges.

When mixed with water, clay becomes plastic-soft and mouldable. The water of plasticity gets eliminated on heating at 100°C when the clay becomes rigid and brittle. Further heating removes structural water of crystallisation and results in oxidation of carbonaceous matter of the clay. At about 900°C, *multite*, $Al_6SiO_2O_{13}$, begins to be formed. This has a *glassy appearance*.

Clay is widely used in making chinaware, fire bricks and many other useful materials.

Fuller's Earth. It is *montmorillonite* in which the principal exchangeable ion is Ca^{2+}. It has a high adsorptive power and pronounced cation exchange properties.

It is widely used as an adsorbent and a cation-exchanger.

Talc. Talc with the formula $Mg_3(OH)_2Si_4O_{10}$ consists of electrically neutral sheets and there are no 'sandwich' type of cations between the sheets. It is soft and smooth and is used as a dry lubricant. It is chemically inert and is used in ceramics, paper manufacture and cosmetics.

Zeolites. Zeolites are alumino-silicates having a three-dimensional network with the general formula $M^{n+}_{x/n}(Al_xSi_yO_{2x+2y})^{x-}.zH_2O$. They are characterised by their open structure which enables them to take up water and other small molecules in their interstices reversibly but not the complex or bigger molecules such as methane and ethane. In zeolites, the cations move freely through the open pore structure and can be exchanged reversibly with other cations. Sodium ions in zeolites, for instance, can be exchanged for calcium ions in hard waters. This explains the use of these materials in water softening operations.

Zeolites as Molecular Sieves. Some crystalline aluminosilicates having open structure with apertures or holes of molecular dimensions can trap small molecules having size smaller than the size of the apertures and can thus act as **'molecular sieves'** for separating such molecules from a mixture of molecules having different sizes. Since the apertures (holes) defined by the cage-like structures of aluminosilicates are highly regular and are of molecular dimensions, these 'molecular sieves' can trap molecules with greater selectivity than do solid adsorbents with large surface areas such as activated charcoal. One such class of compounds is zeolites which can trap cations in their tunnels or interstices of their open structure. Apart from acting as molecular sieves, they can also act as ion exchangers.

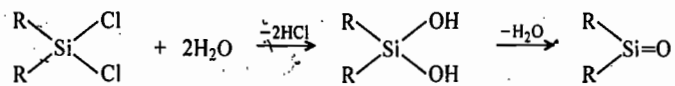
Zeolites are also used in **shape-selective heterogeneous catalysis.** For example, the zeolite ZSM-5 is used as a catalyst in the manufacture of ortho xylene selectively. Meta and para xylenes are not produced in the presence of this catalyst because the catalytic process is controlled by the shape (and size) of the tunnels existing in the structure of this zeolite which permits only the synthesis of ortho xylene.

Silicones

Silicon tetrachloride, $SiCl_4$, when fully hydrolysed, gives silica, SiO_2, which has a stable three-dimensional structure, as mentioned earlier.

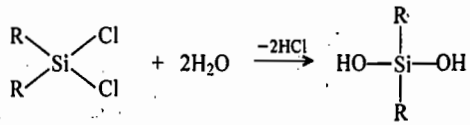
$$SiCl_4 + 4H_2O \xrightarrow{-4HCl} Si(OH)_4 \xrightarrow{-2H_2O} SiO_2$$

However, when an alkyl substituted chlorosilane (which can be obtained from $SiCl_4$ by Grignard reaction) is subjected to similar hydrolysis, *we do not get* the alkyl silicon compound according to the following expected reaction :

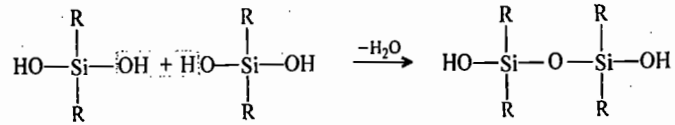


On the contrary, *long chain polymers,* called ***silicones,*** are obtained in this process. For example, in the case of dialkyl dichlorosilane, the reaction proceeds as follows :

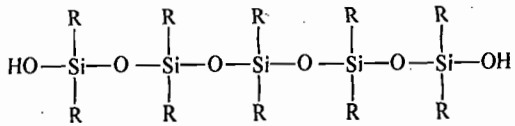
(*i*)



(*ii*)



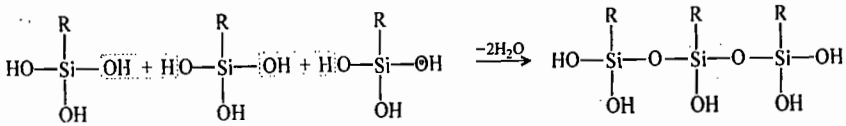
Since an active OH group is left at each end of the chain, polymerisation reaction continues and the length of the chain continues to increase giving a long chain product, as shown below.



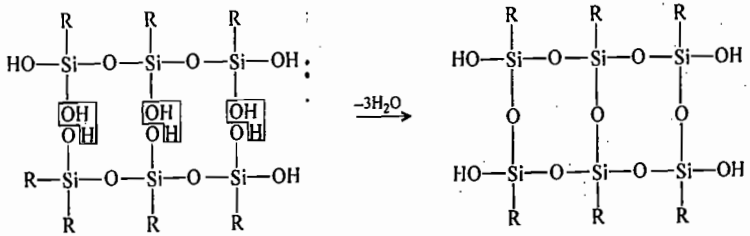
A complex cross-linked polymer is obtained on the hydrolysis of mono alkyl trichlorosilane, $RSiCl_3$, as shown below.

$$RSiCl_3 + 3H_2O \longrightarrow RSi(OH)_3 + 3HCl$$

(*i*)



(*ii*)



It is evident that the structure can be extended in two dimensions to any length in any manner.

The silicones are, evidently, **organosilicon polymers.** It may be noted that unlike carbon atom which cannot hold more than one hydroxyl group, the silicon atom in the compound $RSi(OH)_3$ can hold three hydroxyl groups. It is this property of silicon that makes the formation of organosilicon polymers possible.

As mentioned above, the organosilicon polymers grow further by reaction with other molecules containing one silicon atom. Thus, straight chain or cross-linked polymers are obtained. Depending upon the length of the chain and the nature of groups attached to the silicon atom, they can be obtained in the form of oils, viscous fluids, resins or even rubber-like solids.

Properties and Uses of Silicones. Silicone oils are highly stable and non-volatile even on heating. They are, therefore, used for high temperature oil baths, high vacuum pumps, etc. They do not become too viscous on cooling and are, therefore, used for low-temperature lubrication for which purpose hydrocarbon oils which become too viscous on cooling cannot be used. They are also used as greases, varnishes and resins which can be applied even at as low a temperature as – 40°C.

Silicones are also water-repellents and are good insulators. They are, therefore, used for waterproofing and in electrical condensers.

They provide excellent insulators for electric motors and other electric appliances as they can withstand high temperatures.

The rubber-like silicones retain their plasticity even at low temperatures and resist chemical attack. They are mixed in paints to make them damp-resistant. They are also used for waterproofing and for a variety of other purposes.

Silicones are discussed in some greater details in Chapter 35 on Inorganic Polymers.

Silicon Carbide or Carborundum, SiC. Preparation. Silicon carbide is prepared on a commercial scale by heating silica with carbon at a high temperature (around 2000°C) in an electric furnace.

$$SiO_2 + 3C \longrightarrow SiC + 2CO$$

Physical Properties. Pure silicon carbide is a colourless crystalline solid. The colour of the impure compound varies from yellowish to dark brown. SiC is an extremely hard substance. Of all the known binary compounds of silicon, SiC has the largest thermal stability. Its thermal decomposition with loss of silicon becomes appreciable only around 2700°C.

Chemical Properties. 1. Chemical stability. SiC resists the attack of most of the acids including HF but not H_3PO_4. It is slightly oxidised in air above 1000°C. Silica formed during oxidation forms a protective layer on the surface of SiC and inhibits further oxidation.

2. Reaction with molten alkalies. SiC reacts with molten NaOH to form sodium silicate.

$$SiC + 2NaOH + 2O_2 \xrightarrow{heat} Na_2SiO_3 + H_2O + CO_2$$

3. Reaction with chlorine. SiC reacts with chlorine to give silicon tetrachloride and carbon tetrachloride.

$$SiC + 4Cl_2 \xrightarrow{100°C} SiCl_4 + CCl_4$$

Structure of SiC. Silicon carbide exists in three crystalline forms. In each form, it has infinite three-dimensional array of Si and C atoms in which each carbon atom is tetrahedrally surrounded by four silicon atoms and each silicon atom is tetrahedrally surrounded by four carbon atoms.

Uses. 1. Due to its extreme hardness, SiC is used as an abrasive. 2. SiC has very low coefficient of expansion ($\sim 6\times10^{-6}$) and very high thermal and chemical stability. It is, therefore, used as a refractory material. 3. SiC is used as a high-temperature semiconductor in transistor diode rectifiers. 4. It is mostly used in the fabrication of grinding wheels for sharpening metallic tools. 5. It finds application in nuclear reactors because it serves as an excellent material for making containers for nuclear fuel at high temperatures.

Lead Pigments

A few insoluble compounds of lead are used as pigments in the preparation of oil paints. The important ones are described below.

White Lead, $Pb(OH)_2.2PbCO_3$. It can be prepared in laboratory by mixing alkali carbonate with a solution of lead salt.

$$4Na_2CO_3 + 3Pb(NO_3)_2 + 2H_2O \longrightarrow \underbrace{Pb(OH)_2.2PbCO_3}_{\text{Ppt. of white lead}} + 2NaHCO_3 + 6NaNO_3$$

There are three commercial processes for its manufacture.

1. *Dutch Process.* This is a very old process and is based on the action of acetic acid on metallic lead in the presence of carbon dioxide and moist air.

Small perforated buckets of lead are placed in earthenware pots having perforated shelves in which vinegar or dilute (about 2·5 per cent) acetic acid is placed. The pots are partly covered with wooden planks arranged in rows. The space in between the rows is filled by spent tan bark and horse dung.

It is believed that basic lead acetate is formed first and is then decomposed by the carbon dioxide produced during the fermentation of tan bark and horse dung. The following reactions are probably involved.

$$2Pb + O_2(air) + 2H_2O \longrightarrow 2Pb(OH)_2$$

$$2Pb(OH)_2 + 2CH_3COOH \longrightarrow \underbrace{Pb(OH)_2.(CH_3COO)_2Pb}_{\text{Basic lead acetate}} + 2H_2O$$

$$Pb(OH)_2 + Pb(OH)_2.(CH_3COO)_2Pb + 2CO_2 \longrightarrow \underbrace{Pb(OH)_2.2PbCO_3}_{\text{White lead}} + 2CH_3COOH$$

The heat produced during the fermentation of tan bark maintains the temperature at the optimum level of about 40°C.

This process is now being replaced by better ones given below.

2. *Carter's Process.* In this process, molten lead is atomised in wooden cylinders by blowing in a jet of air or superheated steam. The wooden cylinders keep rotating about their horizontal axes. A spray of dilute acetic acid and a current of air mixed with carbon dioxide are admitted into the cylinders. Here they meet the atomised lead and chemical reactions like those which occur in the Dutch process take place between lead, acetic acid and carbon dioxide. As the overall reaction is exothermic, the temperature remains almost constant at 40°C. The reactions are completed in about 7–10 days when lead is converted into the basic lead carbonate.

3. *Chamber Process.* This process has been developed in recent years. Here sheets of lead are suspended horizontally in large chambers into which carbon dioxide and acetic acid vapours are introduced. The reactions take place as in the above processes and are completed in about 7–10 weeks when the basic carbonate is found deposited on the lead sheets.

White lead mixed with linseed oil is used as white paint. It has a large covering power. But it has one serious drawback that it gets blackened if there is hydrogen sulphide in the atmosphere. Other substitutes such as *lithopone* ($BaSO_4 + ZnS$) and *sublimed white lead* ($PbSO_4 + PbO + ZnO$) have been suggested.

Sublimed white lead. It is also used as a white pigment. Its approximate composition is $PbSO_4$ 75%, PbO 20% and ZnO 5%. It is prepared by roasting galena (PbS) mixed with a small amount of zinc sulphide, in a strong blast of air. The fumes given out during the process are collected and condensed in a separate chamber. The sublimate is the *sublimed white lead.* It has a good covering power and is not so readily darkened by hydrogen sulphide.

Red Lead, Pb_3O_4. It is prepared by heating lead monoxide to 473–480°C in air for a long time.

$$6PbO + O_2 \longrightarrow 2Pb_3O_4$$

Red lead is a brilliant red powder. On heating it becomes violet and finally black. However, on cooling, the original red colour is restored.

Organometallic Compounds of Group 14 Elements. These have been discussed in Chapter 34 on Organometallic Compounds.

QUESTIONS

1. (*a*) Name the elements of Group 14 of the periodic table.
   (*b*) Discuss the variation in properties of Group 14 elements with reference to
   (*i*) Oxidation state (*ii*) Catenation (*iii*) Electronegativity (*iv*) Metallic character.
2. (*a*) What is catenation ? Explain the uniqueness of carbon to catenate. How does the catenation tendency vary in Group 14 elements and why ?
   (*b*) Why is CO_2 a gas and SiO_2 a highly stable solid ?
   (*c*) Describe the structures of CO and CO_2 molecules.

3. (*a*) What are carbides ? How do we classify them ?
   (*b*) Discuss the structure of silicon carbide. Give its important uses in industry.
4. Explain the following :
   (*a*) Acidic character of dioxides of Group 14 elements decreases as we move down the group.
   (*b*) Diamond is a non-conductor while graphite is a good conductor of electricity.
   (*c*) CCl_4 resists hydrolysis while $SiCl_4$ gets readily hydrolysed.
   (*d*) Pb^{4+} compounds are oxidising agents.
5. Discuss the preparation, properties and uses of permono and perdicarbonates.
6. How are perdicarbonates of sodium and potassium prepared ? Illustrate the oxidising character of these compounds.
7. (*a*) What are silicates ? Draw the structures of four different types of silicates and give the name and formula of one example of each type.
   (*b*) Write a short note on silicones.
   (*c*) Why does silicon have less tendency to get bonded to itself than does carbon ?
8. (*a*) Discuss the structure of $(SiO_4)^{4-}$ ion. "All silicates contain the $(SiO_4)^{4-}$ units. They differ only in the manner in which these units are linked together." Justify this statement.
   (*b*) Compare and contrast one significant feature of : (*i*) CO_2 and SiO_2 (*ii*) CCl_4 and $SiCl_4$
9. What are metal cyanides ? How are they classified ? Give the preparation, properties and structures of ionic cyanides, covalent cyanides and complex cyanides.
10. What are metal carbonyls ? Discuss the methods of preparation, properties and structures of some typical metal carbonyls.
11. Discuss the methods of preparation, properties and uses of carbon disulphide.
12. What are intercalation compounds ? Describe in details the intercalation compounds of graphite
    (*i*) with alkali metals (*ii*) with oxoacids (*iii*) with metal halides and (*iv*) with halogens
    What are the typical characteristics of these compounds ?
13. Discuss in details the structure of intercalation compounds of graphte with potassuim metal.
14. What are silicones ? Describe their structures. Give a brief account of their applications in technology.
15. How is calcium carbide manufactured. Discuss its important reactions and structure.
16. How is white lead prepared ? Describe the reactions involved in its preparation from lead.

17 THE ELEMENTS OF GROUP 15

Group 15 contains five elements, namely, **nitrogen, phosphorus, arsenic, antimony** and **bismuth**, and after the first element of the group, they are known as the **nitrogen family.** These elements, except phosphorus, do not occur very abundantly in nature. Nitrogen constitutes only about 0·0045 per cent, phosphorus 0·116 per cent, arsenic 5×10^{-4} per cent, antimony 1×10^{-4} per cent and bismuth $1{\cdot}8\times10^{-5}$ per cent, of the igneous rocks of the earth. Phosphorus is the only abundant element of the group which, in fact, ranks tenth in abundance amongst all the elements. Nitrogen is a very well known element. It constitutes nearly 78 per cent by volume of the atmosphere and is an essential constituent of fertilizers, explosives and food stuffs (proteins). Phosphorus is important because of its occurrence in phosphate rocks which can be converted into phosphatic fertilizers and also because it can form a number of alloys and finds many other uses. Arsenic, antimony and bismuth occur mostly as sulphide ores.

Electronic Configurations. The electronic configurations of these elements are presented in Table 1.

TABLE 1

Electronic Configurations of Elements of Group 15

Element	Atomic number	Electronic Configuration
Nitrogen, N	7	[He] $2s^2p^3$
Phosphorus, P	15	[Ne] $3s^2p^3$
Arsenic, As	33	[Ar] $3d^{10}\,4s^2p^3$
Antimony, Sb	51	[Kr] $4d^{10}\,5s^2p^3$
Bismuth, Bi	83	[Xe] $4f^{14}\,5d^{10}\,6s^2p^3$

As can be seen, the general outer electronic configuration of the elements of Group 15 may be written as $\mathbf{ns^2p^3}$. The three *p* electrons are equally distributed, in each case, among the three *p* orbitals as p_x^1, p_y^1 and p_z^1, in accordance with the Hund's rule. In other words, the *p* orbitals in the outer shells are only half-filled. Since electronic configurations involving fully filled or exactly half-filled orbitals are the most stable, the elements of Group 15, having exactly half-filled *p* orbitals, are also fairly stable and not so reactive (*e.g.*, nitrogen behaves as an almost inert element).

GENERAL CHARACTERISTICS OF GROUP 15 ELEMENTS

Some important physical properties of Group 15 elements are summed up in Table 2.

TABLE 2

Important Physical Properties of Elements of Group 15.

Property	Nitrogen	Phosphorus	Arsenic	Antimony	Bismuth
Atomic number	7	15	33	51	83
Atomic mass (a.m.u.)	14·007	30·97	74·92	121·75	208·98
Density in solid state (g cm^{-3})	1·03	1·82	5·73	6·62	9·78
Atomic volume (cm^3)	17·3	17·0	13·1	18·4	21·3
Atomic radius (Å)	0·75	1·06	1·19	1·38	1·46
Ionic radius of trivalent ion (Å)	1·71	2·12	2·22	2·45	1·20
Ionisation energy (kJ mol^{-1})	1402	1012	944	831	703
Oxidation states	−3, +1, +2, +3, +4, +5	−3, +3, +4, +5	−3, +3, +5	−3, +3, +5	+3, +5
Electronegativity (Pauling's values)	3·0	2·2	2·2	2·0	2·0
Melting point (°C)	−210 (white)	44·1 (at 30 atm)	817	630·5	271·3
Boiling point (°C)	−195·8	280 Sublimes	713	1380	1470
Heat of fusion (kJ mol^{-1})	0·36	0·63	27·7	19·9	10·9

1. Metallic and non-metallic character. The change from non-metallic to metallic character with increase in atomic number in the same group, which was exhibited by elements of Group 14, is also exhibited equally well by the elements of Group 15. The first two elements, nitrogen and phosphorus, are distinctly non-metals, the succeeding two elements, arsenic and antimony, are partly non-metals and partly metals while the last element, bismuth, is a metal.

2. Variation in physical state. There is also a gradual transition in physical state of the elements under ordinary conditions. The first element, nitrogen, is a gas which can be converted into a liquid only at a very low temperature. The next element, phosphorus, though a solid, can pass readily into vapour state. The succeeding elements, arsenic, antimony and bismuth, are solids of varying melting and boiling points, the boiling points rising with increase in atomic masses.

3. Atomic volume and atomic radius. Atomic volumes and atomic radii, as expected, increase with increase in atomic number. Arsenic, however, shows an exceptionally low value of atomic volume.

4. Ionisation energy. The ionisation energy of nitrogen, the first element, is very high, being 1402 kJ mol^{-1}. The values for the succeeding elements decrease systematically from 1012 to 703 kJ mol^{-1} on moving down the group, as is the case in Groups 1 and 2.

5. Melting points and boiling points. The melting points (except for antimony and bismuth) and boiling points increase with increase in atomic number, *i.e.*, as we move down the group from nitrogen to bismuth. The melting point of bismuth is unusually low.

6. Electronegativity. Electronegativity decreases gradually as we move down the group indicating a gradual change from non-metallic to metallic character.

7. Chemical bonding. It is evident from the electronic configurations given in Table 1, that the outer shell is short of three electrons in each element. Since it is not easy, from energy considerations, to gain three electrons to achieve stable configuration, the formation of tri-negative ion (Z^{3-}) is rare. Such an ion is formed only by nitrogen which is the smallest and the most electronegative element of the family. However, covalent compounds of nitrogen are more common. The electronegativities of other elements are so low that they would generally form covalent bonds even with highly electropositive elements. Bismuth compounds, although covalent, do give ionic species in polar solvents like water. This tendency decreases in moving up the group from bismuth through antimony to phosphorus.

8. Positive oxidation states. Since electronegativities decrease as we move down the group towards heavier elements, positive oxidation states are expected to become more frequent on moving down the group. The electronic configuration ns^2p^3 for the outer shell suggests that these elements can have two positive oxidation states, namely, + 3 and + 5. For example, the elements of this group form two types of oxides, M_2O_3 and M_2O_5. The + 3 state becomes more and more common on moving down the group from P to Bi. Nitrogen does not form compounds in +5 state such as NF_5, NCl_5, etc., because it does not have vacant *d* orbitals in its outermost shell which can enable it to extend its octet. Covalency of nitrogen generally is restricted to only three while other members of the group exhibit covalency of five, as in PF_5 and SbF_5. Nitrogen and phosphorus also show oxidation state of +4 because of the ability of one lone pair in NH_3 and PH_3 to form dative bond with Lewis acids. Nitrogen can exist in other oxidation states as well. In combination with oxygen, for example, it is found in +1(N_2O), +2 (NO) and +4(NO_2) oxidation states also.

9. Negative oxidation states. The oxidation state of nitrogen in ammonia (NH_3) is −3. As is evident from the decreasing electronegativities and decreasing ionisation energies, the tendency of the elements to pass into −3 oxidation state decreases on moving down from phosphorus to bismuth. In fact, bismuth, the last member of the group, hardly exhibits negative oxidation state. This shows why the stability of hydrides of these elements decreases as we move down the group.

10. Reluctance of heavier elements to show higher oxidation states. As stated above, the +5 oxidation state becomes less and less common as we move from nitrogen to bismuth. This is due to the fact that heavier elements are reluctant to show higher oxidation states, the reasons for which have already been explained in Chapter 12.

11. Electron-donor properties. All the elements in the tri-positive state (*i.e.*, +3 oxidation state) have a tendency to act as electron pair donors. Nitrogen shows this tendency to the maximum extent.

12. Electron-acceptor properties. Nitrogen does not have *d* orbitals and hence it cannot act as electron-acceptor. Other elements, having vacant *d* orbitals in their valency shells, do act as electron-acceptors.

13. Catenation or self-linkage. Catenation, although, considered to be a property peculiar to carbon, is shown, to some extent, by the elements which lie close to carbon in the periodic table. All the elements of Group 15 show this property but to a much smaller extent than carbon. The decrease in tendency to form chains is mostly due to a decrease in the element-to-element bond energies. The bond energies of C – C, N – N, P – P and As – As bonds are 353·9, 163·1, 200·8 and 146·8 kJ mol^{-1}. It is clear that there is a big drop of bond energy as we move from carbon to the next element nitrogen. The catenation in stable nitrogen compounds is, thus, restricted generally to two or three N atoms as, for example, in N_2H_4, N_3^-, etc. (although very unstable compounds containing chains of upto eight nitrogen atoms have also been synthesised.) Also, as is evident from single bond energies of N – N, P – P and As – As bonds, phosphorus has maximum tendency to catenate amongst Group 15 elements. The extent of catenation in the compounds of Group 15 elements is much less than in the compounds of carbon.

14. Allotropy. All the elements (except bismuth) show allotropy. Thus, two *solid* forms of nitrogen known as α-*nitrogen* with cubic crystalline structure and β-*nitrogen* with hexagonal crystalline structure have been reported. The transition temperature is – 238·5°C. Phosphorus exists in a number of allotropic forms such as *white* phosphorus, *red* phosphorus, *scarlet* phosphorus, metallic or α-*black* phosphorus, β-*black* phosphorus and *violet* phosphorus. Arsenic exists in three allotropic forms, *viz.*,

grey, yellow and *black*. Similarly, antimony exists in three different forms. These are *metallic form, yellow* or *α-antimony* and *black* or *β-antimony*.

15. Chemical reactivity. The various elements differ from one another appreciably in their chemical reactivity. Nitrogen because of its very high dissociation energy (945 kJ mol^{-1}) is practically inert. It combines with oxygen only when heated in an electric arc to a temperature of the order of 2500°C and above to form nitric oxide.

Phosphorus, in one of its allotropic forms known as white phosphorus, on the other hand, is extremely reactive. It burns readily in oxygen forming oxides of phosphorus.

The heavier elements (As, Sb and Bi) burn only when heated in air or oxygen, to form oxides. The difference can be attributed largely to difference in the electronegativities of the five elements. Nitrogen (electronegativity 3) is the most electronegative, the others have values smaller than that of nitrogen, *viz.*, phosphorus 2·2, arsenic 2·2, antimony 2·0 and bismuth 2·0.

16. Combination with metals. All the five elements combine with metals forming compounds in which the elements show normal valency of 3. For example, nitrogen forms **nitrides** (Mg_3N_2), phosphorus forms **phosphides** (Ca_3P_2), arsenic gives **arsenides** (Na_3As), antimony gives **antimonides** (Zn_3Sb_2) and bismuth gives **bismuthides** (Mg_3Bi_2).

Difference between Nitrogen and the rest of the Family Members

As usual, nitrogen, the first element of Group 15, differs considerably from the rest of the family members. These differences can be attributed largely to the following characteristics of nitrogen :

1. Small size 2. High electronegativity and 3. Non-availability of *d* orbitals in valency shell.

The main points of difference are as follows :

1. Nitrogen is a gas while the other members are solids.

2. Nitrogen is diatomic. The two nitrogen atoms are bonded together strongly by sharing of three electron pairs, as shown below :

$$:N\vdots\vdots N: \quad \text{or} \quad N\equiv N$$

Other elements form tetra-atomic molecules such as P_4, As_4 and Sb_4, involving the sharing of only one electron pair between any two atoms of the element concerned.

3. Because of its high electronegativity, nitrogen is distinctly non-metallic while the other two members (As, Sb) are metalloids and bismuth is distinctly a metal.

4. Nitrogen exhibits a large number of oxidation states, such as + 1, + 2, + 3, + 4, +5, – 1, – 2 and – 3 as in N_2O, NO, N_2O_3, N_2O_4, N_2O_5, NH_2OH, N_2H_4 and NH_3, respectively. Other elements do not exhibit such a variety of oxidation states.

5. Except for NF_3, the trihalides of nitrogen (NCl_3, NBr_3, NI_3) are unstable and highly explosive. The trihalides of other elements of this group, on the other hand, are fairly stable. This behaviour of nitrogen can be attributed to its high electronegativity.

6. Hydride of nitrogen (NH_3) is stable. The hydrides of other elements are not stable.

7. The trioxide and pentoxide of nitrogen, N_2O_3 and N_2O_5, are monomeric. The trioxides and pentoxides of other elements, on the other hand, are dimeric (cf. P_2O_6, P_4O_{10}).

8. Nitrogen forms oxides such as N_2O, NO, N_2O_4. No such oxides are formed by other elements.

9. Nitrogen differs markedly from the rest of the elements in its electronic configuration. Its valency shell contains only *s* and *p* orbitals and no *d* orbitals. All other elements of Group 15, on the other hand, have vacant *d* orbitals in their valency shells. Thus, while nitrogen cannot accept any electron pairs, all other elements do. For instance, phosphorus readily forms PCl_5 by accommodating two pairs of electrons from two chlorine atoms in its vacant *d* orbitals. But the corresponding compound of nitrogen, NCl_5, is unknown.

10. Since nitrogen is one of the most electronegative elements (next only to fluorine and oxygen), it extensively enters into hydrogen bond formation in its hydrogen compounds. Other elements, having comparatively low electronegativities, do not form hydrogen bonds.

EXTRACTION OF ELEMENTS OF GROUP 15

Preparation of Nitrogen. Nitrogen is fairly widely distributed in nature both in the free as well as in the combined state. About four-fifths of air is free nitrogen. In the combined state, it occurs mostly as nitrates, *viz.*, $NaNO_3$ (chile saltpeter) and KNO_3 (saltpeter). Coal contains compounds which on distillation yield ammonia which is an important compound of nitrogen. Nitrogen is also an essential constituent of all living cells of animal or vegetable origin where it is present in the form of proteins which contain about 16 per cent of combined nitrogen.

Nitrogen, on laboratory scale, can be obtained by heating ammonium nitrite or ammonium dichromate. It can also be obtained by the action of HNO_2 ($NaNO_2 + H_2SO_4$) or alkali metal hypochlorite (NaOBr) on urea. *Pure nitrogen*, in small amounts, can be obtained by heating sodium or barium azide.

On a **commercial scale**, nitrogen is invariably obtained by liquefying *air* and then carrying out its fractional evaporation. Nitrogen, having a lower boiling point (77·2 K), boils off more readily than the less volatile oxygen (b.p. 90·0 K).

Extraction of Phosphorus. Since phosphorus is an extremely active element, it does not occur free in nature. In the combined form, however, it is widely distributed in nature. It occurs as phosphates in the rocks and in the soil and as phosphoproteins in all living things. The principal minerals containing phosphorus are *phosphorite*, $Ca_3(PO_4)_2$, *apatite*, $3Ca_3(PO_4)_2.CaF_2$ and *chlorapatite*, $3Ca_3(PO_4)_2.CaCl_2$.

Phosphorus is an essential constituent of bones and is also present in the blood, brain and other parts of the body. It is also necessary for the growth of plants. Bone ash (animal charcoal) contains about 80 per cent calcium phosphate.

Phosphorus is manufactured by heating *bone ash* or phosphorite rock [$Ca_3(PO_4)_2$], with sand (SiO_2) and coke (C), in an electric furnace.

$$2Ca_3(PO_4)_2 + 6SiO_2 + 10C \longrightarrow 6CaSiO_3 + 10CO + P_4$$

Extraction of Arsenic. Arsenic occurs rarely in free state. It is found largely in combination with sulphur, oxygen and iron. The important ores are *realgar* (As_2S_2) ; *orpiment* (As_3S_3) and *arseno-pyrites* (FeAsS).

The metal is generally extracted from *arsenopyrites*.

Arsenopyrites on roasting yield the volatile arsenious oxide, As_2O_3, which condenses as a white solid.

$$4FeAsS + 3O_2 \longrightarrow 4FeS + 2As_2O_3$$

Arsenic is obtained by heating arsenious oxide and charcoal together in a crucible.

$$As_2O_3 + 3C \longrightarrow 2As + 3CO$$

Arsenic collects as a sublimate while carbon monoxide escapes.

Extraction of Antimony. Antimony occurs in free state in small amounts only. Its chief source is the sulphide ore, *stibnite*, Sb_2S_3.

The metal can be obtained by heating the sulphide ore with iron.

$$Sb_2S_3 + 3Fe \longrightarrow 2Sb + 3FeS$$

FeS, being lighter, floats over the layer of antimony and can thus be easily separated.

Alternatively, the sulphide ore is first roasted in a free supply of air to convert Sb_2S_3 into Sb_2O_3. The roasted ore is then heated with charcoal in a crucible to reduce it to antimony.

$$2Sb_2S_3 + 9O_2 \longrightarrow 2Sb_2O_3 + 6SO_2$$

$$Sb_2O_3 + 3C \longrightarrow 2Sb + 3CO$$

Extraction of Bismuth. Bismuth occurs in the free state as well as in the combined form. The important sources of the element are *bismuth glance*, Bi_2S_3, *bismuth telluride*, Bi_2Te_3 and the oxide, Bi_2O_3, known as *bismuth ochore*.

Bismuth is isolated by roasting the sulphide ore in a current of air when sulphur burns away as sulphur dioxide and bismuth oxide is formed.

$$2Bi_2S_3 + 9O_2 \longrightarrow 2Bi_2O_3 + 6SO_2$$

The oxide is reduced by heating with carbon.

$$Bi_2O_3 + 3C \longrightarrow 2Bi + 3CO$$

PROPERTIES OF ELEMENTS OF GROUP 15

Properties of Nitrogen. Physical Properties. Nitrogen is a colourless gas without any taste or odour. It does not support combustion or respiration but, unlike carbon dioxide, it is not poisonous. It is only sparingly soluble in water, 1 litre of water dissolving only 23 ml of the gas at N.T.P. Liquid nitrogen is colourless and boils at –195·8°C. On rapid evaporation, the liquid nitrogen changes into an ice-like solid melting at –209·9°C. At –238·5°C, it changes into another solid form.

Naturally occurring nitrogen consists of two isotopes ^{14}N and ^{15}N with an approximate ratio $^{14}N : {}^{15}N = 272{\cdot}0$. The isotope ^{15}N is often used as a radioactive tracer.

Chemical Properties. Nitrogen is an inert diatomic gas having a triple bond electronic structure, *viz.*,

$$:N\vdots\vdots N: \quad \text{or} \quad N{\equiv}N$$

The internuclear distance is 1·095 Å.

The heat of dissociation of nitrogen is extremely large, being 945 kJ per mole.

$$N_2\,(g) \rightleftharpoons 2N\,(g)\ ; \qquad \Delta H = +945 \text{ kJ}$$

The dissociation constant is extremely small and even at 3000°C there is no appreciable dissociation. This speaks for a very great strength of the N ≡ N bond which is principally responsible for the chemical inactivity of free nitrogen.

Important reactions of nitrogen are given below.

1. Combination with highly electropositive metals. Nitrogen readily combines with highly electropositive metals (metals of Group 1), even at room temperature, to give nitrides. For example,

$$6Li + N_2 \longrightarrow 2Li_3N$$

These nitrides are *ionic compounds* in which nitrogen is present as a trinegative anion, N^{3-}. Thus, lithium nitride may be represented as $Li_3^+N^{3-}$.

These nitrides are crystalline compounds and have high melting points.

2. Combination with less electropositive metals. Nitrogen combines with less electropositive metals like magnesium, calcium, strontium and barium at *red heat* ; with boron and aluminium at *bright red heat* and with silicon at *white heat*, to form the corresponding nitrides.

The nitrides formed with metals of Group 2 are generally *ionic* while those formed with elements of Groups 13 and 14 are *covalent* in character.

The nitrides formed with transition metals, such as iron, manganese, molybdenum, tungsten, are true *interstitial compounds* with nitrogen atoms occupying the interstices in the metal structures. These nitrides are extremely hard, have high melting points, possess metallic lustre and metallic conductivity.

3. Combination with hydrogen. Nitrogen combines with hydrogen to give ammonia (Haber process).

$$N_2 + 3H_2 \rightleftharpoons 2NH_3\ ; \qquad \Delta H = -92{\cdot}0 \text{ kJ}$$

The reaction is carried out in the catalytic presence of finely divided iron containing a little molybdenum, at a pressure of 100—1000 atm and temperature of 400 – 550°C.

4. Combination with oxygen. Nitrogen combines with oxygen to give nitric oxide.

$$N_2 + O_2 \rightleftharpoons 2NO\ ; \qquad \Delta H = +180{\cdot}7 \text{ kJ}$$

The reaction is highly endothermic and takes place at elevated temperatures (about 3000°C) ; even then the yield of nitric oxide is not more than 5 per cent by volume.

5. Combination with calcium carbide. Nitrogen combines with calcium carbide to form calcium cyanamide.

$$CaC_2 + N_2 \longrightarrow CaNCN + C$$

The reaction takes place by heating calcium carbide to about 1000°C in a current of nitrogen.

6. Catenation. As already mentioned, nitrogen shows some tendency for catenation, although this tendency is very weak as compared to carbon. Thus, the following compounds of nitrogen containing chains of three or more nitrogen atoms have been reported :

$$R-N=N-NR_2,\ R_2N-N=N-NR_2,\ RN=N-N(R)-N=NR$$

$$RN=N-N(R)-N=N(R)-N=NR$$

R represents some organic alkyl or aryl radical. In some compounds, R may also stand for H. Some cyclic compounds containing rings with upto five consecutive nitrogen atoms have also been reported.

However, these compounds are not very stable. This is because the bond energies of N– N and N = N bonds are quite low.

7. Hydrogen bonding. Since nitrogen is one of the most electronegative elements, next only to fluorine and oxygen, it readily enters into hydrogen bond formation in its hydrogen compounds.

Active Nitrogen. Active nitrogen is produced by the action of an electric discharge upon nitrogen gas at low pressures. The process is accompanied by a yellow glow which persists for several hours and indicates *slow release of energy* in the process.

Active nitrogen, as the name implies, is *highly reactive* chemically. It reacts with liquid mercury and with vapours of sodium, arsenic, phosphorus, etc., giving nitrides.

The exact nature of active nitrogen has not been fully understood. There is some evidence to show that it contains some nitrogen in the atomic state.

The active nitrogen gets deactivated on collision with the walls of the vessel. This process is accompanied by release of energy and accounts for the yellow after-glow.

Properties of Phosphorus. Allotropy. Phosphorus exhibits allotropy. It exists in a number of allotropic forms such as white phosphorus, red phosphorus, scarlet phosphorus, metallic or α-black phosphorus, β-black phosphorus, violet phosphorus, etc. The main allotropic forms, however, are white, red and black phosphorus.

White Phosphorus. *White phosphorus is obtained by rapidly cooling the vapours of phosphorus.* When pure, it is a transluscent waxy solid. *White phosphorus is readily soluble in carbon disulphide* and evaporation of the solution yields octahedral crystals of phosphorus. Below 800°C, the vapour density corresponds to the formula P_4. Above 800°C, P_4 dissociates into P_2. At 1700°C, its formula is P_2. White phosphorus melts at 44·1°C and boils at 280°C.

Its ignition temperature is very low (~ 30°C). When exposed to air it undergoes oxidation which

gradually raises its temperature and ultimately it catches fire when the temperature exceeds 30°C. For this reason it is always kept under water.

It glows in the dark on account of its slow oxidation. This phenomenon is known as *phosphorescence*. During oxidation, it gives a smell like that of garlic.

White phosphorus is extremely poisonous. A dose of 0·15 g or even less, proves fatal. The vapours of phosphorus, if continuously inhaled, cause *necrosis* of the bones particularly those of the jaws and nose. In *very small doses, however, phosphorus acts as a stimulent.*

White phosphorus is readily soluble in turpentine oil and ether.

Phosphorus molecule is now known to have the formula P_4. The four phosphorus atoms lie at the corners of a regular tetrahedron, as shown in Fig. 1. Each phosphorus atom is linked to each of the other three atoms by covalent bonds so that each atom completes its valency shell.

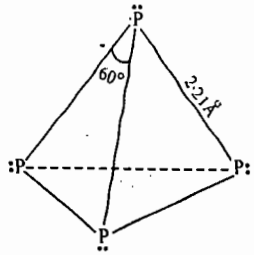


Fig. 1. Tetrahedral phosphorus molecule.

Red Phosphorus. It is a violet red powder consisting, in part, of small crystals and some amorphous variety. It is prepared by heating white phosphorus at 253°C in a cast iron egg-shaped vessel in which *air is replaced* by carbon dioxide gas or coal gas. The red phosphorus obtained may contain some white phosphorus which must be eliminated for obvious reasons. This is done by boiling it with sodium hydroxide solution when any unconverted white phosphorus goes off as phosphine.

$$P_4 + 3NaOH + 3H_2O \longrightarrow PH_3\uparrow + 3NaH_2PO_2$$

Red phosphorus is not attacked by sodium hydroxide. It is then washed repeatedly with hot water and dried.

Red phosphorus differs markedly from white phosphorus. It is stable under ordinary conditions. It does not ignite spontaneously in air and is not poisonous. It sublimes on heating giving vapours which are the same as given by white phosphorus. When the vapours are condensed, white phosphorus results. This gives an easy method of reconverting red phosphorus into white phosphorus.

Red phosphorus, which was once thought to be amorphous, is now known to have minute crystalline structure. It has an iron-grey lustre. It does not show phosphorescence.

Red phosphorus melts at about 610°C under pressure giving a yellow liquid which on cooling gives white phosphorus. It dissolves in alcoholic potash giving a deep red solution from which red phosphorus can be reprecipitated by acidifying the solution. It is insoluble in carbon disulphide and other organic solvents.

Red phosphorus does not melt at a definite temperature. Its density is also variable. Because of this reason, red phosphorus is not regarded as a definite allotropic form of phosphorus. It is thought to be a solid solution of scarlet phosphorus in metallic (α-black) phosphorus. The exact nature of red phosphorus, however, is uncertain.

Metallic or α-Black Phosphorus. This variety is obtained by dissolving red phosphorus in molten lead at 400°C in a sealed tube for sufficiently long time. On cooling, crystals of black phosphorus are obtained. Lead is dissolved out by treatment with dilute nitric acid.

It is a very stable allotrope of phosphorus and does not oxidise in air unless heated very strongly. It does not conduct electricity.

β-Black Phosphorus. It is obtained by heating white phosphorus at 2000°C under a very high pressure of about 4000 atm. It may also be obtained by heating white phosphorus at 220 – 370°C for 8 days in the presence of mercury which acts as a catalyst.

This is the only form of phosphorus whose structure is definitely known. It is crystalline in nature and consists of corrugated sheets, each phosphorus atom being covalently bonded to the three neighbouring

phosphorus atoms, as shown in Fig. 2. The P – P – P angles are of 99°. The P – P distance between two nearest phosphorus atoms is 2·18 Å.

The adjacent layers are 3·68 Å apart. The atoms within a layer are more strongly bound than the atoms in adjacent layers. This gives rise to flaky crystals resembling those of graphite.

It has a definite sharp melting point of 587°C. Its specific gravity is 2·69.

It is also a stable form of phosphorus and does not burn in air even up to 400°C. Like graphite, it is also a fairly good conductor of electricity.

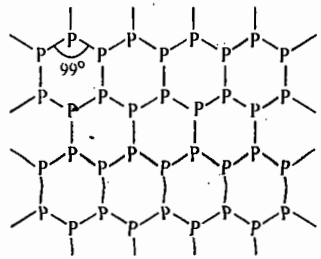

Fig. 2. Layer structure of β-black phosphorus.

Scarlet Phosphorus. This allotrope is obtained in the form of an amorphous scarlet powder by boiling a 10 per cent solution of phosphorus in phosphorus tribromide for about 10 hours. Pure scarlet phosphorus may be prepared by heating phosphorus tribromide with mercury at 240°C.

$$2PBr_3 + 3Hg \longrightarrow 3HgBr_2 + \underset{\text{Scarlet phosphorus}}{2P}$$

Scarlet phosphorus resembles the red variety in its physical properties and the white phosphorus in its chemical properties. It is, however, only slowly oxidised in air.

Violet Phosphorus. This variety is obtained by heating white phosphorus with a trace of sodium at 230°C under high pressure. It is crystalline in structure.

Chemical Properties. Phosphorus is an active element and combines directly with oxygen, sulphur, the halogens, etc. It also combines with a number of metallic elements. White phosphorus is more reactive than the other varieties. This is in accordance with the general principle that the unstable form of any compound or element is more reactive than the stable form. White phosphorus, as expected, has also a higher vapour pressure and is more soluble in various solvents.

Chemical Properties. Some important chemical properties of phosphorus are discussed below.

1. Combustion. Phosphorus burns in air forming phosphorus trioxide and pentoxide.

2. Phosphorescence. White phosphorus undergoes *spontaneous* slow oxidation in air giving a greenish glow which is visible in the dark. This phenomenon is known as *phosphorescence*. The main product of this slow oxidation is phosphorus trioxide.

3. Reaction with caustic alkalies. White phosphorus reacts with hot solution of caustic soda or caustic potash giving phosphine.

$$P_4 + 3NaOH + 3H_2O \longrightarrow 3NaH_2PO_2 + PH_3$$

Red phosphorus does not react with caustic alkalies. This property is made use of in separating red phosphorus from the white variety.

4. Reaction with the halogens. Phosphorus reacts with the halogens forming first the trihalides and then the pentahalides. White phosphorus reacts more vigorously than the red phosphorus. For instance, white phosphorus *spontaneously* catches fire in chlorine forming phosphorus trichloride and pentachloride while the red phosphorus catches fire in chlorine only on heating.

5. Reaction with sulphur. Phosphorus combines with sulphur with explosive violence forming a number of sulphides such as P_2S_3, P_2S_5, P_4S_3 and P_4S_7.

6. Reaction with metals. Phosphorus combines with a number of metals forming phosphides. For example,

$$6Mg + P_4 \longrightarrow 2Mg_3P_2$$

$$6Ca + P_4 \longrightarrow 2Ca_3P_2$$

Sodium and potassium react vigorously accompanying a bright flash.

7. Reducing properties. Since white phosphorus can be easily oxidised, it acts as a strong reducing agent. It reduces nitric acid to nitrogen dioxide and sulphuric acid to sulphur dioxide. It reduces solutions of copper, silver and gold salts to the corresponding metals. For example,

$$P_4 + 8CuSO_4 + 14H_2O \longrightarrow 8Cu + 8H_2SO_4 + 2H_3PO_4 + 2H_3PO_3$$

Thus, a colloidal solution of gold may be prepared by reducing a solution of gold chloride with phosphorus dissolved in ether.

Uses of Phosphorus. 1. It is mostly used in the manufacture of matches. Red variety is preferred to yellow variety owing to its non-poisonous nature. 2. It is used as a rat poison. 3. It is used in making *phosphorus bronze* which is hard, tenacious and not corroded by water. 4. It is used in the manufacture of tracer bullets, incendiary bombs and for producing smoke screens. 5. It is also employed in the preparation of compounds like phosphorus chlorides, phosphoric acids and hypophosphites used in industry and in medicine.

Properties of Arsenic. Physical Properties. Arsenic exists in three allotropic forms ; *grey, yellow* and *black.*

Grey Arsenic. It is a metallic looking brittle solid of density 5·73 g cm^{-3}. It is a feeble conductor of electricity though a good conductor of heat. It sublimes, without melting, at 613°C under atmospheric pressure giving yellow vapours. If heated under pressure it melts at about 500°C.

Yellow Arsenic. It is obtained by rapid cooling of arsenic vapour in carbon disulphide. It is a wax-like solid of much lower density (3·98 g cm^{-3}) than grey arsenic. It is soluble in carbon disulphide. It is readily oxidised causing luminescence, like white phosphorus. On warming gently it reverts to grey arsenic which is the most stable variety. It is non-metallic in nature, has no metallic lustre, is a very poor conductor of electricity and is readily volatile. It is poisonous.

Black Arsenic. Sometimes, during the conversion of yellow into grey arsenic by warming, as mentioned above, black arsenic is formed as an intermediate product. It is also obtained as a deposit when arsine, AsH_3, is passed through a heated tube. It has a density of 4·6 g cm^{-3}. It is a poor conductor of electricity.

Metalloidal Character of Arsenic. *Elements which resemble metals as well as non-metals are called* ***metalloids.*** Like most non-metals, arsenic is non-malleable and exists in three allotropic forms. It forms the hybride AsH_3, which is similar to ammonia, NH_3 and phosphine, PH_3. It gives chlorides which are easily hydrolysed. It reacts with nitric acid to form oxo-acids, as does phosphorus.

Its oxides are amphoteric being soluble in strong acids as well as in strong alkalies. This again shows its dual character because typical non-metals form only acidic oxides while typical metals form only basic oxides.

Arsenic also resembles metals in certain respects. For example, it is a conductor (though feeble) of electricity, forms a number of important alloys with metals and the stable allotropic form (grey arsenic) has a characteristic metallic luster. It is also brittle and has a fairly high density like most metals.

Chemical Properties. Arsenic is comparatively an inert substance at ordinary temperatures. It burns in air with a bluish flame forming white clouds of arsenious oxide, As_2O_3.

It combines readily with chlorine and sulphur forming arsenic chloride and arsenic sulphide, respectively.

It is not attacked by dilute hydrochloric acid or dilute sulphuric acid. Dilute nitric acid has no action at ordinary temperatures but on heating, it oxidises arsenic into arsenious acid.

$$As + HNO_3 + H_2O \longrightarrow H_3AsO_3 + NO$$

Hot concentrated sulphuric acid also oxidises arsenic to arsenious acid.

$$2As + 3H_2SO_4 \longrightarrow 2H_3AsO_3 + 3SO_2$$

Concentrated nitric acid oxidises arsenic to arsenic acid, H_3AsO_4.

$$2As + 10HNO_3 \longrightarrow 2H_3AsO_4 + 10NO_2 + 2H_2O$$

When fused with alkalies, arsenic forms arsenites.

$$2As + 6NaOH \longrightarrow 2Na_3AsO_3 + 3H_2$$

Uses. Arsenic forms alloys with many metals. The addition of 0·5 per cent of arsenic to lead lowers the melting point of the latter. The alloy is harder than lead and is used in making lead shots which are more spherical than shots made with other materials. Compounds of arsenic are used for killing weeds and also in medicine.

Tests for Arsenic when Present in Traces. On account of toxic nature of arsenic, it is often necessary to detect its presence even in very small quantities, in a number of compounds. Further, arsenic is fatal even when administered in extremely small doses. Therefore, in cases of deaths under suspicious circumstances, it becomes necessary to test for compounds of arsenic, generally arsenic oxide, in the tissues of the human body. Any of the following tests may be applied for the purpose.

1. Marsh Test. A flask for the production of pure hydrogen is set up. It contains zinc and dilute sulphuric acid (or hydrochloric acid) both of which must be free from arsenic. The gas is made to pass through a horizontal side tube containing lead acetate to remove hydrogen sulphide, if any, and fused calcium chloride to remove moisture. When all the air has been completely expelled from the apparatus, the horizontal tube is heated at its middle for about 20 minutes. If no black stain is produced, the absence of As_2O_3 in the material used for the generation of hydrogen is proved.

The substance to be tested is suitably brought into solution which is introduced into the flask through a thistle tube. The horizontal tube is heated again as before. If As_2O_3 is present, a black mirror, just a little beyond the heated portion, will deposit. Further, if a flame is brought near the exit, hydrogen, resulting from the decomposition of arsine, will burn.

The reactions involved may be represented as follows :

$$Zn + H_2SO_4 \longrightarrow ZnSO_4 + 2H$$

$$As_2O_3 + 12H \longrightarrow 2AsH_3 + 3H_2O$$

$$2AsH_3 \longrightarrow 2As + 3H_2$$

The concentration of arsenic may be estimated by comparing the intensity of the black stain with a standard stain produced from a known amount of arsenic.

Antimony also gives a similar black deposit under these conditions. However, the two deposits can be distinguished from one another since, while arsenic mirror is soluble in sodium hypochlorite, antimony mirror is not.

2. Gutzeit test. In Gutzeit test, arsenic oxide is converted into arsine by bringing it in contact with zinc and dilute sulphuric acid, as in Marsh test. The gas is then allowed to come into contact with a filter paper moistened with a solution of silver nitrate when metallic silver deposits as a black stain.

$$AsH_3 + 6AgNO_3 + 3H_2O \longrightarrow 6Ag + 6HNO_3 + H_3AsO_3$$

This test is not given by antimony compounds and, therefore, serves to distinguish between arsenic and antimony compounds.

Properties of Antimony. Physical Properties. Like phosphorus and arsenic, antimony exists in different allotropic forms. These are *metallic form, yellow* or *α-antimony and black or β-antimony.*

Metallic Form. This is the common variety of antimony. It has a silvery-white lustre. It is brittle and has specific gravity 6·7. It deposits large rhombohedral crystals when the fused metal is allowed to cool gradually. It shows stronger metallic character than arsenic. However, it is a poor conductor of heat and electricity, like arsenic. It melts at 630·5°C in an atmosphere of carbon monoxide and boils at 1380°C.

Yellow or α-Antimony. This is obtained by the action of ozonised oxygen on liquid stibine at – 90°C.

$$4SbH_3 + 3O_2 \longrightarrow 4Sb + 6H_2O$$

It is unstable and changes readily into the black or β-antimony. It can exist only at low temperatures. It is slightly soluble in carbon disulphide.

Black or β-Antimony. It is an amorphous black powder and is quite stable and reverts only gradually to the metallic form. It is regarded as an intermediate form between the α and metallic forms. It is formed directly by rapidly cooling antimony vapour. On warming, it reverts rapidly to metallic form.

Chemical Properties. 1. Antimony is not attacked by air if it is dry but gets slowly oxidised and tarnished in moist air. When heated in air or oxygen, it burns with a blue flame and forms antimony trioxide, Sb_2O_3 and antimony tetroxide, Sb_2O_4.

2. It is not attacked by water but it decomposes steam at red heat.

$$2Sb + 3H_2O \xrightarrow[\text{(Steam)}]{\text{Red heat}} Sb_2O_3 + 3H_2$$

3. It burns in chlorine forming antimony trichloride, $SbCl_3$. Prolonged treatment gives $SbCl_5$.

With bromine and iodine, only trihalides $SbBr_3$ and SbI_3 are formed.

4. It also combines readily with sulphur and phosphorus forming sulphide and phosphide, respectively.

5. It is not attacked by dilute acids. It is, however, attacked by concentrated hydrochloric acid liberating hydrogen. It is attacked by hot concentrated sulphuric acid giving sulphur dioxide.

With concentrated nitric acid it gets oxidised to meta antimonic acid, $HSbO_3$.

$$2Sb + 10HNO_3 \longrightarrow 2HSbO_3 + 10NO_2 + 4H_2O$$

Uses of Antimony. The main use of antimony is in the making of different alloys. About half of the world's production of antimony is used in the manufacture of lead storage batteries because lead containing a small amount of antimony is harder and more resistant to the action of acids than ordinary lead. It is used for colouring pottery, cloth and paper. Its oxochlorides are used as modrants. Oxides of antimony are used in glass-making. Antimony sulphide is used in the vulcanisation of rubber.

The important alloys of antimony are *type metal, pewter, britannia metal* and *babbit's metal*. Type metal, containing 82 per cent lead and 15 per cent antimony, has low melting point and expands on solidification and, therefore, is highly useful in casting.

Properties of Bismuth. Physical Properties. Bismuth, unlike arsenic and antimony, does not exist in allotropic forms. It has distinct metallic lustre (silvery white with a reddish tinge). It is brittle and has density equal to 9·8 g cm^{-3}. It has a low melting point (271·3°C). It boils at 1470°C. The molten metal expands slightly on passing into solid state. It conducts electricity fairly well, like metals.

Chemical Properties. 1. Bismuth, like antimony, is not attacked by air at ordinary temperatures and does not tarnish. When heated it burns in air to form bismuth trioxide, Bi_2O_3.

2. It combines with chlorine forming bismuth trichloride, $BiCl_3$.

3. Bismuth, like antimony, is not attacked by dilute hydrochloric acid. However, it dissolves in dilute nitric acid forming bismuth nitrate, $Bi(NO_3)_3$. It is not attacked by dilute sulphuric acid. But hot concentrated sulphuric acid attacks the metal giving sulphur dioxide.

Uses. Bismuth is used largely for making alloys having low melting points. Some of these alloys melt even below 100°C and are called **fusible alloys.** The examples of these alloys are :

1. *Woods metal* which melts at 60·4°C and consists of Bi 50%, Pb 25%, Sn 12·5% and Cd 12·5%.
2. *Rose metal* which melts at 93·75°C and consists of Bi 50%, Pb 27%, and Sn 23%.
3. *Lipowitz* which melts at 60°C and consists of Bi 50%, Pb 27%, Sn 13% and Cd 10%.

These alloys are used mainly in making automatic electrical fuses, automatic fire alarms, automatic sprinklers, automatic safety plugs of boilers, etc.

COMPOUNDS OF GROUP 15 ELEMENTS

I. A Comparative Study

1. Hydrides

All the elements of this group form volatile trihydrides of the formula MH_3, *viz.*, NH_3 (ammonia), PH_3 (phosphine), AsH_3 (arsine), SbH_3 (stibine) and BiH_3 (bismuthine). The lighter elements also form hydrides of the formula M_2H_4, *viz.*, N_2H_4 (hydrazine), P_2H_4 (diphosphine) and As_2H_4 (diarsine). Nitrogen forms hydride of the formula HN_3 as well. This is called hydrazoic acid.

The most important hydrides of elements of Group 15 are the trihydrides. A comparative study of trihydrides of Group 15 elements is given below.

Trihydrides of Group 15 Elements. Preparation. The trihydrides of Group 15 elements are prepared from binary metal compounds such as Mg_3N_2, Ca_3P_2, Zn_3As_2, Mg_3Sb_2, Mg_3Bi_2, by the action of water or dilute acids. For example,

$$Mg_3N_2 + 6H_2O \longrightarrow 3Mg(OH)_2 + 2NH_3$$
$$Mg_3N_2 + 6HCl \longrightarrow 3MgCl_2 + 2NH_3$$
$$Ca_3P_2 + 6H_2O \longrightarrow 3Ca(OH)_2 + 2PH_3$$
$$Zn_3As_2 + 6HCl \longrightarrow 3ZnCl_2 + 2AsH_3$$

They can also be prepared by the reduction of trichlorides of these elements, MCl_3, with $LiAlH_4$.

$$MCl_3 + 3LiAlH_4 \longrightarrow MH_3 + 3LiCl + 2AlH_3$$
(M = N, P, As, Sb)

The most important trihydride, *viz.*, **ammonia,** NH_3, which is extensively used in the manufacture of HNO_3 and important chemical fertilizers such as ammonium sulphate, urea, calcium ammonium nitrate, ammonium-calcium phosphate, is prepared on an *industrial scale* by the **Haber process.** It involves the direct combination of nitrogen and hydrogen according to the equation

$$N_2 + 3H_2 \rightleftharpoons 2NH_3 ; \qquad \Delta H = -92{\cdot}0 \text{ kJ}$$

The reaction is reversible, exothermic and proceeds forward with a tremendous decrease in volume. Hence, according to Le Chatelier's principle, *low temperature* and *high pressure* will be favourable for a better yield of ammonia. In actual practice, the reaction is allowed to take place at 450 – 550°C under a pressure of 100 – 1000 atm.

In order to accelerate the reaction at this low range of temperature, a catalyst is required. The best catalyst known is *highly porous finely divided iron* containing small amounts of *promoters* usually molybdenum or oxides of potassium and aluminium. The yield of ammonia varies from about 10 to 40 per cent depending upon the pressure. A mixture of N_2 and H_2 is now-a-days obtained by *partial oxidation* of hydrocarbons (derived from naphtha, natural gas or coal gas) by oxygen-enriched air in the

presence of a catalyst (nickel supported on magnesite).

$$\text{Hydrocarbon} + O_2 + \underbrace{O_2 + N_2}_{\text{Air}} \xrightarrow{\text{Catalyst}} xCO + \underbrace{yH_2 + N_2}$$

Carbon monoxide is eliminated by the usual methods.

The trihydride **PH_3** is generally prepared by boiling white phosphorus with a concentrated solution of sodium hydroxide in an inert atmosphere of carbon dioxide, oil gas or hydrogen.

$$P_4 + 3NaOH + 3H_2O \longrightarrow 3NaH_2PO_2 + PH_3$$

The trihydrides **AsH_3** and **SbH_3** are prepared by the reduction of compounds of arsenic and antimony by nascent hydrogen generated by the action of sulphuric acid on zinc. Thus,

$$As_2O_3 + 12H \longrightarrow 2AsH_3 + 3H_2O$$

$$AsCl_3 + 6H \longrightarrow AsH_3 + 3HCl$$

$$SbCl_3 + 6H \longrightarrow SbH_3 + 3HCl$$

The trihydride **BiH_3** is extremely unstable and decomposes readily even at ordinary temperatures into Bi and H_2. The hydride BiH_3, therefore, is difficult to prepare.

Structure. The trihydrides have **pyramidal structure**, as illustrated in the case of ammonia in Fig. 3. In this case, nitrogen orbitals undergo sp^3 hybridisation.

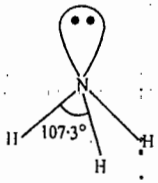

Fig. 3. Pyramidal structure of NH_3 molecule.

Three of the four sp^3 hybrid orbitals are used in forming three N – H bonds while the fourth is occupied by a lone pair of electrons. Due to larger lone pair–bond pair repulsion than bond pair–bond pair repulsion, the molecule gets a little distorted and the bond angle H – N – H decreases from 109·5° (normal tetrahedral angle) to 107·3°. The other hydrides also have pyramidal structure but the bond angle decreases as we go down the group, as shown below.

NH_3	PH_3	AsH_3	SbH_3
107·3°	93·6°	91·8°	91·3°

The variation in bond angle may be explained on the basis of the size and electronegativity of the central atom. As we move down the group, the size of the central atom goes on increasing and its electronegativity goes on decreasing. As a result, the location of the bond pairs of electrons shifts more and more away from the central atom as we go from NH_3 to SbH_3. Consequently, the bonded pairs of electrons will move away from each other to greatest extent in NH_3 and least extent in SbH_3. Therefore, the bond angle is maximum in NH_3 and minimum in SbH_3.

Properties. 1. Boiling points. The boiling points of the trihydrides of Group 15 elements are given below.

NH_3	PH_3	AsH_3	SbH_3	BiH_3
–34·5°C	–87·5°C	–62·4°C	–18·4°C	+16·8°C

Except for ammonia, the boiling point increases as we move down the group. The abnormally high boiling point of ammonia is due to the association of its molecules through hydrogen bonding.

2. Basic character. All the trihydrides have one lone pair of electrons on the central atom and, therefore, they behave as Lewis bases. On going down the group, the basic character of these hydrides decreases. For example, NH_3 is distinctly basic and forms salts with acids both weak and strong [*e.g.*, NH_4Cl, $(NH_4)_2CO_3$]. PH_3 is also a base but very much weaker than NH_3 The hydrides of As, Sb and Bi have no basic character at all. The decrease in basic character of the hydrides is due to the decrease in the availability of the lone pair of electrons as we go down the group. The size of the central atom

increases as move from N to Bi. As a result, the electron charge cloud of the lone pair diffuses over larger volume and, therefore, the electron charge donor capacity (*i.e.*, basic strength) of the elements decreases as we go down the group.

3. Thermal stability. The thermal stability of the trihydrides of Group 15 elements decreases as we move from NH_3 to BiH_3. Thus, while ammonia (NH_3) is most stable, phosphine (PH_3), arsine (AsH_3), stibine (SbH_3) and bismuthine (BiH_3) are progressively less stable. Bismuthine, the last hydride, is extremely unstable and has a fleeting existence with a half-life period of only 20 minutes under ordinary conditions.

As we go down the group, the size of the central atom increases and, therefore, its tendency to form stable covalent bond with comparatively small hydrogen atom decreases. Consequently, the strength of M – H bond and hence the thermal stability goes on decreasing as we move from NH_3 to BiH_3. The largest atom, bismuth, forms least stable bond with hydrogen so that the hydride formed (BiH_3) is so unstable that it cannot be kept above – 45°C.

4. Reducing character. With progressive decrease in stability, the reducing character of the trihydrides increases as we move down the group. Thus, while ammonia, being stable, is not a good reducing agent, the other hydrides, being unstable, act as good reducing agents.

5. Formation of complexes. Aqueous ammonia forms stable complex ions with many cations notably of transition metals, *e.g.*, Ag^+, Cu^{2+}, Cd^{2+}.

$$Ag^+ + 2NH_3 \rightleftharpoons [Ag(NH_3)_2]^+$$

This property is made use of in the separation of silver, copper and cadmium from other cations in qualitative analysis.

Compared with ammonia, PH_3, AsH_3, SbH_3, BiH_3 have lesser tendency to form complexes with cations of transition metals.

6. Precipitation of metals from their aqueous salt solutions. Ammonia precipitates heavy metals as *hydroxides* from their aqueous salt solutions. For example,

$$FeCl_3 + 3NH_4OH \longrightarrow \underset{\text{Ppt.}}{Fe(OH)_3} + 3NH_4Cl$$

Phosphine, arsine, stibine and bismuthine precipitate metals such as silver, copper, etc., as *phosphides, arsenides, antimonides* and *bismuthides*, respectively, when these gases are passed through aqueous solutions of salts of these metals. Thus,

$$3CuSO_4 + 2PH_3 \longrightarrow \underset{\text{Ppt.}}{Cu_3P_2} + 3H_2SO_4$$

$$3AgNO_3 + AsH_3 \longrightarrow \underset{\text{Ppt.}}{Ag_3As} + 3HNO_3$$

$$3AgNO_3 + SbH_3 \longrightarrow \underset{\text{Ppt.}}{Ag_3Sb} + 3HNO_3$$

$$3CuSO_4 + 2BiH_3 \longrightarrow \underset{\text{Ppt.}}{Cu_3Bi_2} + 3H_2SO_4$$

7. Hydrogen bonding. As already discussed under reactions of nitrogen, ammonia molecules are bonded together through hydrogen bonding. This is because nitrogen is much more electronegative than hydrogen and also because ammonia molecule is not symmetrical but is *pyramidal* in structure.

Electronegativities of P, As, Sb and Bi (2·2, 2·2, 2·0 and 2·0, respectively) are quite close to that of hydrogen (2·1). Hence, PH_3, AsH_3, SbH_3 and BiH_3 do not show hydrogen bonding.

Some of the physical constants of the hydrides of Group 15 elements are summed up in Table 3.

TABLE 3

Some Physical Constants of Hydrides of Elements of Group 15

Physical Constants	NH_3	PH_3	AsH_3	SbH_3	BiH_3
Melting point (°C)	– 77·8	– 133·5	– 116·3	– 88·0	–
Boiling point (°C)	– 34·5	– 87·5	62·4	– 18·4	16·8
Bond angle H – X – H	107·3°	93·6°	91·8°	91·3°	–
Bond length H – X (Å)	1·02	1·42	1·52	1·71	–
Heat of formation (kJ mol^{-1})	– 46·1	– 9·6	66·4	145·1	277·8

2. Halides

Trihalides. All the elements of this group form trihalides of the general formula MX_3. These are mostly covalent and only partly ionic. The ionic character, however, increases as we go down the group. Thus, $BiCl_3$ and BiF_3 are predominantly ionic. The trihalides, particularly the chlorides, are readily hydrolysed, the products of hydrolysis are, however, different in different cases. Thus, while nitrogen trichloride (NCl_3) hydrolyses giving hypochlorous acid and ammonia,

$$NCl_3 + 3H_2O \longrightarrow NH_3 + 3HClO$$

the trichlorides of phosphorus and arsenic are completely and irreversibly hydrolysed into hydrochloric acid and the oxoacid or the oxide of the element.

$$PCl_3 + 3H_2O \longrightarrow 3HCl + H_3PO_3$$

$$2AsCl_3 + 3H_2O \longrightarrow 6HCl + As_2O_3$$

Antimony and bismuth trichlorides are only partly and reversibly hydrolysed to hydrochloric acid and oxochlorides of the metal. Thus,

$$SbCl_3 + H_2O \rightleftharpoons SbOCl + 2HCl$$

$$BiCl_3 + H_2O \rightleftharpoons BiOCl + 2HCl$$

The addition of excess of hydrochloric acid suppresses the hydrolysis by shifting the equilibrium towards the left.

The trihalides of P and As (especially the fluorides and chlorides) show electron-acceptor properties and, therefore, act as Lewis acids.

$$PF_3 + F_2 \longrightarrow PF_5$$

$$SbF_3 + 2F^- \longrightarrow [SbF_5]^{2-}$$

$$SbCl_3 + 2Cl^- \longrightarrow [SbCl_5]^{2-}$$

All the trihalides have **pyramidal structure.**

The most important trihalide is the trichloride of phosphorus. This has been described below in some details.

Phosphorus Trichloride. Phosphorus trichloride is a low boiling liquid (b.p. 74°C) having a pungent odour. It fumes in moist air.

Chemical Properties. 1. As mentioned above, PCl_3 is violently hydrolysed by water giving phosphorous acid and hydrochloric acid gas.

$$PCl_3 + 3H_2O \longrightarrow 3HCl + H_3PO_3$$

2. It reacts with chlorine or sulphur chloride forming phosphorus pentachloride.

$$PCl_3 + Cl_2 \longrightarrow PCl_5$$

$$3PCl_3 + SCl_2 \longrightarrow PCl_5 + 2PSCl_3$$

3. It readily combines with oxygen or sulphur trioxide forming phosphorus oxotrichloride.

$$2PCl_3 + O_2 \longrightarrow 2POCl_3$$

$$3PCl_3 + SO_3 \longrightarrow POCl_3 + SO_2$$

4. Phosphorus trichloride undergoes many substitution reactions. Some of these are given below :

$$\left.\begin{array}{l} PCl_3 \xrightarrow{ROH} P(OR)_3 \\ PCl_3 \xrightarrow{NH_3} P(NH_2)_3 \\ PCl_3 \xrightarrow{RSH} P(SR)_3 \\ PCl_3 \xrightarrow{R_2NH} P(NR_2)_3 \end{array}\right\} \text{R = alkyl radical}$$

$$PCl_3 \xrightarrow{AgCN} P(CN)_3$$

$$PCl_3 \xrightarrow{AgCNO} P(NOC)_3$$

$$PCl_3 \xrightarrow{PF_3} PCl_2F + PClF_3$$

5. PCl_3 forms an adduct with BBr_3.

$$PCl_3 + BBr_3 \longrightarrow [BBr_3(PCl_3)]$$

6. PCl_3 replaces CO from carbonyl complexes.

$$PCl_3 + Ni(CO)_4 \longrightarrow Ni(PCl_3)_4 + 4CO$$

Pentahalides. While phosphorus, arsenic and antimony form pentahalides, nitrogen and bismuth do not. Nitrogen cannot form pentahalide because nitrogen does not have vacant *d* orbitals in its valence shell and, therefore, cannot expand its octet. Phosphorus, arsenic and antimony form pentahalides because of the availability of vacant *d* orbitals in their outer shells. Bismuth does not form pentahalides because its lower +3 oxidation state is more stable than +5 state, the reason for which has been discussed in Chapter 12.

The pentahalides have a **trigonal bipyramidal structure.**

They are thermally less stable than the trihalides. PCl_5 exists as $[PCl_4]^+[PCl_6]^-$ in the crystalline state. PBr_5 and PI_5 also exist in ionic forms as $[PBr_4]^+[Br]^-$ and $[PI_4]^+I^-$, respectively, in solid state.

Amongst the pentahides, the most important is phosphorus pentachloride which has been described below.

Phosphorus Pentachloride. Phosphorus pentachloride is a yellowish white crystalline compound having a sharp odour. It sublimes on heating at 160°C and melts at 45°C under pressure.

Chemical Properties. 1. Phosphorus pentachloride dissociates on heating into phosphorus trichloride and chlorine.

$$PCl_5 \rightleftharpoons PCl_3 + Cl_2$$

2. It is violently hydrolysed by water giving phosphorus oxochloride or phosphoric acid depending upon the quantity of water.

$$PCl_5 + H_2O \xrightarrow{\text{Insufficient water}} POCl_3 + 2HCl$$

$$PCl_5 + 4H_2O \xrightarrow{\text{Excess of water}} H_3PO_4 + 5HCl$$

3. It reacts with compounds containing hydroxyl groups forming chloro derivatives. In all these cases, the hydroxyl group is replaced by chlorine. For example,

$$\underset{\text{Acetic acid}}{CH_3COOH} + PCl_5 \longrightarrow \underset{\text{Acetyl chloride}}{CH_3COCl} + POCl_3 + HCl$$

$$\underset{\text{Ethyl alcohol}}{C_2H_5OH} + PCl_5 \longrightarrow \underset{\text{Ethyl chloride}}{C_2H_5Cl} + POCl_3 + HCl$$

$$\underset{\text{Sulphuric acid}}{HO.SO_2.OH} + 2PCl_5 \longrightarrow \underset{\text{Sulphuryl chloride}}{Cl.SO_2.Cl} + 2POCl_3 + 2HCl$$

4. It reacts with P_4O_{10} to form phosphorus oxotrichloride.

$$6PCl_5 + P_4O_{10} \longrightarrow 10POCl_3$$

5. When heated with ammonium chloride, polymeric phosphonitrilic chloride is formed.

$$nPCl_5 + nNH_4Cl \longrightarrow (NPCl_2)_n + 4nHCl$$

6. Phosphorus pentachloride combines with Cl^- acceptors to form tetrahedral $[PCl_4]^+$ ion.

$$PCl_5 + BCl_3 \longrightarrow [PCl_4]^+[BCl_4]^-$$

7. It is reduced to phosphorus trichloride by hydrogen.

$$PCl_5 + H_2 \longrightarrow PCl_3 + 2HCl$$

8. It combines with potassium fluoride as follows :

$$PCl_5 + 6KF \longrightarrow KPF_6 + 5KCl$$

Other Halides. In addition to trihalides and pentahalides, some other halides are also known. Nitrogen forms fluorides such as N_2F_4 (dinitrogen tetrafluoride), N_2F_2 (dinitrogen difluoride) and N_3F (trinitrogen fluoride). Several mixed halides and hydrohalides of nitrogen such as NCl_2F, $NClF_2$, $NBrF_2$, NF_2H, NCl_2H, etc., are also known. However, these are unstable and difficult to isolate. Phosphorus also forms P_2Br_4 (dinitrogen tetrabromide) and several mixed halides such as PCl_4F, $PClF_4$, PCl_2F_3. Arsenic and antimony also form mixed halides such as AsF_2Cl, $AsFCl_2$, $AsClBr_2$, $AsCl_2Br$, $SbCl_4F$, etc.

Pseudohalides of phosphorus are also known. Examples are $P(NCS)_3$, $PF_2(NCS)$, $P(CN)_3$ and $P(NCO)_3$.

3. Oxohalides

Nitrogen forms two types of oxohalides. These are nitrosyl halides, XNO and nitryl halides, XNO_2. The **nitrosyl halides** are covalent gases and can be prepared by direct combination of NO with the halogen X_2.

$$2NO + X_2 \longrightarrow 2XNO$$

Nitrosyl halides are powerful oxidising agents. They are thermally unstable. They are readily hydrolysed by water to form a mixture of oxides and oxoacids of nitrogen.

$$3XNO + 2H_2O \longrightarrow HNO_2 + 2NO + 3HX$$

The **nitryl halides** are prepared by the following reactions :

$$HNO_3 + ClSO_3H \longrightarrow ClNO_2 + H_2SO_4$$

$$NaNO_2 + F_2 \longrightarrow FNO_2 + NaF$$

$$N_2O_4 + 2CoF_3 \longrightarrow 2FNO_2 + 2CoF_2$$

These are colourless reactive gases, the reactions being similar to those of XNO. Their hydrolysis yields nitric acid and HX, *e.g.*,

$$ClNO_2 + H_2O \longrightarrow HNO_3 + HCl$$

The most important oxohalides of phosphorus are phosphoryl halides, POX_3. These are prepared by (*i*) the controlled hydrolysis of PX_5 (*ii*) by the oxidation of PX_3 or (*iii*) by the action of P_4O_{10} on PX_5.

4. Oxides

All the elements of Group 15 are capable of forming trioxides and pentoxides of the general formulae R_2O_3 and R_2O_5.

Trioxides. Nitrogen trioxide, N_2O_3, exists pure only in the solid state at low temperatures. In the liquid state, it is dissociated into NO and NO_2.

$$N_2O_3\,(g) \rightleftharpoons NO\,(g) + NO_2\,(g)$$

In the vapour state, it is almost entirely present as an equimolar mixture of NO and NO_2.

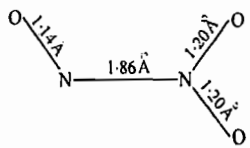
It is best obtained by interaction of stoichiometric quantities of NO and NO_2. On cooling such a mixture below $-20°C$, a blue liquid corresponding to the composition N_2O_3 is obtained. The oxide N_2O_3 is formally referred to as the anhydride of nitrous acid since with water it gives nitrous acid, HNO_2. When dissolved in alkalies it produces nitrites.

Phosphorus trioxide exists as a dimer and is formulated as P_4O_6. It is prepared by the combustion of white phosphorus in a limited supply of air when both P_4O_6 and P_4O_{10} are formed. The vapour of the mixture of oxides are passed through a condenser in which water at 50 – 60°C is circulated. P_4O_{10} being solid at 60°C separates out easily. The oxide P_4O_6 is considered as an anhydride of phosphorous acid since it dissolves in water to give phosphorous acid, H_3PO_3.

The **trioxides of arsenic, antimony** and **bismuth** are obtained by the direct reaction of metals with oxygen.

The trioxides of nitrogen, phosphorus and arsenic are *acidic*. The trioxide of antimony is *amphoteric* while that of bismuth is *basic* in character.

Structures. The structure of N_2O_3 is not definitely known. The spectroscopic studies, however, reveal that its structure is as shown below. It may be noted that lines between the atoms do not show exact bond order.



Based on the tetrahedral structure of phosphorus molecule, the **tetrahedral** structure assigned to P_4O_6 is as shown in Fig. 4.

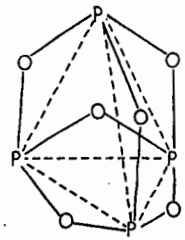


Fig. 4. Structure of phosphorus trioxide.

It is evident that in P_4O_6, the phosphorus atoms lie at the corners of a tetrahedron and the six oxygen atoms are present along the edges in between the phosphorus atoms. Each phosphorus atom is covalently bonded to three oxygen atoms each of which is bonded to two phosphorus atoms (Fig. 4). In this manner all the phosphorus and oxygen atoms have 8 electrons in each of their valency shells.

This structure has been confirmed by X-ray diffraction data.

The oxides **As_4O_6 and Sb_4O_6** also have **tetrahedral structures.**

At higher temperatures, As_4O_6 and Sb_4O_6 partially transform into As_2O_3 and Sb_2O_3. Both the latter compounds have sheet-like structures consisting of pyramidal AsO_3 and SbO_3 units.

Another mixed oxide $Sb^{III}Sb^{V}O_4$ is known in two crystallographic forms α and β and can be obtained by heating Sb_2O_3 in dry air upto 500°C.

Pentoxides. Nitrogen pentoxide, N_2O_5 is prepared by the dehydration of HNO_3 with phosphorus pentoxide. The mixture of HNO_3 and P_2O_5 is distilled in an all-glass apparatus in the presence of ozonised oxygen. The latter is essential to avoid decomposition of N_2O_5.

Phosphorus pentoxide, P_4O_{10}, is obtained by burning phosphorus in a free supply of air or oxygen. The pentoxide formed is purified further by sublimation at 360°C.

Arsenic pentoxide and antimony pentoxide are obtained by the oxidation of the metals with concentrated HNO_3.

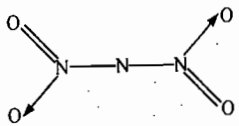
The structure of As_2O_5 consists of strands of AsO_6 octahedra and AsO_4 tetrahedra. Sb_2O_5 can also be obtained by the hydrolysis of $SbCl_5$ followed by dehydration.

Bismuth pentoxide is obtained by the action of strong oxidising agents on Bi_2O_3. The pentoxide, however, is extremely unstable and rapidly loses oxygen to form the trioxide.

All the pentoxides are *acidic* in nature but the acidity decreases as we move down the group. Thus, N_2O_5 is the strongest acidic oxide while Bi_2O_5 is the weakest. All the pentoxides can readily lose oxygen to form lower oxides. Hence they act as strong oxidising agents.

Amongst the various pentoxides, P_2O_5 has the strongest affinity for water. It can extract water from several inorganic and organic compounds and thus acts as a *strong dehydrating agent*. It dehydrates H_2SO_4 to SO_3, HNO_3 to N_2O_5, cellulose to carbon and amides to nitriles.

Structures. N_2O_5 has a simple structure which may be represented as shown.



All the terminal NO bond distances are equal due to resonance between N = O and N → O bonds in the molecule.

The structure assigned to P_4O_{10} molecule is shown in Fig. 5. In this structure, the phosphorus atoms lie at the corners of a tetrahedron with six oxygen atoms lying along the edges and the remaining four occupying positions along the extended three-fold axes of the tetrahedron. The twelve P – O distances between the P atoms and shared O atoms are 1·62 Å each while the other four apical P – O distances are 1·39 Å each. Thus, while the former P – O bonds are single bonds, the latter are double bonds with considerable $p\pi - d\pi$ bonding.

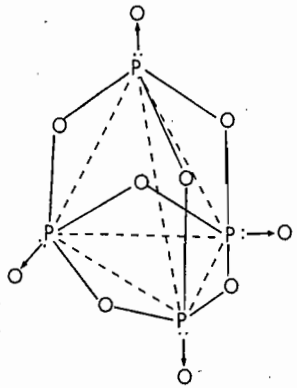


Fig. 5. Structure of phosphorus pentoxide molecule.

The structures of pentoxides of other elements of the group have not been fully established.

Other Oxides. Nitrogen, phosphorus, antimony and bismuth also form **dioxides** of the general formula RO_2. Amongst these, the most thoroughly studied and best understood is the dioxide of nitrogen, **NO_2.**

Nitrogen dioxide, NO_2. This oxide also exists as a dimer N_2O_4, known as **dinitrogen tetroxide.** The two oxides are in a temperature-dependent equilibrium :

$$N_2O_4 \rightleftharpoons 2NO_2$$

In the solid state, the oxide consists only of N_2O_4 molecules and is colourless. At – 11·2°C, the solid melts. Even in the liquid state, partial dissociation occurs and the liquid may be considered as a dilute solution of NO_2 in N_2O_4. The colour of the liquid gradually changes from yellow to orange with rise in temperature indicating an increase in the percentage of NO_2. At 22°C, the liquid boils giving brown vapours. At 100°C, the composition of the mixture has been found to be 90 per cent NO_2 and 10 per cent N_2O_4. Above 140°C, the dissociation is complete and the oxide consists only of NO_2 molecules. Beyond this temperature, the nitrogen dioxide starts dissociating into nitric oxide and oxygen, both of

which are colourless.

$$\underset{\text{Brown}}{2NO_2} \rightleftharpoons \underset{\text{Coloureless}}{2NO + O_2}$$

Above 620°C, the gas becomes colourless indicating complete dissociation into NO and O_2. All these changes are reversed on cooling. At some intermediate temperature (found to be 300°C experimentally), the equilibrium mixture contains equimolar quantities of NO_2 and NO. Thus, if the gas at 300°C is treated with an alkali, it produces pure nitrite.

$$NO + NO_2 + 2NaOH \longrightarrow 2NaNO_2 + H_2O$$

This fact is utilised in the commercial preparation of sodium nitrite.

Nitrogen dioxide, when dissolved in water, gives a mixture of nitrous acid and nitric acid.

$$2NO_2 + H_2O \rightleftharpoons HNO_2 + HNO_3$$

Hence, it is formally known as the 'mixed anhydride' of these two acids.

The hot aqueous solution of NO_2 gives NO because of the disproportionation of HNO_2 ($3HNO_2 \longrightarrow HNO_3 + 2NO + H_2O$). The overall reaction is

$$3NO_2 + H_2O \longrightarrow 2HNO_3 + NO$$

In aqueous solution, it oxidises sulphur dioxide to sulphuric acid.

$$SO_2 + H_2O + NO_2 \longrightarrow H_2SO_4 + NO$$

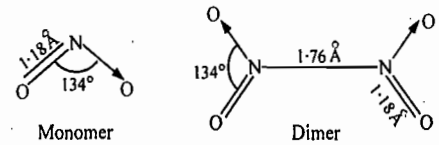
The manufacture of sulphuric acid by Lead Chamber Process is based on the oxidation of sulphur dioxide by nitrogen dioxide in the presence of steam.

Structure. Nitrogen dioxide is known to have the electronic structure, $:\ddot{O}::\dot{N}:\ddot{O}:$ or O=N→O. Obviously, nitrogen dioxide *has an unpaired electron* and, therefore, it behaves as a typical odd molecule. It is coloured and has a tendency to polymerise to give a colourless **dimer,** N_2O_4, with even number of electrons, as shown :

$$\begin{array}{ccccccc} O & = & N & - & N & = & O \\ & & \downarrow & & \downarrow & & \\ & & O & & O & & \end{array}$$

The monomer, NO_2, is known to have an angular structure with ONO bond angle = 134° and NO distance = 1·18 Å.

The planar structures of the monomer and the dimer are shown below.



Monomer Dimer

All the terminal NO bond distances in the dimeric N_2O_4 molecule are equal due to resonance between N = O and N_2 → O bonds.

Nitrogen also forms two additional oxides, *viz.*, nitrous oxide and nitric oxide, which are very important and are described below in some details.

Nitrous Oxide, N_2O. Nitrous oxide is prepared in the laboratory as well as on a commercial scale by carefully heating ammonium nitrate to about 250°C.

$$NH_4NO_3 \longrightarrow N_2O + 2H_2O$$

In the laboratory, the gas is collected over *hot* water (as the gas is fairly soluble in *cold* water) and on a commercial scale it is stored in steel cylinders under a pressure of about 100 atm.

Physical Properties. Nitrous oxide is a colourless gas fairly soluble in cold water but practically insoluble in hot water. It can be easily liquefied at room temperature by applying pressure as its critical temperature is 35°C. It has a faint odour. When inhaled in moderate quantities, it produces hysterical laughter, hence the name *laughing gas*. In small amounts, it acts as an anaesthetic.

Chemical Properties. Chemically nitrous oxide is relatively inert. It does not react with halogens, alkali metals and even ozone at room temperature.

At high temperatures, it decomposes into nitrogen and oxygen.

$$2N_2O \xrightarrow{600°C} 2N_2 + O_2$$

Nitrous oxide reacts with molten alkali metal amides to form azides.

$$NaNH_2 + N_2O \xrightarrow{200°C} NaN_3 + H_2O$$

Uses. Commercially, it is used as the propellant gas in 'whipped' cream bombs. It is also used as an anaesthetic.

Structure. Nitrous oxide is known to be a *resonance hybrid* of two highly polar and linear structures with *opposing* dipole moments, as represented below :

$$:N\equiv N-\overset{+}{\underset{..}{O}}: \longleftrightarrow :\overset{..}{N}=\overset{+}{N}=\ddot{O}:$$

This structure readily accounts for a very low dipole moment (0·1 D) of N_2O. Thus, N_2O has linear structure. The N – N and N – O bond lengths are 1·12 Å and 1·19 Å, respectively, as shown :

$$N \overset{1\cdot12\,Å}{—} N \overset{1\cdot19\,Å}{—} O$$

Nitric Oxide, NO. Nitric oxide is usually prepared by the action of cold dilute nitric acid on copper turnings.

$$3Cu + 8HNO_3 \longrightarrow 3Cu(NO_3)_2 + 4H_2O + 2NO$$

On a commercial scale, nitric oxide is obtained by the catalytic oxidation of ammonia.

$$4NH_3 + 5O_2 \xrightarrow[750-900°C]{Pt} 4NO + 6H_2O$$

Physical Properties. Nitric oxide is a colourless gas which readily combines with atmospheric oxygen giving brown nitrogen dioxide. Hence, the gas must be handled out of contact with air. Since its critical temperature is very low (– 93°C), it can be liquefied with some difficulty. The liquid has a blue colour which boils at – 142·8°C and freezes at – 150°C. It is neutral in character.

Chemical Properties. The most important reactions of nitric oxide are oxidation and reduction reactions.

1. It readily combines with oxygen giving brown nitrogen dioxide.

2. It is easily oxidised to nitric acid by strong oxidising agents such as potassium permanganate, potassium dichromate, halogens, etc. Thus, acidified potassium permanganate is decolourised when nitric oxide is passed into it.

$$6KMnO_4 + 9H_2SO_4 + 10NO \longrightarrow 3K_2SO_4 + 6MnSO_4 + 4H_2O + 10HNO_3$$

The reaction with $KMnO_4$ is quantitative and is, therefore, used for the estimation of nitric oxide.

3. *Nitric oxide is oxidised to nitrogen dioxide with concentrated nitric acid.*

$$2HNO_3 + NO \rightleftharpoons 3NO_2 + H_2O$$

This reaction is of particular interest because it explains why metals like copper, mercury, etc., give nitric oxide with dilute nitric acid but nitrogen dioxide with concentrated nitric acid. In the case of dilute nitric acid, that is, when sufficient water is present, the reaction is pushed backwards giving nitric oxide but with concentrated nitric acid, the reaction proceeds in the forward direction giving nitrogen dioxide. It follows from this that *at some intermediate concentration of nitric acid, both* NO *and* NO_2 *should be formed. It is actually so.* A 5 M solution of nitric acid on reaction with copper gives an almost equimolar mixture of NO and NO_2

4. Nitric oxide is reduced also equally easily. With sulphurous acid it is reduced to nitrous oxide while with chromous or stannous ions, it yields hydroxyl amine.

$$2NO + H_2SO_3 \longrightarrow N_2O + H_2SO_4$$

$$2NO + 6H \xrightarrow[\text{or } Cr^{2+}]{Sn^{2+}} 2NH_2OH$$

5. Nitric oxide directly combines with halogens (fluorine, chlorine, bromine but not iodine) to give the corresponding nitrosyl halides.

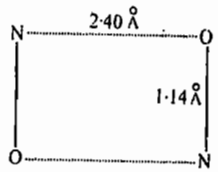
$$\underset{\text{Halogen}}{2NO + X_2} \longrightarrow \underset{\text{Nitrosyl halide}}{2NOX}$$

These halides are highly reactive and are used as powerful oxidising agents.

6. Nitric oxide is absorbed in ferrous sulphate solution giving a dark brown coloration (*a test for nitric oxide and nitrates*). The brown colour is due to the formation of a hydrated nitrosyl complex of iron, having the formula $[Fe(H_2O)_5NO]^{2+}$. This compound is responsible for the formation of brown ring in the 'ring test' for nitrates.

This complex is stable only at low temperatures. On heating, it decomposes to set free nitric oxide. The reaction, therefore, provides a method for the purification of the gas as well as for its separation from other gases.

Structure of nitric oxide. Nitric oxide molecule has 11 valency electrons. Evidently, all of these cannot be paired. The molecule, therefore, contains an *odd electron*. Nitric oxide, therefore, is *paramagnetic* in the gaseous state. But it is *diamagnetic* in the solid state. The reason is that in the latter state, loose dimers are formed in which the unpaired electrons of the two NO monomeric units get paired up. The structure of the dimer is as shown.



The electronic structure of nitric oxide is conventionally represented as a resonance hybrid of two structures, as shown below :

$$:N=\ddot{O}: \longleftrightarrow :\overset{..}{N}=\overset{+}{O}:$$

The bond length in nitric oxide (1·14 Å) is in between that of a double bond and a triple bond.

The electronic structure of NO is best explained on the basis of molecular orbital theory (Chapter 4). The molecular orbital structure of NO is

$$NO : KK'\sigma(2s)^2\sigma^*(2s)^2\sigma(2p_z)^2\pi(2p_x)^2\pi(2p_y)^2\pi^*(2p_x)^1$$

or

$$KK'\sigma_1^2\sigma_2^{*2}\sigma_3^2\pi_1^2\pi_2^2\pi_3^{*1}$$

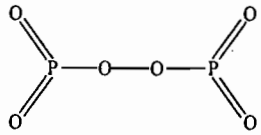
The bond order in this case is given by

$$\text{Bond order} = \tfrac{1}{2}\,(\text{Number of electrons in BMOs} - \text{Number of electrons in ABMOs})$$

$$= \tfrac{1}{2}\,[8 - 3] = 2\tfrac{1}{2}$$

Thus, the molecular orbital theory predicts $2\frac{1}{2}$ bonds in nitric oxide.

The lesser known oxides of phosphorus are phosphorus peroxide P_2O_6 and phosphorus suboxide P_2O_2. The structure of suboxide is not well known. The structure of P_2O_6 is as shown.



5. Oxoacids

All the elements of Group 15 form **oxoacids.**

Nitrogen forms a large number of oxoacids such as $H_2N_2O_2$, H_2NO_2, HNO_2, HNO_3, HOONO and HNO_4.

Phosphorus forms much larger number of oxoacids such as H_3PO_2, H_3PO_3, $H_4P_2O_6$, H_3PO_4, $H_4P_2O_7$, HPO_3, H_4PO_5 and $H_4PO_5P_8$.

Arsenic forms two oxoacids, H_3AsO_3 and H_3AsO_4.

Antimony forms only one oxoacid, H_2SbO_3, which, however, is unstable and exists only in solution.

Bismuth gives one stable oxoacid, namely, meta bismuthic acid, $HiBO_3$, which is obtained as a scarlet red solid.

A brief description of the various oxoacids is given below.

Oxoacids of Nitrogen

Hyponitrous Acid, $H_2N_2O_2$. For preparing hyponitrous acid, its sodium salt is first obtained by the reduction of sodium nitrite with sodium amalgam.

$$2NaNO_2 + 4H_2 \xrightarrow{Na-Hg} Na_2N_2O_2 + 2H_2O$$

The solution of sodium hyponitrite is then neutralised with acetic acid and treated with silver nitrate when a yellow precipitate of silver hyponitrite, $Ag_2N_2O_2$, is obtained.

$$Na_2N_2O_2 + 2AgNO_3 \longrightarrow Ag_2N_2O_2 + 2NaNO_3$$

The precipitate is separated, washed and treated with a solution of HCl in ether.

$$Ag_2N_2O_2 + 2HCl \longrightarrow H_2N_2O_2 + 2AgCl$$

Silver chloride gets precipitated and is filtered off. The filtrate containing hyponitrous acid in ether is evaporated to dryness in vacuum when hygroscopic crystals of the acid are obtained.

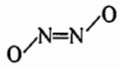
Properties. Pure hyponitrous acid forms white leaflets which decompose on rubbing.

In aqueous solution, the acid decomposes on warming to give nitrous oxide and water, the reaction being irreversible.

$$H_2N_2O_2 \longrightarrow N_2O + H_2O$$

Hyponitrous acid is a very weak dibasic acid ($K_1 = 1{\cdot}26\times10^{-7}$, $K_2 = 10^{-11}$). It behaves as a strong reducing agent.

From a study of the infrared spectra of sodium, mercury and silver salts of hyponitrous acid, it has been found to have the structure as shown.



This structure readily accounts for a zero dipole moment of the acid as the moment of one part of the molecule is internally balanced by the moment of the other part.

Nitroxylic Acid, $H_4N_2O_4$. This acid is also called **hydronitrous acid.** It is highly explosive and has not been obtained as such. Only the salts of the acid have been isolated. The sodium salt, for example, can be prepared by the electrolysis of sodium nitrite in liquid ammonia or by the reduction of sodium nitrite with sodium metal in liquid ammonia.

$$2NaNO_2 + 2Na \xrightarrow{Liq.\ NH_3} Na_4N_2O_4$$

The sodium salt, which is obtained as a fine yellow powder, must be handled in complete absence of oxygen and moisture. It readily gets oxidised when exposed to atmospheric oxygen.

$$Na_4N_2O_4 + O_4 \longrightarrow (NaO)_2N - O - O - N(ONa)_2$$
$$\longrightarrow 2NaNO_2 + Na_2O_2$$

It decomposes in the presence of water.

Nitrous Acid, HNO_2. The free acid is unknown. It exists only in solution and there, too, it is unstable. Solutions of nitrous acid can be easily obtained by acidifying solutions of nitrites with mineral acids.

An aqueous solution of the acid, free of salts, can be obtained by acidifying barium nitrite with a calculated amount of dilute sulphuric acid. The reaction is carried out in the cold and the precipitated barium sulphate is removed by filtration.

Properties. 1. Nitrous acid is a weak acid with a dissociation constant of $6{\cdot}0\times10^{-6}$ at 25°C. As mentioned earlier, the free liquid acid does not exist although it can be obtained in the vapour phase when the following equilibrium is established :

$$2HNO_2 \rightleftharpoons NO + NO_2 + H_2O$$

Even in aqueous solution, the acid is unstable and changes slowly at room temperature and rapidly on heating, into nitric acid.

$$3HNO_2 \longrightarrow HNO_3 + H_2O + 2NO$$

Thus, in aqueous solution, nitrous acid undergoes what is known as *autoxidation.*

On account of its unstable nature, nitrous acid is prepared *in situ* by the action of dilute mineral acids on sodium or potassium nitrite.

2. Nitrous acid behaves both as a *reducing* as well as an *oxidising agent.* It reduces potassium permanganate, potassium dichromate, hydrogen peroxide and other strong oxidising agents. It oxidises strong reducing agents, such as hydriodic acid, sulphurous acid, etc.

It oxidises iron (II) and titanium (III) to higher valency states, in acid medium.

$$Fe^{2+} + HNO_2 + H^+ \longrightarrow Fe^{3+} + NO + H_2O$$
$$Ti^{3+} + HNO_2 + H^+ \longrightarrow Ti^{4+} + NO + H_2O$$

3. Nitrous acid decomposes urea and other aliphatic amino compounds giving nitrogen.

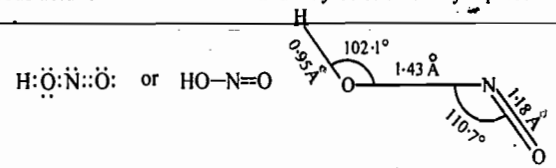
$$\underset{\text{Urea}}{NH_2CONH_2} + 2HNO_2 \longrightarrow CO_2 + 2N_2 + 3H_2O$$

$$\underset{\text{Ethyl amine}}{C_2H_5NH_2} + HNO_2 \longrightarrow C_2H_5OH + N_2 + H_2O$$

4. With aromatic amines and at low temperatures, the well known *diazo reaction* takes place, yielding diazonium salts.

$$\underset{\text{Aniline hydrochloride}}{C_6H_5NH_2.HCl} + HNO_2 \longrightarrow \underset{\text{Benzene diazonium chloride}}{C_6H_5N_2Cl} + 2H_2O$$

Structure. Nitrous acid is a monobasic acid and may be structurally represented as follows:



Microwave spectroscopic studies have shown that nitrous acid in the gaseous state has the trans configuration, as shown above.

Nitric Acid, HNO_3. Nitric acid can be conveniently prepared in the **laboratory** by heating a mixture of sodium nitrate and concentrated sulphuric acid in a glass retort.

$$NaNO_3 + H_2SO_4 \longrightarrow NaHSO_4 + HNO_3$$

The vapours of nitric acid are condensed in a water-cooled receiver.

On a **commercial scale,** the acid is now almost invariably prepared by the catalytic oxidation of ammonia (**Ostwald's process**). The ammonia obtained by the Haber process is mixed with about 10 volumes of air and passed over a platinum or platinum-rhodium gauze at 750 – 900°C when ammonia is oxidised to nitric oxide.

$$4NH_3 + 5O_2 \xrightarrow[750\text{–}900°C]{Pt} 4NO + 6H_2O\,; \qquad \Delta H = -90{\cdot}0 \text{ kJ}$$

Since the reaction is exothermic, the heat of the reaction maintains the temperature of the catalyst. The yield varies from 90 to 95 per cent.

The nitric oxide is then oxidised by air to nitrogen dioxide which is cooled to about 50°C and absorbed in water (in the presence of air) to give nitric acid.

$$2NO + O_2 \rightleftharpoons 2NO_2$$
$$4NO_2 + 2H_2O + O_2 \longrightarrow 4HNO_3$$

Properties. 1. Anhydrous nitric acid is a colourless liquid boiling at 84·1°C and freezing at –41·55°C to a crystalline solid. The pure acid undergoes autoionization giving nitrate ion and nitronium ion.

$$2HNO_3 \rightleftharpoons \underset{\text{Nitronium ion}}{NO_2^+} + NO_3^- + H_2O$$

2. The aqueous solution containing about 70 per cent of nitric acid by mass forms a constant boiling mixture, boiling at 120·5°C. This is the usual concentrated nitric acid and has a density of 1·4048 g cm^{-3} at 20°C. It is colourless but often develops a yellow colour on account of its photochemical decomposition to nitrogen dioxide.

$$2HNO_3 \xrightarrow{h\nu} 2NO_2 + H_2O + 1/2\,O_2$$

Pure nitric acid can be obtained by distilling the less concentrated acid with concentrated sulphuric acid. The *fuming nitric acid* is obtained by dissolving an excess of nitrogen dioxide in concentrated nitric acid. It is brown in colour.

3. Oxidising Properties of Concentrated Nitric Acid. Since concentrated nitric acid can easily lose its oxygen according to the equation

$$2HNO_3 \longrightarrow 2NO_2 + H_2O + O,$$

it acts as a powerful **oxidising agent.**

The oxidising action of nitric acid has been shown to be more due to NO_2 produced than due to oxygen. Thus colourless nitric acid has practically no action on sulphur, phosphorus, metals, etc. But the oxidation starts instantaneously on introducing a small amount of NO_2 (nitric acid itself decomposes at high temperatures to give NO_2). During the course of oxidation, more and more of NO_2 is formed and the reaction, therefore, becomes faster and faster. Because of this reason, the fuming nitric acid, containing dissolved NO_2, is much stronger in its oxidising action. If the NO_2 formed during the reduction of nitric acid is constantly removed, for instance by adding urea, the oxidising action ceases.

It readily oxidises solid non-metals and metalloids to their respective oxoacids. Thus, phosphorus, sulphur, iodine, arsenic, antimony and tin are oxidised to phosphoric acid (H_3PO_4), sulphuric acid (H_2SO_4), iodic acid (HIO_3), arsenic acid (H_3AsO_4), antimonic acid (H_3SbO_4) and meta stannic acid (H_2SnO_3), respectively.

Carbon is oxidised first to *mellitic acid*, $C_6(COOH)$ and then to carbon dioxide. Graphite gives a greenish yellow insoluble acid, named as *graphitic acid*, $C_{11}H_4O_5$.

4. Oxidising Reactions of Dilute Nitric Acid. Dilute nitric acid can also give oxygen easily according to the equation

$$2HNO_3 \longrightarrow 2NO + H_2O + 3O$$

Hence, reducing agents such as hydrogen sulphide, hydrogen iodide, ferrous sulphate, etc., are oxidised *even* by dilute nitric acid.

5. Action on Metals. a. Metals lying below hydrogen in the electrochemical series. Metals such as Na, K, Ca, Mg, Al, Zn, etc., lying below hydrogen in the electrochemical series normally displace hydrogen from dilute acids. Nitric acid also *primarily* behaves in the same manner. But, since it is a strong oxidising agent and hydrogen is a reducing agent, *secondary reactions* take place resulting in the reduction of nitric acid to give NO, N_2O, N_2 or NH_3, depending upon the nature of the metal, the temperature and the concentration of the acid. Thus, *dilute* nitric acid reacts with zinc in the *cold* giving N_2O or N_2 according to the following equations :

$$4Zn + 10HNO_3 \longrightarrow 4Zn(NO_3)_2 + N_2O + 5H_2O$$
$$5Zn + 12HNO_3 \longrightarrow 5Zn(NO_3)_2 + N_2 + 6H_2O$$

Very dilute nitric acid gives NH_3 which, of course, is neutralised by nitric acid to form NH_4NO_3.

$$4Zn + 10HNO_3 \longrightarrow 4Zn(NO_3)_2 + 3H_2O + NH_4NO_3$$

Similarly, iron and tin also give NH_4NO_3 with *dilute* nitric acid.

Lead gives nitric oxide with dilute nitric acid in cold.

Magnesium and manganese give hydrogen.

Concentrated nitric acid essentially behaves as an oxidising agent and metals like aluminium, iron, chromium, etc., are rendered **'passive'** probably due to *surface oxidation.*

b. Metals lying above hydrogen in the electrochemical series. Metals such as Cu, Hg, Ag, lying above hydrogen in the electrochemical series, *do not* liberate hydrogen from acids. In the case of these metals, the action of nitric acid involves only the oxidation of the metals into the metallic oxides which dissolve in the acid to form nitrates accompanied by evolution of NO or NO_2 according as the acid is dilute or concentrated. For instance, *concentrated* acid attacks copper giving NO_2.

$$Cu + 4HNO_3 \longrightarrow Cu(NO_3)_2 + 2H_2O + 2NO_2$$

Dilute nitric acid gas gives NO.

$$3Cu + 8HNO_3 \longrightarrow 3Cu(NO_3)_2 + 4H_2O + 2NO$$

c. Noble metals like Au, Pt, Rh and Ir are not attacked by nitric acid. Gold and platinum, however, are attacked by *aqua regia* (3 parts conc. HCl and 1 part conc. HNO_3) which contains free atomic chlorine.

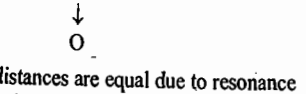
$$HNO_3 + 3HCl \longrightarrow 2H_2O + 2Cl + NOCl$$

The atomic chlorine attacks gold and platinum forming soluble chlorides which form complexes with HCl, *e.g.*,

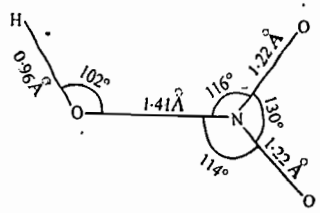
$$Au + 3Cl \longrightarrow AuCl_3$$
$$AuCl_3 + HCl \longrightarrow HAuCl_4$$

6. Action on Proteins. Nitric acid attacks proteins giving a yellow nitro compound called **xanthoprotein.** Hence, nitric acid stains the skin and renders wool yellow. This is used as a delicate test for proteins.

Structure. Nitric acid is a monobasic acid and may be structurally represented as shown :



Both the terminal NO bond distances are equal due to resonance between $N = O$ and $N \rightarrow O$ bonds in the molecule.



Gaseous nitric acid is a *planar* molecule. The bond lengths and bond angles are as shown.

Peroxonitrous Acid, HOONO. Peroxonitrous acid is isomeric with nitric acid. It is unstable though some of its salts are stable.

It is formed as an unstable intermediate during the oxidation of acidified aqueous solutions of nitrates and nitrites using hydrogen peroxide. These solutions are orange-red and are more oxidising than either H_2O_2 or HNO_3. These are found to contain peroxonitrites of the formula M(OONO).

Peroxonitric Acid, HNO_4. Peroxonitric acid is obtained by dissolving nitrogen pentoxide in anhydrous hydrogen peroxide.

$$N_2O_5 + H_2O_2 \longrightarrow HNO_3 + HNO_4$$

Peroxonitric acid is unstable and explosive. It smells like bleaching powder.

It is a strong oxidising agent. It oxidises aniline to nitrobenzene and liberates bromine from a solution of potassium bromide.

Oxoacids of Phosphorus

Hypophosphorous Acid (Phosphinic Acid), H_3PO_2. This acid is prepared by heating white phosphorus with alkalies like barium hydroxide when barium hypophosphite (precipitate) is formed which is separated and treated with a calculated quantity of sulphuric acid to recover the acid itself.

$$3Ba(OH)_2 + 2P_4 + 6H_2O \longrightarrow 2PH_3 + 3Ba(H_2PO_2)_2$$

$$3Ba(H_2PO_2)_2 + 3H_2SO_4 \longrightarrow 3BaSO_4 + 6H_3PO_2$$

Barium sulphate is separated by filtration and the solution concentrated when hypophosphorous acid separates out in the form of well defined crystals.

Properties. 1. It is a colourless crystalline solid (m.p. 26·3°C) soluble in water.

2. It is a monobasic acid, ionising as

$$H_3PO_2 \longrightarrow H^+ + H_2PO_2^-$$

The other two hydrogen atoms are not ionisable.

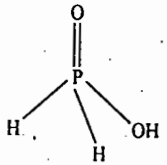
3. The acid as well as its salts are **strong reducing agents.** Thus, mercuric chloride is reduced to mercurous chloride and mercury. The acid itself is oxidised to orthophosphoric acid.

4. The acid is reduced to phosphine when treated with zinc and dilute hydrochloric acid.

5. When a concentrated solution of the acid is heated to 40°C or above, it decomposes giving phosphine and phosphorous acid.

$$3H_3PO_2 \longrightarrow PH_3 + 2H_3PO_3$$

Structure. Hypophosphorous acid, as already mentioned, is a fairly strong acid, its ionisation constant being 1×10^{-2}. It has only one ionisable hydrogen atom, *i.e.*, the acid is monobasic. This suggests the presence of only one OH group in its molecule. X-ray analysis and Raman spectra of salts have suggested the structure as shown.



Phosphorous Acid (Phosphonic Acid), H_3PO_3. As already explained, phosphorous acid is obtained by the hydrolysis of phosphorus trichloride and phosphorus trioxide.

Properties. 1. It is a colourless deliquescent crystalline solid (m.p. 70·1°C), extremely soluble in water.

2. It is a strong acid. Although it contains three hydrogen atoms, only two are ionisable. Hence, it is a dibasic acid ionising as

$$H_3PO_3 \longrightarrow H^+ + H_2PO_3^- \;; \quad K_1 = 1\times10^{-2}$$

$$H_2PO_3^- \longrightarrow H^+ + HPO_3^{2-} \;; \quad K_2 = 2\times10^{-7}$$

It gives two series of salts, such as NaH_2PO_3 and Na_2HPO_3, known as primary phosphites and secondary phosphites, respectively. The third series (*e.g.*, Na_3PO_3) is unknown.

3. Phosphorous acid and its salts (phosphites) are **strong reducing agents** as they are readily oxidisable to phosphoric acid and phosphates, respectively.

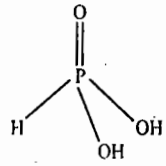
$$HPO_3^{2-} + 3OH^- \longrightarrow PO_4^{3-} + 2H_2O + 2e^-$$

Thus, phosphorous acid reduces salts of copper, silver, gold, etc., to the respective metals.

4. On heating, phosphorous acid decomposes into phosphine and phosphoric acid.

$$4H_3PO_3 \longrightarrow 3H_3PO_4 + PH_3$$

Structure. It is a dibasic acid which suggests the presence of two OH groups. The third hydrogen is not ionised. The structure for this acid is as shown.



Hypophosphoric Acid, $H_4P_2O_6$. This acid is prepared by controlled oxidation of red phosphorus with sodium chlorite solution at room temperature when disodium salt of hypophosphoric acid crystallises at *p*H 5·2.

$$2P + 2NaClO_2 + 8H_2O \longrightarrow Na_2H_2P_2O_6.6H_2O + 2HCl$$

The free acid is obtained by passing the solution of sodium salt through a column of a cation exchanger in its H^+ form.

$$2H\text{-(Resin)} + Na_2P_2O_6 \longrightarrow 2Na\text{-(Resin)} + H_4P_2O_6$$

Properties. 1. It is a solid, melting at 70°C. It forms well defined crystals having composition $H_4P_2O_6.2H_2O$ which melt at 62°C.

2. It is stable towards alkalies and does not decompose even when heated with 80% NaOH at 200°C. However, in the presence of acids, it is readily hydrolysed giving a mixture of phosphorous and phosphoric acids.

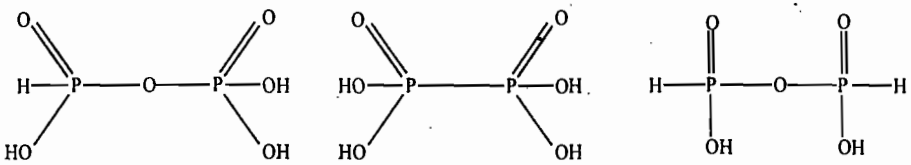
$$H_4P_2O_6 + H_2O \longrightarrow H_3PO_3 + H_3PO_4$$

3. It slowly undergoes rearrangement and disproportionation above room temperature to give a mixture of isohypophosphoric acid, pyrophosphoric acid and pyrophosphorous acid.

Structure. Hypophosphoric acid is a tetrabasic acid, the dissociation constants for the four stages of ionisation being

$$K_1 = 6{\cdot}4\times10^{-3} \quad K_2 = 1{\cdot}5\times10^{-5} \quad K_3 = 5{\cdot}4\times10^{-8} \quad K_4 = 9{\cdot}4\times10^{-11}$$

Accordingly, the structure of the acid is given below. The structures of isohypophosphoric acid (which is a tribasic acid) and pyrophosphorous acid (which is a dibasic acid) are also given below.



iso hypophosphoric acid hypophosphoric acid pyrophosphoric acid

Orthophosphoric Acid, H_3PO_4. This is the best known oxoacid of phosphorus and is commonly known as **phosphoric acid.** It is prepared by the following methods.

1. By adding phosphorus pentoxide to water and boiling the solution.

$$P_4O_{10} + 6H_2O \longrightarrow 4H_3PO_4$$

A small amount of metaphosphoric acid that may be formed, changes readily into orthophosphoric acid in the boiling solution.

2. In the laboratory, the best method for its preparation is to react pure white phosphorus with a solution of nitric acid of specific gravity 1·2 (obtained by adding an equal volume of water to concentrated nitric acid of density 1·4); when the following reaction takes place :

$$P_4 + 20HNO_3 \longrightarrow 4H_3PO_4 + 20NO_2 + 4H_2O$$

The solution is concentrated by heating and when it becomes syrupy at about 166 – 170°C, it is allowed to cool over concentrated sulphuric acid in a vacuum desiccator. The phosphoric acid separates out in a crystalline form.

Manufacture. There are two methods of its manufacture.

1. By the action of concentrated sulphuric acid with rock phosphate or bone ash each of which contains calcium phosphate.

$$Ca_3(PO_4)_2 + 3H_2SO_4 \longrightarrow 3CaSO_4 + 2H_3PO_4$$

The mixture is allowed to stand after reaction when calcium sulphate settles down. The clear supernatant syrupy liquid is separated. It contains about 85 per cent phosphoric acid (*syrupy* phosphoric acid) and this is the form in which it is generally used.

2. Phosphorus pentoxide is first prepared commercially by the combustion of phosphorus vapour in air or by heating calcium phosphate and sand in electric furnace.

$$P_4 + 5O_2 \longrightarrow P_4O_{10}$$

$$2Ca_3(PO_4)_2 + 6SiO_2 \longrightarrow 6CaSiO_3 + P_4O_{10}$$

Phosphorus pentoxide in either case is then dissolved in water giving phosphoric acid.

$$P_4O_{10} + 6H_2O \longrightarrow 4H_3PO_4$$

Properties. 1. The concentrated phosphoric acid (85%) is a clear 'syrupy' liquid which on the removal of water at a low temperature in vacuum yields six-sided prismatic crystals melting at 42·3°C.

2. It combines with water giving the semi-hydrate of the formula $2H_3PO_4.H_2O$ which melts at about 29°C.

3. It decomposes on heating, giving pyrophosphoric acid at 250°C,

$$2H_3PO_4 \xrightarrow{250°C} H_4P_2O_7 + H_2O$$

and metaphosphoric acid at higher temperatures.

$$H_4P_2O_7 \xrightarrow{600°C} 2HPO_3 + H_2O$$

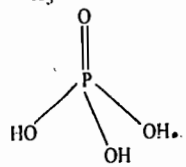
4. It is a tribasic acid, ionising in three stages, as represented below :

$$H_3PO_4 \rightleftharpoons H^+ + H_2PO_4^- ; \qquad K_1 = 7{\cdot}5\times10^{-3}$$

$$H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-} ; \qquad K_2 = 6{\cdot}2\times10^{-8}$$

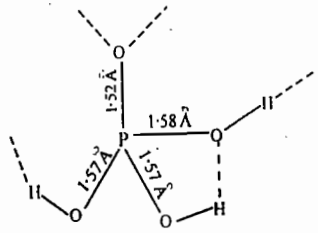
$$HPO_4^{2-} \rightleftharpoons H^+ + PO_4^{3-} ; \qquad K_3 = 1{\cdot}0\times10^{-13}$$

As is evident from the ionisation constants given above, the first ionisation takes place to a considerable extent, the second ionisation takes place only slightly while the third ionisation is extremely small. It forms three series of salts.



Being a tribasic acid, the structure of the acid is as shown.

The crystalline phosphoric acid has a hydrogen bonded layer structure in which tetrahedral PO_4 groups are bonded by hydrogen bonds, as shown in the figure. The hydrogen bonding is responsible for the **syrupy** nature of the acid.



Pyrophosphoric Acid, $H_4P_2O_7$. This acid is also called diphosphoric acid. It is obtained by heating orthophosphoric acid to 250°C.

$$2H_3PO_4 \longrightarrow H_4P_2O_7 + H_2O$$

It is a obtained in pure form by heating orthophosphoric acid with $POCl_3$.

$$5H_3PO_4 + POCl_3 \longrightarrow 3H_4P_2O_7 + 3HCl$$

Properties. 1. It is a colourless crystalline solid melting at 61°C.

2. It is reconverted into orthophosphoric acid on boiling with water. It is a slightly stronger acid than phosphoric acid.

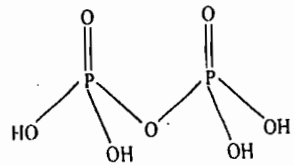
$$H_4P_2O_7 + H_2O \longrightarrow 2H_3PO_4$$

Th dissociation constants for the four stages of dissociation are : $K_1 = 1\times10^{-1}$; $K_2 = 3{\cdot}2\times10^{-2}$; $K_3 = 1{\cdot}7\times10^{-6}$; $K_4 = 6{\cdot}0\times10^{-9}$

3. It is a tetrabasic acid. However, only two series of salts, *e.g.*, $Na_2H_2P_2O_7$, and $Na_4P_2O_7$, are readily obtained. Tetraethyl ester, $(C_2H_5)_4P_2O_7$, has also been obtained.

4. When heated strongly, it yields metaphosphoric acid.

$$H_4P_2O_7 \xrightarrow{600°C} 2HPO_3 + H_2O$$



Structure. Pyrophosphoric acid has been assigned the structure as shown :

Metaphosphoric Acid, HPO_3. This acid is obtained on treating phosphorus pentoxide with a small amount of water,

$$P_4O_{10} + 2H_2O \longrightarrow 4HPO_3$$

or on heating orthophosphoric acid or pyrophosphoric acid strongly.

$$H_3PO_4 \xrightarrow{600°C} HPO_3 + H_2O$$

$$H_4P_2O_7 \xrightarrow{600°C} 2HPO_3 + H_2O$$

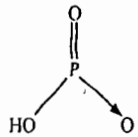
Properties. 1. It is a transparent glassy solid and is, therefore, also known as **glacial phosphoric acid.** It melts at 38·4°C within a range. It is soluble in water.

2. The solution of the acid in water changes into orthophosphoric acid on boiling.

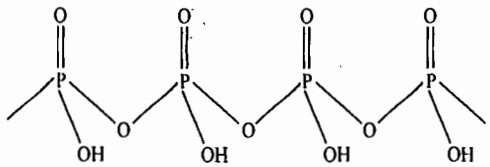
$$HPO_3 + H_2O \longrightarrow H_3PO_4$$

3. *It is a monobasic acid forming salts known as metaphosphates, e.g.,* $NaPO_3$.

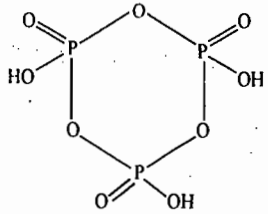
Structure. Metaphosphoric acid is monobasic. The structure of the monomer, based on its formation from orthophosphoric acid by the elimination of water molecule, may be represented as shown.



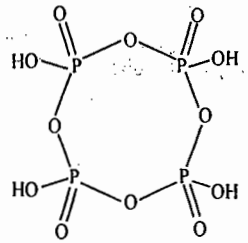
However, it does not exist as a simple monomer, rather it exists as a polymer. The acid is, therefore, represented as $(HPO_3)_n$ and has the structure given below :



Trimetaphosphoric acid $(HPO_3)_3$ and tetrametaphosporic acid $(HPO_3)_4$, are known to have cyclic structures, as shown below :



$(HPO_3)_3$
Trimetaphosphoric acid



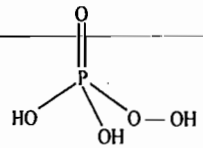
$(HPO_3)_4$
Tetrametaphosphoric acid

Peroxophosphoric Acids. Two peroxophosphoric acids are known. They are **peroxomonophosphoric acid, H_3PO_5** and **peroxodiphosphoric acid, $H_4P_2O_8$.** Both are strong oxidising agents.

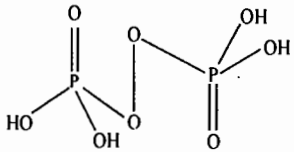
Peroxomonophosphoric acid is obtained in solution by treating phosphorus pentoxide with 30% hydrogen peroxide.

Peroxodiphosphoric acid is obtained by electrolysis of a concentrated solution of secondary potassium phosphate and potassium fluoride.

Structures. The structures of the two peroxophosphoric acids are represented below :

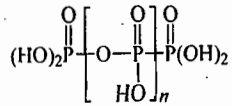


Peroxomonophosphoric acid



Peroxodiphosphoric acid

Apart from these, a number of polyphosphoric acids and their salts are known. Their general structure is as given below.



(n = 1 to 18)

Oxoacids of Arsenic, Antimony and Bismuth

Oxoacids of Arsenic. The nature of the lower oxoacid of arsenic, *viz.*, arsenious acid, H_3AsO_3 is not fully established. It is, therefore, safely represented as $As_2O_3.xH_2O$. It is readily oxidised even on exposure to air. The higher oxoacid, *viz.*, *arsenic acid,* H_3AsO_4, is well known. It is obtained by reacting arsenic metal with concentrated HNO_3 when white crystals of $H_3AsO_4.1/2H_2O$ are obtained. Unlike H_3PO_4, it is a moderately strong oxidising agent in acid solution. H_3AsO_4 is tribasic but it is somewhat weaker than H_3PO_4.

Oxoacids of Antimony. No lower oxoacid of antimony is known. The higher acid, too, exists only in solution. It has the formula H_3SbO_3. It is formed by the oxidation of antimony metal with concentrated HNO_3.

Oxoacids of Bismuth. Bismuth gives one well defined oxoacid, *viz.*, metabismuthic acid, $HBiO_3$, which exists as a scarlet red solid. The compound H_3BiO_3 is basic in character and can be better represented as $Bi(OH)_3$

6. Sulphides

With the exception of nitrogen, all the elements of Group 15 form sulphides. Phosphorus directly combines with sulphur above 100°C to form a number of sulphides, the most important of which are P_4S_3, P_4S_5, P_4S_7 and P_4S_{10}. The sulphide P_4S_3 is used commercially in match industry. The structures of all the four sulphides are known. The sulphide P_4S_{10} has the same structure as P_4O_{10}. The structures of other sulphides are as shown in Fig. 6. It may be noted that the lines between the atoms do not indicate the exact bond order.

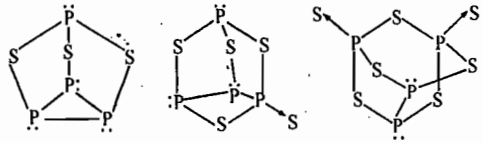


Fig. 6. Structures of P_4S_3, P_4S_5 and P_4S_7

Arsenic directly combines with sulphur to form the sulphides As_4S_3, As_4S_4, As_2S_3 and As_2S_5. The last two sulphides can also be precipitated by passing H_2S gas through solutions of As (III) and As (V) salts acidified with HCl.

Antimony forms the sulphides Sb_2S_3, Sb_2S_4 and Sb_2S_5 by direct interaction of antimony and sulphur. The sulphides Sb_2S_3 and Sb_2S_5 can also be obtained by precipitation with H_2S from Sb (III) and Sb (V) salt solutions.

Bismuth gives dark brown Bi_2S_3 on precipitation of Bi(III) salt solutions by H_2S. A sulphide BiS_2 is obtained as grey needles by direct interaction of Bi and sulphur at 1250°C under high pressure.

The stability of sulphides increases with increase in atomic mass of the element. Their acidic character decreases on moving down the group. The sulphides of arsenic and antimony are soluble in yellow ammonium sulphide while bismuth sulphide is not. The solubility is due to the formation of anionic complexes.

II. Important Compounds of Elements of Group 15

NITRIDES

Nitrides can be prepared either by the direct reaction of nitrogen or ammonia with the metal or by

thermal decomposition of metal amides.

$$Ca + N_2 \longrightarrow Ca_3N_2$$

$$3Mg + 2NH_3 \longrightarrow Mg_3N_2 + 3H_2$$

$$3Ba(NH_2)_2 \longrightarrow Ba_3N_2 + 4NH_3$$

The nitrides can be classified into the following groups :

1. Salt-like Nitrides. Lithium and alkaline earth metals form nitrides in which the bonding is essentially ionic. Hence, their formulae can be represented as $(Li^+)_3N^{3-}$ and $(M^{2+})_3N_2^{3-}$ (M = Ca, Ba, Sr, Be, Mg). Thermodynamic stability of alkaline earth metal nitrides depends upon the type of the metal ion in the nitride. Thus, whereas Be_3N_2 melts without decomposition at 2200°C, Mg_3N_2 decomposes readily even at about 300°C.

2. Covalent Nitrides. Some common examples of covalent nitrides are BN (graphite-like polymorphs), C_2N_2, P_3N_5, S_2N_2, S_4N_4, etc. The properties of covalent nitrides depend upon the element bonded with nitrogen. These nitrides have, therefore, been described at appropriate places in the book while discussing the compounds of these elements.

3. Diamond-like Nitrides. Group 13 elements (B, Al, Ga, In and Tl) form nitrides with the formula MN. Of these, BN exists in two polymorphic forms analogous to graphite and diamond. The rest of the nitrides of the elements of Group 13 have diamond or SiC structure. The metal – nitrogen bond varies from covalent to partly ionic to essentially metallic as we move down the group, *i.e.*, as we move from lighter to heavier elements. These nitrides are quite hard and stable.

4. Interstitial Nitrides. Interstitial nitrides are formed by transition and innner transition metals. Examples are : ScN, LaN, CeN, TiN, ZrN, HfN, VN, TaN, NbN, CrN, MoN, WN, Ti_2N, etc. The nitorgen atoms in these nitrides occupy the interstitial sites in cubic or hexagonal close packed metal lattices. Some of the nitrides have variable composition and are similar in properties to the interstitial carbides and borides. These nitrides are very hard and chemically inert refractory materials. Their hardness approaches that of diamond. They are highly conducting like metals and have metallic lustre. They are used for making crucibles and high temperature reaction vessels. They have also been tried as heterogeneous catalysts.

5. Nitrido Complexes. The nitrido complexes are prepared by thermal decomposition of azides or by deprotonation of coordinated ammonia. Most of the nitrido complexes have a terminal $[\equiv N]^{3-}$ group as in $[VCl_3N]^-$, $[MoO_3N]^-$, $[WCl_5N]^{2-}$, $[RuN(OH)_2X_4]^-$. The metal to nitrogen distance is much shorter than the normal sigma M – N distance. The nitgrogen in nitrido complexes can also act as a bridge as in $[(H_2O)Cl_4Ru - N - RuCl_4(OH)_2]^{3-}$ complex.

PHOSPHIDES

Stable binary phosphides are formed by almost all elements. They exist in a large number of stoichiometries such as M_2P, M_3P_2, MP_2, MP, M_4P_3, MP_5, M_4P_3, M_6P_5, etc.

Preparation. Binary phosphides are prepared

1. By direct combination of the elements at elevated temperature :

$$nM + mP \xrightarrow{\text{Heat}} M_nP_m$$

2. By the electrolysis of fused metal phosphates to which appropriate metal oxides and halides are added. Thus,

$$\underbrace{(NaPO_3)_n + NaCl + WO_3}_{\text{Fused}} \xrightarrow{\text{Electrolysis}} W_3P$$

3. Reduction of phosphate of the metal with carbon at high temperature.

$$Ca_3(PO_4)_2 + 8C \xrightarrow{1200°C} Ca_3P_2 + 8CO$$

4. Interaction of a metal with phosphine :

$$2PH_3 + 4Ti \longrightarrow 2Ti_2P + 3H_2$$

5. Stoichiometries of phosphides can be changed by heating a given metal phosphide with the metal or phosphorus. Thus,

$$Th_3P_4 + Th \xrightarrow{900°C} 4ThP$$

$$4RuP + P_4 \xrightarrow{650°C} 4RuP_2$$

Classification of Phosphides. Phosphides can be classified into the following categories :

1. Metal-rich phosphides. They are hard, brittle and refractory materials with a metallic lusture. They have high thermal and electrical conductivity. The P atom in crystals of such phosphides is surrounded by 6, 7, 8, and 9 metal atoms. (The exact type of crystal structure depends upon the M/P size ratio). Their structures have more M atoms than P atoms.

2. Monophosphides (MP). These can adopt a variety of crystalline structures depending on their M/P size ratios. Phosphides of elements of Group 13 have zinc blende type of structure ; SnP has NaCl type of crystal structure, VP has hexagonal NiAs type of crystal structure whereas MoP has WC type of structure. More complicated crystal structures also exist for these monophosphides.

3. Phosphorus-rich Phosphides. (M_nP_m, m > n). Such phosphides have lower melting points and lower thermal stabilities compared to metal-rich or monophosphides. They are semiconductors and contain catenated P atoms in their crystal structures, *i.e.*, such phosphides may contain chains, double chains, and layers of P atoms in their crystal structure, as in PdP_2, $ZnPbP_{14}$ and CuP_2, respectively.

4. Phosphides with Ionic-Covalent Bonding. Examples are phosphides of Li, Be, Mg and lanthanides. These phosphides have appreciable ionic–covalent and metal–metal bonding character.

Uses. Ferrophosphorus is used for blasting rocks when mixed with dynamite. It is also used in the manufacture of steel. Monophosphides are valuable semiconductors. Ca_3P is used by navy to generate flares in the sea. Nb, Ta and W give phosphides which are resistant to attack by oxygen even at very high temperatures.

ARSENIDES, ANTIMONIDES AND BISMUTHIDES

Alkali metals form arsenides, antimonides and bismuthides of general formula M_3A (A = As, Sb, Bi). Similarly, alkaline earth metals form compounds of the formula M_3A_2 with arsenic, antimony and bismuth. Some of the alkali metals form compounds with As, Sb and Bi having formula MA. Of these, LiBi and NaBi have alloy structures and are superconductors below 2·47 K and 2·22 K, respectively. Some others such as LiAs, NaSb and KSb have parallel spirals of long length containing As and Sb atoms. They have metallic lusture and conduct electricity. Sc, Y, La, lanthanides and actinides form compounds with As, Sb, Bi which have the stoichiometries MA, M_3A_4 and MA_2. These compounds are crystalline and are metallic in nature.

Transition metals form a large number of compounds with As, Sb, Bi of which the important ones are $CoAs_3$ and NiAs. Their crystal structure is similar to that of FeS_2 (pyrites).

Group 13 metals (Al, Ga, In, Tl) form a number of compounds with As, Sb and Bi which are commercially used as semiconductors.

Group 14 elements also form compounds like GeAs, $GeAs_2$, SnAs (a superconductor below 3·5 K) and Sn_4As_3 (a superconductor below 1·2 K), Sn and Pb also form a number of industrially important compounds with As, Sb and Bi.

HYDRAZINE, N_2H_4

Preparation. 1. Raschig's method. Hydrazine is prepared on a **commercial** as well as **laboratory scale** by boiling aqueous ammonia with an alkaline solution of sodium hypochlorite in the presence of a small amount of glue or gelatin. The over-all reaction is as follows :

$$2NH_3 + NaOCl \longrightarrow N_2H_4 + NaCl + H_2O$$

Actually, the reaction proceeds in two steps. In the first step, hypochlorite reacts with ammonia giving chloramine, NH_2Cl.

(*a*) $$NH_3 + NaOCl \longrightarrow NaOH + NH_2Cl$$

The chloramine then reacts with ammonia producing hydrazine.

(*b*) $$NH_3 + NaOH + NH_2Cl \longrightarrow N_2H_4 + NaCl + H_2O$$

The hydrazine produced may react with chloramine giving nitrogen.

(*c*) $$2NH_2Cl + N_2H_4 \longrightarrow 2NH_4Cl + N_2$$

This decreases the yield of hydrazine.

The presence of a small amount of glue or gelatin has been found to be very useful for suppressing the undesirable reaction (*c*) and also for catalyzing the reaction (*b*). The resulting solution contains 60 – 70 per cent of hydrazine which is distilled to get a dilute aqueous solution of hydrazine that may be concentrated to about 85 per cent by further distillation. Anhydrous hydrazine may be obtained by further distillation over barium oxide, sodium hydroxide or potassium hydroxide.

Alternatively, the hydrazine present in the resulting solution is precipitated as sparingly soluble crystalline hydrazine sulphate, on treatment with sulphuric acid.

$$N_2H_4 + H_2SO_4 \longrightarrow \underset{\text{Hydrazine sulphate}}{N_2H_4.H_2SO_4}$$

The precipitate is removed and treated with an alkali when hydrazine hydroxide $H_2N.NH_3OH$ is obtained. This is distilled under reduced pressure over an alkaline dehydrating agent, such as barium oxide or solid sodium hydroxide, to liberate free hydrazine.

$$N_2H_5OH + BaO \longrightarrow \underset{\text{Hydrazine}}{N_2H_4} + Ba(OH)_2$$

Physical Properties. Anhydrous hydrazine is a colourless fuming liquid (m.p. 2°C and b.p. 113·5°C), soluble in water in all proportions. It is also soluble in alcohol. It is strongly hygroscopic.

Chemical Properties. 1. Hydrazine may be regarded as derived from NH_3 by the replacement of one H atom by the NH_2 group. It behaves as a diacid base.

$$N_2H_4\,(aq) + H_2O \rightleftharpoons N_2H_5^+ + OH^- ; \qquad K_b = 8{\cdot}5\times10^{-7}$$

$$N_2H_5^+\,(aq) + H_2O \rightleftharpoons N_2H_6^{2+} + OH^- ; \qquad K_b = 8{\cdot}9\times10^{-16}$$

Thus, it forms two series of hydrazinium salts containing $N_2H_5^+$ and $N_2H_6^{2+}$ ions. For example, with hydrochloric acid it forms hydrazine monochloride $N_2H_5^+Cl^-$ and hydrazine dichloride $(N_2H_6)^{2+}Cl_2^-$.

2. Hydrazine burns rapidly and completely in air with a considerable evolution of heat.

$$N_2H_4 + O_2 \longrightarrow N_2 + 2H_2O ; \qquad \Delta H = -622 \text{ kJ}$$

This has created lot of interest in this compound and some of its alkyl derivatives are used as potential **rocket fuels.**

3. It reacts with sodium in an inert atmosphere giving sodium hydrazide and evolving hydrogen.

$$2N_2H_4 + 2Na \longrightarrow 2N_2H_3Na + H_2$$

4. It reacts with nitrous acid giving hydrazoic acid.

$$N_2H_4 + HNO_2 \longrightarrow 2H_2O + \underset{\text{Hydrazoic acid}}{HN_3}$$

5. Since hydrazine and its salts can be readily oxidised to nitrogen, they are used as powerful reducing agents. Thus, hydrazine reduces salts of platinum, gold and silver to the metallic state.

$$PtCl_4 + N_2H_4 \longrightarrow Pt + N_2 + 4HCl$$

$$4AuCl_3 + 3N_2H_4 \longrightarrow 4Au + 3N_2 + 12HCl$$

$$4AgNO_3 + N_2H_4 \longrightarrow 4Ag + N_2 + 4HNO_3$$

Similarly, it reduces Fehling solution to red cuprous oxide, ferric chloride to ferrous chloride and iodates to iodides.

$$4Cu(OH)_2 + N_2H_4 \longrightarrow 2Cu_2O + 6H_2O + N_2$$

$$4FeCl_3 + N_2H_4 \longrightarrow 4FeCl_2 + N_2 + 4HCl$$

$$2IO_3^- + 3N_2H_4 \longrightarrow 2I^- + 6H_2O + 3N_2$$

Uses. Hydrazine is used as rocket fuel. It is also used as a reagent in organic chemistry.

Structure of hydrazine. Structurally, hydrazine resembles hydrogen peroxide in that both H_2O_2 and N_2H_4 exist in gauche forms at room temperature. The plane containing N – N bond and one of the N – H bonds of one N is at an angle of 95° to the plane containing the N – N bond and one of the N – H bonds of the other N. Thus, the lone pairs of electrons on the two nitrogens are not cis to each other but are at an angle of 95° to each other (Fig. 7).

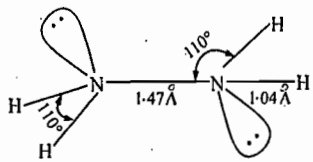

Fig. 7. Structure of hydrazine.

The N – N distance is 1·47 + 0·02 Å, the N – H distance is 1·04 Å and HNH and HNN angles are about 110°C each.

HYDRAZOIC ACID, HN_3

Hydrazoic acid, although formally referred to as a hydride of nitrogen, bears no resemblance to NH_3 and N_2H_4. While ammonia and hydrazine are basic, HN_3 is acidic in character.

Preparation. It is prepared by treating an aqueous solution of hydrazine hydrochloride with nitrous acid ($NaNO_2$ and HCl).

$$N_2H_4.HCl + N_2O \longrightarrow HN_3 + HCl + 2H_2O$$

An alternative method is to first prepare sodium azide (NaN_3) by the oxidation of sodamide by nitrous oxide or sodium nitrate.

$$NaNH_2 + N_2O \xrightarrow{190°C} NaN_3 + H_2O$$

$$3NaNH_2 + NaNO_3 \xrightarrow{175°C} NaN_3 + 3NaOH + NH_3$$

Sodium azide is then distilled with dilute sulphuric acid under reduced pressure.

$$2NaN_3 + H_2SO_4 \longrightarrow Na_2SO_4 + 2HN_3$$

The distillate is an aqueous solution of hydrazoic acid which is concentrated to about 91 per cent by simple heating and dehydrated further with fused calcium chloride.

Properties. Free hydrazoic acid is a colourless liquid, boiling at 37°C. It is dangerously explosive and dissociates into its constituents with the evolution of a large amount of heat.

$$2HN_3 \longrightarrow 3N_2 + H_2\,; \qquad \Delta H = -51{\cdot}5\ \text{kJ}$$

It is a weak acid, its strength being equal to that of acetic acid ($K_a = 1{\cdot}8\times10^{-5}$). Thus,

$$HN_3\,(aq) \rightleftharpoons H^+\,(aq) + N_3^-\,(aq)\,; \qquad K_a = 1{\cdot}8\times10^{-5}$$

It forms salts with alkalies and active metals (Zn, Mg, etc.).

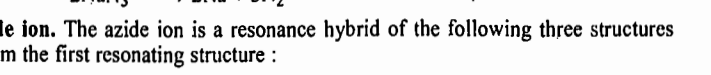
$$HN_3 + NaOH \longrightarrow NaN_3 + H_2O$$

$$2HN_3 + Mg \longrightarrow Mg(N_3)_2 + H_2$$

Salts of heavy metals are highly explosive. Thus, azides of lead, mercury and barium are used in detonation caps because these azides explode on being struck sharply. The azides of alkali metals are not explosive and decompose smoothly and quantitatively when heated to 300°C or above. Thus, sodium azide decomposes to give sodium and nitrogen.

$$2NaN_3 \longrightarrow 2Na + 3N_2$$

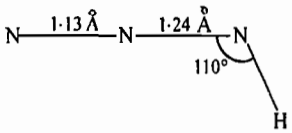
Structure of the azide ion. The azide ion is a resonance hybrid of the following three structures with major contribution from the first resonating structure :



Thus, **the azide ion** has a linear, symmetrical structure, as shown below. The lines between the atoms do not show exact bond order.

$$[N \overset{1{\cdot}16\,\text{Å}}{—} N \overset{1{\cdot}16\,\text{Å}}{—} N]^-$$

In **hydrazoic acid, HN_3,** however, the symmetry is lost and the molecule has a bent structure, as shown. The lines between the atoms do not show the exact bond order.



The electronic structure of the acid is a resonance hybrid of the following two structures :

HYDROXYLAMINE, NH_2OH

It may be regarded as derived from ammonia by the replacement of one H atom by an OH group.

It is prepared by the reduction of nitrites with sulphur dioxide under carefully controlled conditions. A concentrated solution of sodium nitrite is mixed with a solution of sodium carbonate and sulphur dioxide at a temperature below 3°C is passed till the solution becomes just acidic. The following reactions are supposed to take place :

$$Na_2CO_3 + SO_2 + H_2O \longrightarrow NaHSO_3 + NaHCO_3$$

$$NaNO_2 + 3NaHSO_3 \longrightarrow \underset{\substack{\textit{Hydroxlamine}\\ \textit{sodium sulphonate}}}{HON(SO_3Na)_2} + Na_2SO_3 + H_2O$$

The sulphonate can be easily hydrolysed to hydroxylamine.

$$HON(SO_3Na)_2 + 2H_2O \longrightarrow NH_2OH + 2NaHSO_4$$

Alternatively, it is prepared by the electrolytic reduction of nitric acid in 50% H_2SO_4 using amalgamated lead cathode.

$$NO_2 - OH + 6H^+ + 6e^- \longrightarrow NH_2OH + 2H_2O$$

It is a colourless solid melting at 33°C. It is freely soluble in water and lower alcohols. It is unstable and decomposes violently even at 20°C.

$$3NH_2OH \longrightarrow NH_3 + N_2 + 3H_2O$$

The aqueous solution of hydroxylamine is less basic than ammonia ($K_b = 1{\cdot}8\times10^{-5}$). Thus,

$$NH_2OH\,(aq) + H_2O \longrightarrow NH_3OH^+ + OH^-\,; \qquad K_b = 6{\cdot}6\times10^{-9}$$

Like H_2O_2, it acts as an oxidising as well as a reducing agent depending upon circumstances.

NITROGEN TRIFLUORIDE, NF_3

It is conveniently prepared by fluorinating ammonia in the catalytic presence of Cu.

$$4NH_3 + 3F_2 \xrightarrow{Cu} NF_3 + 3NH_4F$$

It can also be prepared by the electrolysis of NH_4F.

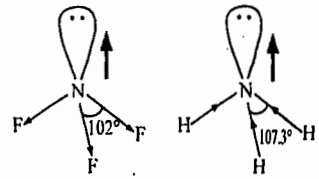
It is a colourless gas (m.p. – 207°C ; b.p. – 129°C) which is quite stable thermodynamically.

The gas acts as a fluorinating agent. It thus converts Cu into CuF.

$$2NF_3 + 2Cu \longrightarrow N_2F_4 + 2CuF$$

As, Sb and Bi also get fluorinated by interaction with NF_3.

NF_3 has a pyramidal structure with FNF angle = ~ 102° and dipole moment = 0·24 D, compared with HNH angle = ~ 107° and dipole moment = 1·48 D in the case of NH_3. The difference in the dipole moments of NF_3 and NH_3 (both of which have pyramidal structure though) is due to the fact that while the dipole moments due to N – F bonds in NF_3 are in *opposite direction* to the direction of the dipole moment of the lone pair on N atom, the dipole moments of N – H bonds in NH_3 are in the *same direction* as the direction of the dipole moment of the lone pair on N atom, an shown.



Because of its lower dipole moment, NF_3 is a weaker ligand than NH_3.

NF_3 is known to form complexes such as $[NF_4]^+$ and $F_3N \rightarrow O$. Thus,

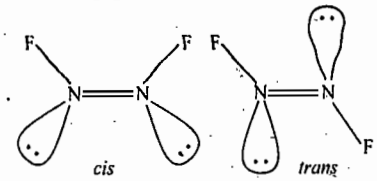
$$NF_3 + 2F_2 + SbF_5 \xrightarrow[\text{High pressure}]{200°C} [NF_4^+][SbF_6]^-$$

DINITROGEN DIFLUORIDE, N_2F_2

Dinitrogen difluoride is best prepared by reacting NHF_2 with KF.

$$2KF + 2HNF_2 \xrightarrow[\text{temperature}]{\text{low}} 2KF.HNF_2 \xrightarrow{\text{Room temperature}} N_2F_2 + 2KHF_2$$

The reaction yields both cis and trans isomers whose structures are as shown.



Both the isomeric forms are gases at room temperature, the cis form boiling at – 106°C and the trans form boiling at –112°C. The cis form is thermodynamically more stable than the trans form.

Above 70°C, nearly 90% of N_2F_2 is present in the cis form :

$$\text{trans } N_2F_2 \overset{>70^\circ C}{\rightleftharpoons} \underset{(\sim 90\%)}{\text{cis } N_2F_2}$$

If, however, the isomeric mixture is treated with $AlCl_3$ or the chlorides of bivalent Mn, Co, Ni and Fe, at low temperature, the major product is trans N_2F_2.

The cis form reacts *selectively* with AsF_5 to form $[N_2F]^+[AsF_6]^-$ which when reacted with NaF – HF, regenerates the original compounds. The trans form does not react with AsF_5.

$$\underset{\text{Mixture of } cis \text{ and trans isomers}}{N_2F_2} + AsF_5 \longrightarrow \underset{\text{Formed by cis } N_2F_2}{[N_2F]^+[AsF_6]^-} + \underset{trans}{N_2F_2}$$

$$[N_2F]^+[AsF_6]^- \xrightarrow{NaF-HF} \underset{cis}{N_2F_2} + AsF_5$$

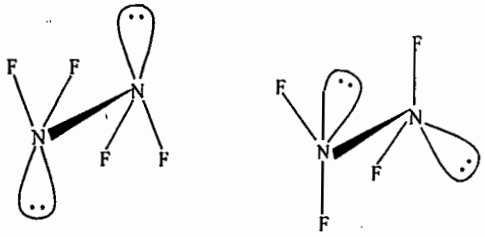
DINITROGEN TETRAFLUORIDE, N_2F_4

N_2F_4 is prepared by reacting HNF_2 with NaClO.

$$2HNF_2 \xrightarrow{NaClO} N_2F_4 + H_2O$$

HNF_2, in turn, is obtained by first fluorinating urea and then treating the fluorinated product with concentrated sulphuric acid.

N_2F_4 exists both in the staggered and the gauche conformations as shown below :



Staggered Form (Side View) Gauche Form

It is a colourless gas (b.p. – 73°C ; m.p. – 164°C).

It is a strong fluorinating agent. Thus,

$$SiH_4 + N_2F_4 \longrightarrow SiF_4 + N_2 + 2H_2$$

$$10Li + N_2F_4 \longrightarrow 4LiF + 2Li_3N$$

$$AsF_5 + N_2F_4 \longrightarrow [N_2F_3]^+[AsF_6]^-$$

N_2F_4 easily yields, at room temperature, the free radical $\cdot NF_2$ which reacts readily with a number of compounds. For example,

$$N_2F_4 \rightleftharpoons 2(\cdot NF_2) \xrightarrow{Cl_2} 2ClNF_2$$

$$N_2F_4 \rightleftharpoons 2(\cdot NF_2) \xrightarrow{2NO} 2ONNF_2$$

TRISILYLAMINE, $N(SiH_3)_3$

Trisilylamine is prepared by reacting monochlorosilane with ammonia.

$$3SiH_3Cl + 4NH_3 \longrightarrow N(SiH_3)_3 + 3NH_4Cl$$

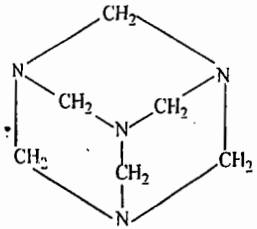
Trisilylamine is a trigonal planar compound with N orbitals in sp^2 hybrid state, unlike trimethyl or triethylamine which is pyramidal and has N orbitals in sp^3 hybrid state. There is considerable $d\pi$ overlap between the *p* orbital (containing the lone pair) of N atom and the vacant $d\pi$ orbitals of Si atoms. The trigonal planar structure of $N(SiH_3)_3$ is, thus, strengthened due to $p\pi - d\pi$ bonding.

Since the lone pairs of electrons of N atom are engaged in $p\pi - p\pi$ bonding between N and Si, they are no longer available for donation to Lewis acids. Trisilylamine, therefore, behaves as a much weaker base compared to trimethylamine or triethylamine. Hence, trisiylamine does not form adducts with BH_3 even at low temperature whereas trimethylamine or triethylamine does so readily. Due to the same reason, $N(SiH_3)_3$ acts as a much weaker ligand compared to $N(CH_3)_3$ and $N(C_2H_5)_3$.

HEXAMETHYLENE TETRAMINE, HEXAMINE, UROTROPINE, $(CH_2)_6N_4$

Hexamethylene tetramine is prepared by reacting formaldehyde with concentrated ammonia solution.

$$6HCHO + 4NH_3 \longrightarrow (CH_2)_6N_4 + 6H_2O$$

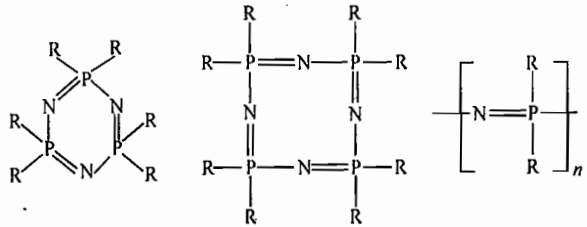


Hexamine has a complicated ring structure. The bonding (but not the exact orientations of the rings) in the compound is roughly as shown.

It is a white crystalline compound soluble in water. It is basic in nature and is used for adjusting the *p*H of aqueous solutions during *p*H-sensitive complexometric titrations. Hexamine is used for the treatment of gout and rheumatism.

PHOSPHAZINES, $(NPR_2)_n$

Phosphazines are cyclic or chain polymers which contain $-N=\underset{R}{\overset{R}{P}}-$ as the repeating unit. Common phosphazines exist as cyclic trimers, cyclic tetramers and also as linear polymers, as shown below.



Cyclic Trimer Cyclic Tetramer Linear Polymer

Chlorophosphazines. Two important chlorophosphazines are described here.

Hexachlorocyclotriphosphazine, $(NPCl_2)_3$. It is prepared by the reaction of PCl_5 with NH_4Cl in the presence of $C_2H_4Cl_2$ or C_6H_5Cl under controlled conditions.

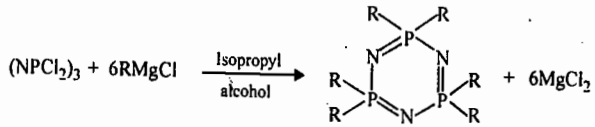
$$3PCl_5 + 3NH_4Cl \xrightarrow[\text{or } C_6H_5Cl]{C_2H_4Cl_2} (NPCl_2)_3 + 12HCl$$

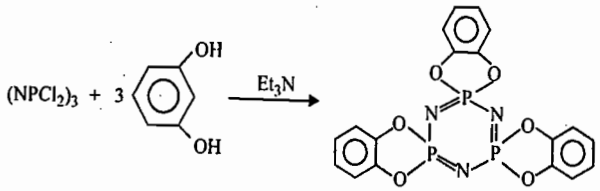
The above reaction produces a mixture of $(NPCl_2)_3$ and $(NPCl_2)_4$. Any tetramer produced along with the trimer can be easily separated since the trimer sublimes in vacuum at 50°C as a white crystalline solid whereas the tetramer does not do so under these conditions.

Hexachlorocyclotriphosphazine is the key material for the synthesis of a number of linear polymers. Thus,

$$(NPCl_2)_3 + 6NaF \longrightarrow (NPF_2)_3 + 6NaCl$$

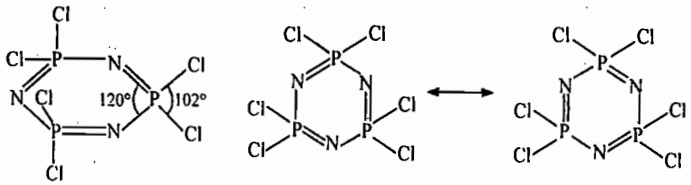
$$(NPCl_2)_3 + 6NaOR \longrightarrow [NP(OR)_2]_3 + 6NaCl$$



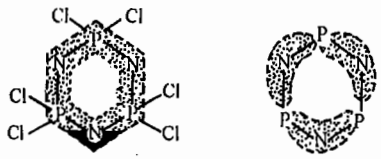


The mechanism of replacement of Cl by other nucleophiles is not well understood. However, it appears to involve S_N2 attack on P atom.

Structure of Hexachlorocyclotriphosphazine. The trimer is known to be a planar six-membered ring (structure I) in which the bond angles are consistent with sp^2 hybridisation of N orbitals and an approximate sp^3 hybridisation of P orbitals of the ring. Resonance structures II and III can also be drawn, as in the case of benzene, indicating aromaticity in the ring.



But unlike benzene which involves extensive $p\pi$–$p\pi$ bonding, phosphazine involves $p\pi$–$d\pi$ bonding. The extent of π bonding in phosphazine appears to be quite appreciable as the N – P distance (1·6 Å) is considerably shorter than the normal N – P single bond distance (1·75 – 1·8Å). The main question about the π bonding is whether the π electron charge cloud is *delocalised on all the ring atoms*, as shown in (I) or *there are more intensely localised islands within the NPN segments*, as shown in (II).

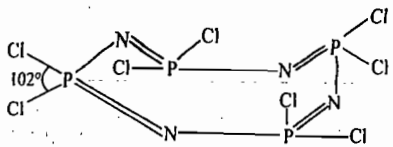


Complete delocalisation of π electron charge cloud. (I)

Localised islands of π electron charge cloud over NPN segments. (II)

This question remains unanswered. However, considering the difference in the electronegativities of N and P and the location of a lone pair of electrons on each N atom of the ring, structure (II) appears to be more probable than structure (I).

Structure of Octachlorocyclotetraphosphazine. $(NPCl_2)_4$ has a 'tub-like' structure, as shown.



This structure is, evidently, non-planar.

Phosphazines of high molar masses have been discussed in details in Chapter 35 on 'Inorganic Polymers'.

Another polymeric nitrogen compound of phosphorus is $P_4(NR)_6$, the structure of this compound is analogous to P_4O_6 in which the bridging oxygens are replaced by bridging NR groups. Another polymeric nitrogen compound is $P(N(CH_3)_2)_3$ which is analogous to $P(OR)_3$ in which OR groups are replaced by $N(CH)_3$ groups.

Organometallic Compounds of Grop 15 Elements

These have been discussed in details in Chapter 34 on Organometallic Compounds.

FERTILIZERS

Essential Nutrients for Plants. Plants require phosphorus, potassium, nitrogen, sulphur, calcium, iron and magnesium, besides traces of a few other elements such as copper, boron, zinc, manganese, molybednum and cobalt for their growth and health. These elements are generally present in the soil to more or less extent in the form of minerals or otherwise. However, after a few years of continuous cropping, the soil becomes poorer and poorer in these materials and there is need to put back what has been taken out from the soil by successive crops. If the soil is not replenished by what it has lost, in time, it would become less productive and, in extreme cases, may become even infertile. In order to keep up soil fertility and to get good yields of various crops, it is necessary to add materials containing nitrogen, phosphorus and potassium in the form of *manures* which may be natural or artificial. The artificial manures are called **chemical fertilizers.** Nitrogen, phosphorus and potassium are regarded as essential plant nutrients.

Functions of Essential Nutrients

1. **Nitrogen.** Nitrogen is highly essential for rapid growth of plants and hence it improves the yields of crops. It also raises protein content of the crops and thus adds to their food value.

2. **Phosphorus.** Phosphates, the potential source of phosphorus for plants, are highly valuable fertilizers. Experiments have shown that phosphates promote early growth as well as early maturity of plants. The addition of phosphates also increases resistance of plants to frost and disease and helps in formation of high yielding seeds.

3. **Potassium.** Potassium develops a healthy root system which helps the plants to get regular supply of nutrients from the soil. As a result, we get a healthy plant which develops sufficient resistance towards various diseases. It also helps in the formation of albuminoids and carbohydrates in the various plants.

Potassium compounds are generally used in mixed fertilizers containing nitrogen and phosphorus. Such materials are commonly referred to as **N.P.K. fertilizers.**

Types of Manures. There are two types of manures :

1. *Natural* and 2. *Artificial Manures* (*i.e., Chemical Fertilizers*)

Natural Manures. Natural manures generally added to soil include animal dung, blood, bones, horns, hair stock, leather waste, fish scrap, night soil, animal excreta, guano, sewage, sludge, etc. Manures prepared out of vegetable growth such as leaves, barks, seeds, ashes, etc., are also included in this category. Leguminous plants grown in the soil are also ploughed back into the soil for replenishing nitrogen content of the soil.

Artificial Manures or Fertilizers. Artificial manures are generally called **fertilizers.** These are chemical compounds containing nitrogen, phosphorus or potassium.

Every compound of nitrogen, phosphorus or potassium *cannot* be used as a fertilizer. A good fertilizer must be *soluble in water* and nitrogen, phosphorus or potassium contained in it should be in such a form that it can *readily be made available* to the plants. The common **nitrogenous fertilizers** are ammonium sulphate, ammonium nitrate, urea and nitrates of potassium and calcium. The most important **phosphatic manure** is calcium superphosphate. The most widely used compound of **potassium** is

potassium nitrate. Potassium chloride and potassium sulphate are also used in fertilizers.

Sometimes it is necessary to add certain chemicals which are not plant nutrients themselves but they help the nutrients already present in the soil to be more readily available to the plants. These are called **stimulant fertilizers.** Examples are lime and gypsum.

NITROGENOUS FERTILIZERS

Although sufficient amount of nitrogen is available in the atmosphere, it is of no use as such for the plants because excepting *leguminous plants, algae, fungi* and *mosses*, no other plant can assimilate free nitrogen for its growth. This nitrogen, therefore, has to be converted into those forms of chemical compounds which can easily be assimilated by plants.

The important nitrogenous compounds used as fertilizers are described below.

1. Ammonium sulphate. There are two important sources of ammonium sulphate.

a. Ammonia liquor obtained from dry distillation of coal. The bituminous coal which is used for this purpose contains about 1·5 per cent of nitrogen in combined state. During the process of distillation, this nitrogen gets converted into ammonium salts and collects along with other volatile matter as *ammonia liquor*. The ammonium salts present in the liquor are ammonium carbonate, $(NH_4)_2CO_3$, ammonium sulphide, $(NH_4)_2S$, ammonium chloride, NH_4Cl and ammonium sulphate, $(NH_4)_2SO_4$.

In order to recover ammonia, the liquor is mixed with lime and heated in stills by steam when the salts decompose evolving ammonia.

$$2NH_4Cl + Ca(OH)_2 \longrightarrow CaCl_2 + 2H_2O + 2NH_3$$

$$(NH_4)_2SO_4 + Ca(OH)_2 \longrightarrow CaSO_4 + 2H_2O + 2NH_3$$

Ammonia coming off from the salts along with steam is passed through 60 per cent sulphuric acid when crystals of ammonium sulphate, $(NH_4)_2SO_4$, separate out.

$$2NH_3 + H_2SO_4 \longrightarrow (NH_4)_2SO_4$$

b. Ammonia obtained from Haber process. As is well known, ammonia is prepared commercially by direct combination of nitrogen and hydrogen at a temperature of about 500°C and under a pressure of 100–1000 atm in the presence of a catalyst (finely divided iron with a little molybdenum).

$$N_2 + 3H_2 \overset{100-1000\text{ atm, }500°C}{\rightleftharpoons} 2NH_3$$

Ammonia obtained as above is converted into ammonium sulphate by treatment with sulphuric acid as mentioned above or with gypsum in the presence of CO_2.

$$2NH_3 + CO_2 + CaSO_4.2H_2O \longrightarrow (NH_4)_2SO_4 + CaCO_3 + H_2O$$

Calcium carbonate is removed by filtration. It is an important by-product. The solution is concentrated and crystallised. Ammonium sulphate contains theoretically over 25 per cent ammonia. The compound, as obtained commercially, however, contains only about 20 per cent of ammonia. This ammonia cannot be easily utilized by plants. It is first converted into nitrite and nitrate ions through the action of *nitrifying bacteria* present in the soil. The nitrite and nitrate can be taken up easily by plants from the soil.

Ammonium sulphate should not be used too frequently as this renders the soil *acidic*. This is particularly so when the soil is poor in lime which, if present, can neutralise acidity to some extent. It should be used after the seeds have germinated.

2. Calcium Ammonium Nitrate (CAN). It is also known as **nitro limestone**. Ammonia synthesised by Haber process is partly converted into nitric acid by Ostwald's process using platinum or platinum-rhodium as the catalyst. Nitric acid and ammonia are then made to react with each other to give ammonium nitrate.

The solution is concentrated and treated with powdered limestone. The slurry so obtained is converted into small *pellets* in specially designed evaporators and sold under the name **calcium ammonium nitrate.**

Ammonium nitrate is explosive. The function of limestone is to prevent it from exploding.

Calcium ammonium nitrate is *hygroscopic*. The pellets are, therefore, coated with soap stone to protect them from moisture.

Calcium ammonium nitrate is considered to be superior to ammonium sulphate in some respects. Firstly, it is *more soluble in water* and secondly, the presence of calcium *prevents development of acidity in the soil.*

3. Urea. Urea is a better manure than either ammonium sulphate or calcium ammonium nitrate. This is because the ammonia liberated by hydrolysis

$$O{=}C(NH_2)_2 + H_2O \longrightarrow 2NH_3 + CO_2$$

is assimilated by the soil through the interaction of *nitrifying bacteria* as in the case of ammonium sulphate or calcium ammonium nitrate. The only thing that it leaves behind is carbon dioxide which, unlike sulphate or nitrate ion, does no harm to the soil. The sulphate and nitrate ions render the soil acidic.

Another advantage lies in the fact that it contains much higher percentage of nitrogen than either ammonium sulphate or ammonium nitrate. There is also no risk in storage of urea as it is not subject to explosion hazards.

However, there is one disadvantage. Urea is not so stable as other nitrogenous fertilizers. It decomposes even at lower temperatures particularly in humid atmosphere releasing ammonia and carbon dioxide.

Urea is prepared on a large scale by reacting ammonia (obtained from Haber process) with carbon dioxide at 135°C and about 220 atm pressure to yield ammonium carbamate, some of which decomposes simultaneously to give urea.

(*i*) $$2NH_3 + CO_2 \longrightarrow \underset{\text{Amm. carbamate}}{NH_2COONH_4}$$

(*ii*) $$NH_2COONH_4 \longrightarrow \underset{\text{Urea}}{NH_2CONH_2} + H_2O$$

The undecomposed ammonium carbamate is processed separately under reduced pressure to give urea.

In the modern manufacturing plants, the production of urea has been made highly economical. Hydrogen required for the manufacture of ammonia and carbon dioxide required for reacting with ammonia, are both obtained from *naphtha*. For this purpose, crude naphtha from oil refineries is subjected to *partial combustion* in specially designed burners to give a mixture of hydrogen and carbon monoxide. The mixture is made to react with *steam* in the presence of a *catalyst* (usually a mixture of Fe, Cr and Co) when carbon monoxide is oxidised to carbon dioxide.

$$\underbrace{CO + H_2}_{\text{From naphtha}} + \underset{\text{(steam)}}{H_2O} \longrightarrow CO_2 + 2H_2$$

Carbon dioxide is separated by washing with water under pressure or by treatment with $KHCO_3$ solution.

The hydrogen, obtained as above, is converted into ammonia by Haber process. The carbon dioxide, recovered easily from the aqueous or the alkali carbonate solution, is compressed and reacted with ammonia to give urea, as indicated by chemical equations (*i*) and (*ii*) given above.

PHOSPHATIC FERTILIZERS

The *phosphate rock*, which is primarily tricalcium phosphate, $Ca_3(PO_4)_2$ and *apatite*, $CaF_2.3Ca_3(PO_4)_2$, are too little soluble in water to serve as a source of phosphorus for plants. These are, therefore, converted into calcium dihydrogen phosphate which is commonly known as *calcium superphosphate*. This is the most important phosphatic fertilizer. Other such fertilizers are : *triple phosphate, phosphatic slag and nitrophosphate.*

Calcium Superphosphate. This is manufactured by treating the insoluble phosphate rock with a calculated quantity of sulphuric acid (commercial) when we get the more soluble calcium dihydrogen phosphate (superphosphate) and calcium sulphate.

$$Ca_3(PO_4)_2 + 2H_2SO_4 \longrightarrow 2CaSO_4 + Ca(H_2PO_4)_2$$

A sufficient amount of water is then added to convert calcium sulphate into its dihydrate, $CaSO_4.2H_2O$ (gypsum).

The mixture of calcium dihydrogen phosphate and gypsum is marketed under the name of superphosphate of lime and is used as a fertilizer.

Being soluble in water and containing about 18 per cent of P_2O_5, it is considered a good phosphatic fertilizer. However, care should be taken in its storage as it has a tendency to set in the form of hard lumps.

Phosphatic Slag. Phosphatic slag is a by-product of steel industry. This results from the presence of small amounts of phosphorus in iron ores.

When during smelting the iron ore is heated with lime stone in the presence of air, calcium phosphate and calcium silicate appear as slag. The following reactions are probably involved :

$$4P + 5O_2 \longrightarrow 2P_2O_5$$

$$3CaO + P_2O_5 \longrightarrow Ca_3(PO_4)_2$$

$$CaO + SiO_2 \longrightarrow CaSiO_3$$

The slag being lighter rises on the top of the molten iron and is easily separated. It contains 14 – 18 per cent of P_2O_5 and 40 per cent of lime which is useful in lowering soil acidity.

Phosphatic slag is also known as **Thomas slag.** It is well ground and used as a valuable fertilizer.

Nitrophosphate. Nitrophosphate is prepared in the same way as superphosphate from phosphatic rock, using nitric acid instead of sulphuric acid. The advantage of this fertilizer is that in addition to phosphorus, it contains nitrogen as well.

POTASH FERTILIZERS

Potassium Nitrate, KNO_3. Potassium nitrate is the chief potash fertilizer. This occurs as an efflorescent on the soil at a number of places in India and other tropical countries. The presence of nitrogen as nitrate ion adds to the value of this fertilizer.

Potassium chloride and **potassium sulphate** are also used as fertilizers.

Mixed Fertilizers. A fertilizer which contains more than one of the major plant nutrients, is called a *mixed fertilizer*. In most cases, mixed fertilizers contain nitrogenous, phosphatic and potash fertilizers. Ammonium sulphate, ammonium nitrate or calcium ammonium nitrate is used as a source of nitrogen. Calcium superphosphate is used as a source of phosphorus while potassium chloride or potassium sulphate is used as source of potassium. These are referred to as **N.P.K. fertilizers.**

QUESTIONS

1. (*a*) Name the elements of Group 15 of the periodic table. How do the following properties vary in this group :
   (*i*) Ionisation energy (*ii*) Catenation (*iii*) Metallic character (*iv*) Electronegativity ?
2. (*a*) Why is nitrogen anomalous in its behaviour as compared to the other members of its group ? Discuss with examples.
   (*b*) Explain with reasons : (*i*) NF_5 is not known while PF_5 is so well known. (*ii*) NH_3 has higher boiling point than PH_3. (*iii*) Nitrogen is a gas while phosphorus is a solid at room temperature. (*iv*) Nitrogen molecule is diatomic but phosphorus molecule is tetratomic.
3. Name the hydrides of Group 15 elements. Discuss the variation in their properties with reference to (*a*) basic character (*b*) thermal stability (*c*) reducing character (*d*) bond angle (*e*) covalent nature.
4. Give a brief account of the halides of Group 15 elements with special reference to the properties of PCl_3 and PCl_5.
5. Give a detailed description of the oxides of the elements of Group 15 with special reference to the oxides of nitrogen and phosphorus. Give the structures of these oxides.
6. Give a detailed description of the oxoacids of nitrogen. Give their important characteristics and structures.
7. Give a detailed description of oxoacids of phosphorus. Give their important characteristics and strcutures.
8. Give a brief description of the sulphides of Group 15 elements. Give the structure of the well known sulphides of phosphorus.
9. (*a*) How are hydrazine and hydrazoic acid prepared ? Give their properties and structures.
   (*b*) Give the preparation, properties and uses of hydroxyl amine.
10. Write short notes on :
    Nitrogen trifluoride, Dinitrogen difluoride, Dinitrogen tetrafluoride, Tri silylamine, Urotropine.
11. What are phosphazines ? How are they prepared ? Discuss the structures of important chlorophosphazines.
12. What are artificial manures ? Give the preparation of artificial manures which are in common use. Discuss their relative merits and demerits.

18 THE ELEMENTS OF GROUP 16

Group 16 contains five elements, namely, **oxygen, sulphur, selenium, tellurium** and **polonium** and after the first element of the group, they are also named as **oxygen family.** The first four elements of the group are non-metals. These are also collectively known as **chalcogens** (meaning *ore forming*) because many metal ores occur as oxides, sulphides, etc. Oxygen is the most abundant element and constitutes 46·5 per cent of earth's crust. As water, it comprises 89 per cent of the ocean. It also occurs free and constitutes about 21 per cent by volume of the atmosphere. Sulphur occurs less abundantly and forms nearly 0·052 per cent of the earth's crust. It also occurs in the free state. The other members of the family, *viz.*, selenium, tellurium and polonium, are comparatively rare and constitute, respectively, only 10^{-7}, 10^{-7} and 10^{-14} per cent of the earth's crust.

Electronic Configurations. The electronic configurations of these elements are given in Table 1.

As can be seen, the general outer electronic configuration of the elements of Group 16 may be written as ns^2p^4.

TABLE 1
Electronic Configurations of Elements of Group 16

Element	Atomic Number	Electronic Configuration
Oxygen, O	8	[He] $2s^2p^4$
Sulphur, S	16	[Ne] $3s^2p^4$
Selenium, Se	34	[Ar] $3d^{10}\ 4s^2p^4$
Tellurium, Te	52	[Kr] $4d^{10}\ 5s^2p^4$
Polonium, Po	84	[Xe] $4f^{14}\ 5d^{10}\ 6s^2p^4$

GENERAL CHARACTERISTICS OF GROUP 16 ELEMENTS

Some important properties of elements of Group 16 are summed up in Table 2.

TABLE 2
Important Properties of Elements of Group 16

Property	Oxygen	Sulphur	Selenium	Tellurium	Polonium
Atomic number	8	16	34	52	84
Atomic mass (a.m.u.)	15·999	32·064	78·96	127·60	(210)
Density in solid state (g cm^{-3})	1·14	2·07	4·79	6·23	(9·2)
Atomic radius (Å)	0·73	1·09	1·16	1·35	–
Ionic radius (Å) of divalent ion	1·40	1·84	1·98	2·21	–
Atomic volume (c.c.)	14·0	15·5	16·5	20·5	22·7
Ionisation energy (kJ mol^{-1})	1313·7	999·4	940·9	869·5	813·5
Oxidation states	–2, –1	–2, +2, +4, +6	–2, +2, +4, +6	–2, +2, +4, +6	+2, +4
Electronegativity (Pauling's values)	3·5	2·6	2·5	2·1	2·0
Melting point (°C)	–218·8	114·00	217·0	449·5	254·0
Boiling point (°C)	–183·0	444·6	685·0	989·8	962
Heat of fusion (kJ mol^{-1})	0·22	1·42	5·3	17·7	11·0
Heat of atomisation (kJ mol^{-1})	250	280	207	197	145

1. Atomic volume, atomic radius and **density,** as expected, increase gradually with increase in atomic number.

2. Melting points and boiling points. The melting points and boiling points increase regularly with increase in atomic number, *i.e.,* as we move down the group. The melting point of polonium, however, is rather low.

3. Ionisation energy. The ionisation energy of the first element, oxygen, is very high being 1313·7 kJ per mole. The values for the succeeding elements decrease systematically from 999·4 to 813·5 kJ per mole on moving down the group.

4. Metallic and non-metallic character. The first four elements are non-metals but the non-metallic character is stronger in oxygen and sulphur and weaker in selenium and tellurium. The last element, polonium, is distinctly a metal. However, it is radioactive and is only short-lived.

5. Electronegativity. Electronegativity decreases gradually as we move down the group which also indicates a change from non-metallic to metallic character.

6. Oxidation states. As is evident from Table 2, all the elements have s^2p^4 configuration in their outer shells. These elements, therefore, tend to gain or share two electrons in order to attain a noble gas configuration. Since oxygen has a very high electronegativity, it tends to complete its valency shell preferably by gaining electrons. Even if the octet is completed by sharing of electrons, these electrons, for the purpose of determining the oxidation state, are counted towards oxygen because, excepting F_2O, oxygen forms the electronegative atom in all its compounds. Oxygen, thus, exhibits oxidation state of –2 only. Thus, most of the metal oxides are ionic and contain oxygen as di-negative anion, O^{2-}. However, there are a few exceptions in which the oxidation state of oxygen is not –2. For example, the oxidation state of oxygen in H_2O_2 is –1 and in F_2O it is + 2.

The electronegativities of other elements are, however, low. Their compounds, even with most electropositive elements, are rarely more than 50% ionic. Hence, there is much less probability of the formation of di-negative ions in the case of S, Se and Te. Since the electronegativities and ionisation energies decrease as we move down the group, the tendency of the elements to pass into –2 oxidation state decreases on moving from sulphur to polonium. The least electronegative element, polonium, in fact, does not exhibit negative oxidation state at all. Rather it shows +2 oxidation state.

Excepting oxygen, all the elements have vacant *d* orbitals in their valency shells. In the ground state, they have only two unpaired electrons which permit formation of two bonds. In the excited state, however, one of the *p* electrons goes to the vacant *d* orbital of the same shell, thus, making 4 unpaired electrons available for chemical bonding. This accounts for +4 oxidation state. Thus, S, Se and Te are tetravalent in their typical compounds with oxygen.

On further excitation, the *s* electrons also get unpaired thereby making *6 unpaired electrons available* for bond formation. This explains +6 oxidation state. Thus, in their compounds with fluorine these elements exhibit an oxidation state of +6.

In the case of oxygen, the 2*p* electrons on excitation have to go to 3*s* orbital, there being no *d* orbitals in *L* shell. But, since too much energy is required to excite an electron into a higher shell (in this case from *L* to *M* shell), the electrons in oxygen do not get unpaired. Therefore, oxygen, behaves as a divalent and only as a divalent element.

7. Molecular structure. Oxygen exists in the form of a stable diatomic molecule, O_2. This accounts for its being a gas. The succeeding elements, however, have more complex molecules and exist in solid state. For example, sulphur and selenium occur as S_8 und Se_8 molecules at room temperature and have a puckered ring structure, as shown for sulphur in Fig. 1.

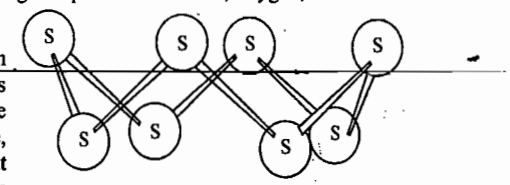


Fig. 1. Puckered ring structure of sulphur, S_8, molecule.

A question arises as to why oxygen forms only O_2 molecule and is, therefore, a gas while sulphur forms S_8 molecule and, therefore, is a solid.

The answer lies in the tendency of oxygen atom to form multiple bonds with itself, a tendency which is missing in the case of sulphur atom. The bond energy of oxygen–oxygen double bond (O = O) is quite large being about three times that of oxygen–oxygen single bond (O – O). On the other hand, sulphur–sulphur double bond (S = S) is not very strong, its bond energy being less than twice the value for sulphur–sulphur single bond (S – S). As a result, the catenated – O – O – O – chains are less stable as compared to O = O bond while catenated – S – S – S – chains are more stable as compared to S = S bond. Therefore, at room temperature, while oxygen exists as a diatomic gas, sulphur exists as S_8 solid.

Tellurium exists in two forms one of which is metallic and the other non-metallic. Polonium also exists in two forms known as α-form and β-form, both of which are metallic.

8. Catenation. The first two elements, oxygen and sulphur, show the property of catenation, the latter showing it to a larger extent. Thus, fairly stable polyoxides and polysulphides are known, *e.g.*,

H – O – O – H H – S – S – H H – S – S – S – H H – S – S – S – S – H

9. Allotropy. Like the elements of Groups 14 and 15, all the elements of Group 16 show allotropy. Thus, oxygen exists in two allotropic forms, O_2 and O_3 (ozone). Sulphur occurs in a number of allotropic forms such as *rhombic* (or α) sulphur, *monoclinic* (or β) sulphur, *plastic* (or γ) sulphur, *colloidal* (or δ) sulphur, λ *sulphur* and μ *sulphur*. These are all non-metallic in character. Selenium exists in two forms : the *red form* which is non-metallic and *grey form* which is metallic in nature.

EXTRACTION OF THE ELEMENTS OF GROUP 16

Preparation of Oxygen. Oxygen occurs in the free state in the atmosphere, being about one-fifth of the air by volume. It also occurs in abundance in the combined state being about 46·5 per cent of the earth's crust in the form of numerous compounds. It is present to the extent of 89 per cent by mass in pure water.

Oxygen can be prepared by thermal decomposition of some unstable oxides (*e.g.*, HgO, Ag_2O) as well as salts rich in oxygen (*e.g.*, KNO_3, $KClO_3$, $K_2Cr_2O_7$, etc.). Oxygen is set free on heating some of the higher oxides such as $KMnO_4$, $K_2Cr_2O_7$ with sulphuric acid.

In the laboratory, oxygen is usually prepared by heating a 5:1 mixture of $KClO_3$ and MnO_2 (catalyst).

A more convenient laboratory method of preparing oxygen is by the action of water on sodium peroxide :

$$2Na_2O_2 + 2H_2O \longrightarrow 4NaOH + O_2$$

The most important source of **commercial oxygen** is air. For this purpose, air is liquefied and then fractionated to get oxygen (as well as nitrogen). Oxygen is also obtained commercially by the electrolysis of water.

Extraction of Sulphur. Sulphur is one of the widely occurring elements and constitutes nearly 0·1 per cent of the earth's crust. In the free state, it occurs in volcanic regions of Sicily, Iceland, Mexico and Louisiana and Texas states of U.S.A. In smaller quantities, it occurs in Newzealand, Russia, Japan and Baluchistan (Pakistan). However, it occurs more abundantly in the combined state as *galena* (PbS), *copper pyrites* ($CuFeS_2$), *cinnabar* (HgS), *zinc blende* (ZnS), *iron pyrites* (FeS_2), *gypsum* ($CaSO_4.2H_2O$), *celestite* ($SrSO_4$) and *heavy spar* ($BaSO_4$). It also occurs as hydrogen sulphide in spring waters, coal gas, sewage gas, etc. Sulphur forms an essential constituent of many natural products of plant and animal origin, *e.g.*, garlic, mustard, eggs, hair, etc.

There are two main sources of world supply of sulphur. One is from deposits in Louisiana and Texas States of U.S.A. and the other is from deposits in Sicily. Each source has a special method of its own for the extraction of the element.

1. Frasch Process. Sulphur in American deposits occurs at a depth of about 250 – 400 metres and is covered by sand, clay and rocks. Therefore, it is not possible to carry out ordinary mining operations. It was in 1901 that Frasch developed a very ingenious process for bringing sulphur to the surface. Three concentric pipes are sunk from the surface down to the sulphur deposit. Superheated water at 170–180°C is admitted through the outermost pipe, while hot, compressed air is forced down the innermost pipe. The hot water melts the sulphur and a foam of water, sulphur and air is produced. This foam is brought up to the surface through the middle pipe by the action of the air blast. The process is continuous. The sulphur obtained is about 99·5 per cent pure and is marketed as such.

2. Sicillian Process. Sulphur deposits in Sicily are associated with nearly 75 per cent of clay and gypsum. In order to recover sulphur, the sulphur-bearing rock is stacked on a sloping floor of a circular kiln called **calcroni** and ignited. A part of the sulphur is burnt and acts as a fuel. The rest of the sulphur melts and collects at the lowest point of the inclined bottom of the kiln. The method is wasteful since nearly one-third of the sulphur is lost.

The calcroni kilns have now been replaced by more economical kilns called **Gill's kilns.** These kilns, consisting of a series of chambers connected with one another, are arranged in a circle and have a common chimney at the centre. Each chamber has an inlet of air. Air enters the first chamber containing the hot residue of a former operation while other chambers contain crude sulphur. Air is thus heated up and then it passes to the next chamber where some of the sulphur gets burnt and the heat produced melts the rest. The hot gases then pass to the other chambers, in turn, heating the crude sulphur present there. In this way, the loss of heat is reduced to a minimum. The recovery of sulphur is about 80 per cent. The melted sulphur is collected in wooden moulds and is called *block sulphur*. This contains nearly 95 per cent sulphur. It may be purified further by sublimation.

Extraction of Selenium. Selenium occurs in small amounts in sulphide ores, particularly in copper pyrites and iron pyrites. It constitutes nearly 10^{-8} per cent of the earth's crust.

Selenium is recovered from the *fine dust* formed during the treatment of sulphide ores of copper and iron, in the form of a solution in potassium cyanide.

$$KCN + Se \longrightarrow KCNSe$$

Selenium gets precipitated on the addition of hydrochloric acid to the solution.

$$KCNSe + HCl \longrightarrow Se + HCN + KCl$$

Selenium is also recovered from anode mud during the electrorefining of copper. The anode mud containing traces of selenium in the form of selenides of Cu, Ag, etc., is heated with Na_2CO_3 in free supply of air. The resulting compound Na_2SeO_3 is then heated with H_2SO_4 and H_2SeO_3 thus formed is treated with SO_2 to give Se.

$$Ag_2Se + Na_2CO_3 + O_2 \xrightarrow{\Delta} Na_2SeO_3 + CO_2 + 2Ag$$

$$Cu_2Se + Na_2CO_3 + 2O_2 \xrightarrow{\Delta} Na_2SeO_3 + CO_2 + 2CuO$$

$$Na_2SeO_3 + H_2SO_4 \longrightarrow H_2SeO_3 + Na_2SO_4$$

$$H_2SeO_3 + 2SO_2 + H_2O \longrightarrow Se + 2H_2SO_4$$

Extraction of Tellurium. It occurs, like selenium, in sulphide ores, particularly in copper pyrites. It also occurs as tellurides of silver and gold. It constitutes nearly 2×10^{-7} per cent of the lithosphere.

Tellurium is extracted from the anode-mud resulting from the electrolytic refining of copper. The mud is fused with a mixture of sodium nitrate and sodium hydroxide when the soluble sodium tellurite is formed. Tellurium is precipitated as oxide from the solution on the addition of an acid.

$$Te + 2NaOH + O_2 \text{ (from } NaNO_3) \longrightarrow Na_2TeO_3 + H_2O$$

$$Na_2TeO_3 + H_2SO_4 \longrightarrow Na_2SO_4 + H_2O + TeO_2 \downarrow$$

The oxide is then reduced to elementary tellurium on heating with carbon.

Extraction of Polonium. Polonium is a radioactive element and has been known since 1898. It occurs in nature in radium minerals such as *pitch blende* to the extent of 5×10^{-9} per cent.

It can be obtained in small (milligram) quantities by the bombardment of ^{209}Bi with neutrons.

$$^{209}_{83}Bi + ^{1}_{0}n \longrightarrow ^{210}_{83}Bi + \gamma \text{ rays}$$

$$^{210}_{83}Bi \longrightarrow ^{210}_{84}Po + \beta \text{ rays}$$

PROPERTIES OF ELEMENTS OF GROUP 16

Properties of Oxygen. Physical Properties. Oxygen is colourless, odourless and tasteless gas. It is slightly soluble in water and is slightly heavier than air. It can be liquefied by application of pressure when cooled below its critical temperature (–118·7°C). The liquid is pale blue in colour and is strongly magnetic. It boils at –183°C and freezes to a bluish white solid at –219°C. The O–O bond distance in O_2 is 1·21 Å.

Chemical Properties. 1. Oxygen is highly reactive. It forms stable compounds (oxides) with all elements except the noble gases. Most of these oxides are formed by direct combination of oxygen with the element concerned. However, oxides of the halogens and of gold, silver and platinum are formed indirectly.

Oxygen is a vigorous supporter of combustion.

Oxygen brings about oxidation of several organic and inorganic compounds on heating in the presence of a catalyst.

Uses. 1. The chief importance of oxygen lies in its supporting vital processes such as combustion and respiration. It is also used for artificial respiration. For this purpose, it is mixed with carbon dioxide or helium. It is also used in providing suitable atmosphere for breathing in submarines or aeroplanes flying at high altitudes.

2. In industry, its important application is in producing oxy-hydrogen and oxy-acetylene flames used in welding and cutting of metals.

3. Liquid oxygen mixed with finely divided carbon is used as a substitute for dynamite in coal mining. Liquid oxygen mixed with liquid fuels (alcohol or petrol) is used in the propulsion of rockets.

Structure of Oxygen Molecule. The electronic structure $:\underset{\cdot\cdot}{O}::\underset{\cdot\cdot}{O}:$ with no unpaired electron fails to account for the paramagnetic behaviour of oxygen although it accounts for the high dissociation energy of oxygen molecule.

Suitable explanation for the existence of two unpaired electrons and consequent paramagnetic behaviour, alongwith a very high dissociation energy of O_2 molecule, has been offered by the **molecular orbital theory** according to which the structure of O_2 molecule is as follows :

$$O_2 : KK\ \sigma(2s)^2\ \overset{*}{\sigma}(2s)^2\ \sigma(2p_z)^2 \pi(2p_x)^2\ \pi(2p_y)^2\ \overset{*}{\pi}(2p_x)^1\ \overset{*}{\pi}(2p_y)^1$$

or $$KK\ \sigma_1^2\ \overset{*}{\sigma}{}_2^2\ \sigma_3^2\ \pi_1^2\ \pi_2^2\ \overset{*}{\pi}{}_3^1\ \overset{*}{\pi}{}_4^1$$

Bond order in this case is evidently 2. Oxygen molecule thus contains a double bond which accounts for its high bond dissociation energy. This structure also accounts for two unpaired electrons and hence its paramagnetic character.

Anomalous Behaviour of Oxygen. Oxygen differs considerably from the rest of the family members. The differences can be attributed largely to the following characteristics of oxygen.

(*i*) Small size (*ii*) High electronegativity and (*iii*) Non-availability of *d orbitals* in the valency shell.

The main **points of difference** are as follows.

1. Oxygen is a *gas* while the other members are solids.

2. Oxygen is *diatomic*, O_2, while the rest of the members have complex molecular structures. For example, sulphur and selenium occur as S_8 and Se_8 molecules which have puckered ring structures.

3. Because of very high electronegativity, oxygen is distinctly *non-metallic* while the other two members (Se, Te) show weak non-metallic character and the last element (Po) is distinctly a metal.

4. Because of its high electronegativity, oxygen is *more ionic in its compounds* than the rest of the members. Thus, the dinegative anion, O^{2-}, is quite common but the dinegative anions of other elements, *viz.*, S^{2-}, Se^{2-} and Te^{2-} are much less common.

5. Because of high electronegativity, oxygen exhibits an oxidation state of only –2. It does not show any positive oxidation state except in OF_2 in which oxygen exhibits an oxidation state of +2. Other members, however, show both negative and positive oxidation states. Positive oxidation states are more frequent.

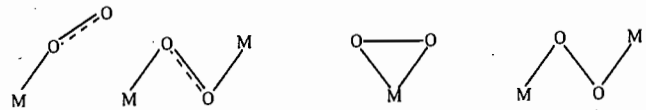
6. Again, on account of high electronegativity, oxygen extensively enters into *hydrogen bond formation*. Other elements because of low electronegativities do not form hydrogen bonds. It is because of hydrogen bonding that the hydride of oxygen (H_2O) is a liquid with a high boiling point and the hydrides of other elements (*e.g.*, H_2S, H_2Se, etc.) are gases with very low boiling points.

7. Maximum covalency of oxygen is two because it cannot expand its valency shell beyond the octet (there being no vacant *d* orbitals). Other elements, because of vacant *d* orbitals, can exercise covalency of 4 and 6.

8. Another striking feature which distinguishes oxygen from the rest of the family members is its paramagnetic behaviour in the gaseous, liquid and solid states.

9. Oxygen molecule is highly stable. Its bond dissociation energy is 494·6 kJ per mole. As a result oxygen combines with other elements (metals or non-metals) only at high temperatures. The reaction requires high energy of activation. It is for this reason that in nature oxide ores are fewer than sulphide ores.

10. There are several oxygen-carrying metalloproteins like haemoglobin, myoglobin, etc., present in biological systems in which O_2 is coordinated to the metal ion. Apart from this, a number of transition metal peroxo and superoxo compounds have been synthesised in which O_2 is ligated to the metal ion in the following manner :



Bonding in superoxo compounds Bonding in peroxo compounds

The O – O distance in superoxo compounds is shorter (1·25 – 1·30Å) than in peroxo compounds (1·45 – 1·50 Å).

Atomic Oxygen. Oxygen molecule is very stable. It dissociates only to a small extent when heated to a very high temperature, the reaction being highly endothermic.

$$O_2 \longrightarrow 2(O)\ ; \qquad \Delta H = +494{\cdot}6 \text{ kJ}$$

However, when an electric discharge is passed through oxygen at a very low pressure, it dissociates to the extent of about 20 per cent.

Atomic oxygen oxidises chlorine to Cl_2O and ClO_2, bromine to BrO_2 and hydrogen bromide to bromine and water.

It reacts vigorously with aliphatic alcohols like methanol and ethanol and with hydrocarbons like methane, acetylene and benzene. It reacts with nitric oxide giving a characteristic greenish white luminescence which serves to detect the presence of atomic oxygen.

$$NO + O \longrightarrow NO_2^*$$

$$NO_2^* \longrightarrow NO_2 + h\nu$$

NO_2^* stands for an excited NO_2 molecule which changes to normal NO_2 molecule after emitting an energy $h\nu$ in the form of electromagnetic radiation.

Atomic oxygen reacts slowly with hydrogen, molecular oxygen and carbon monoxide, as shown below :

$$H_2 + O \longrightarrow \cdot OH + H\cdot$$

$$O_2 + O \longrightarrow O_3$$

$$CO + O \longrightarrow CO_2$$

OZONE, O_3

Ozone is an unstable triatomic allotropic form of oxygen. It is a constituent of the upper atmosphere.

Preparation. Ozone is generally prepared by passing silent electric discharge through oxygen. The concentration of ozone approaches upto 10 per cent by this method. It is believed that some of the oxygen molecules get dissociated in the process and then atomic oxygen combines with oxygen molecules to give ozone.

Another method of preparing ozone with a higher yield consists in electrolysing a concentrated solution of perchloric acid at –50°C between a lead cathode and a platinum anode. It is believed that oxidation of water occurs at the anode giving ozone.

Properties. It is a light blue gas which condenses at –120°C as a dark blue liquid. The liquid freezes at –193°C.

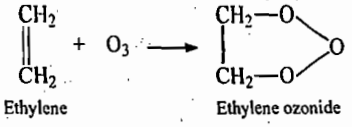
It is one of the strongest oxidising agents. The reduction potential in acid solutions is +2·07 V. This is represented as

$$O_3 + 2H^+ + 2e^- \longrightarrow O_2 + H_2O\,; \qquad E^\circ = 2{\cdot}07\ V$$

There are only three other substances having reduction potentials higher than +2·07 V. These are fluorine, atomic oxygen and F_2O.

It oxidises moist sulphur to sulphuric acid, lead sulphide to lead sulphate, Fe^{2+} to Fe^{3+} state and liberates iodine from aqueous potassium iodide. It is seen that one oxygen atom per molecule of ozone is used up in all such reactions.

However, a few reactions in which all the three atoms of oxygen are used up are also known. Thus, all the three atoms are added up at unsaturated sites when reacted with ethylene.



Structure of Ozone. It is known from electron diffraction and microwave spectroscopy that ozone molecule is angular, the angle between the three oxygen atoms being 116·8° and the O – O distance being 1·28 Å.

Nature of bonding involved in the formation of ozone molecule is best illustrated on the basis of valence bond theory as well as the molecular orbital theory.

Valence Bond Concept. Since the angle O – O – O is close to 120°, the $2s$, $2p_x$ and $2p_y$ orbitals of the central oxygen atom are assumed to hybridise to give three sp^2 hybrid orbitals. Two of the three sp^2 hybrid orbitals are used up for sigma bonding with the terminal oxygens and the third one accommodates a lone pair of electrons. The p_z orbital of the central oxygen atom, which is left out of hybridisation, overlaps with the p_z orbital of either of the terminal oxygen atoms leading to structures a and b, as shown in Fig. 2. Since both the O – O bonds in ozone molecule are of equal length, it leads to the conclusion that the structures a and b are in resonance with each other as shown.

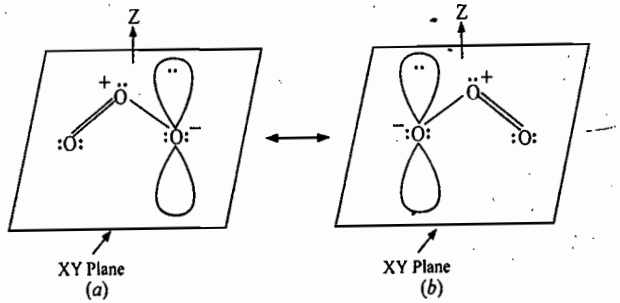


Fig. 2. Resonance structure of O_3 molecule.

Molecular Orbital Concept. As mentioned above, two of the three sp^2 hybrid orbitals of the central oxygen atom are utilised for sigma bonding with the terminal oxygen atoms and the third one accommodates a lone pair of electrons. The remaining p_z orbital of the central oxygen atom can linearly combine with the p_z orbital of the terminal oxygen atom to yield three pi molecular orbitals designated as ψ_1, ψ_2 and ψ_3. These molecular orbitals are represented in Fig. 3.

All the lobes of p_z orbitals of the three O atoms above the plane as well as below the plane of ozone molecule produce a positive overlap in ψ_1. Therefore, it is a *bonding molecular orbital and has lowest energy*. The BMO is thus written as :

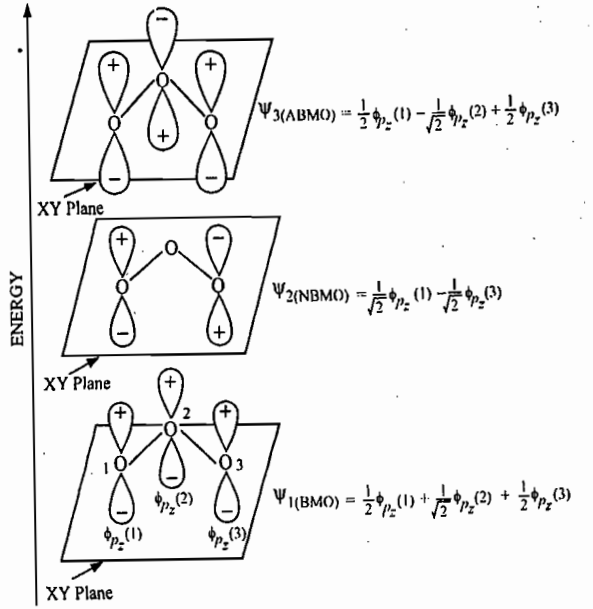

Fig. 3. The pi molecular orbitals of O_3

$$\psi_{1(BMO)} = \frac{1}{2}\phi_{p_z}(1) + \frac{1}{\sqrt{2}}\phi_{p_z}(2) + \frac{1}{2}\phi_{p_z}(3)$$

The $\phi_{p_z}(2)$ orbital does not participate in the formation of ψ_2. Also, $\phi_{p_z}(1)$ and $\phi_{p_z}(3)$ orbitals are too far away and figure in the representation of $\psi_{2(NBMO)}$ with opposite signs (Fig.3), Hence, their lobes cannot overlap. That is why $\psi_{2(NBMO)}$ is a *non-bonding molecular orbital*. The NBMO is thus written as :

$$\psi_{2(NBMO)} = \frac{1}{2}\phi_{p_z}(1) - \frac{1}{\sqrt{2}}\phi_{p_z}(3)$$

In ψ_3, the overlap amongst the lobes above the plane as well as below the plane of the ozone molecule is negative. This type of overlap opposes bonding and hence ψ_3 is an *antibonding molecular*

orbital and has highest energy. The ABMO is written as

$$\Psi_{3(ABMO)} = \frac{1}{2}\phi_{p_z}(1) - \frac{1}{\sqrt{2}}\phi_{p_z}(2) + \frac{1}{2}\phi_{p_z}(3)$$

The relative energies of the three molecular orbitals are shown in Fig. 4.

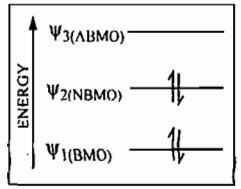

Fig. 4. Relative energies of the three MOs involved in the structure of ozone.

Out of the 18 valence electrons of the oxygen atoms, 14 electrons are either used up in sigma bonding or are present as lone pairs. The remaining 4 valence electrons are accommodated in the bonding and non-bonding molecular orbitals as shown above. Since only two electrons are present in the bonding molecular orbitals, the bond order of the pi bond which is delocalised over all the three oxygen atoms is *one*.

Allotropes of Sulphur. Sulphur exists in several allotropic forms, the more important of which are discussed below

1. Rhombic, octahedral or α-sulphur. This is the common form of sulphur and is stable at temperatures below 95·6°C. In order to get good crystals of rhombic sulphur, a solution of roll sulphur in carbon disulphide is allowed to evaporate slowly. Its specific gravity is 2·06. It melts at 114°C when heated *rapidly* (so as to avoid its transformation into monoclinic sulphur, which is a slow process). It is soluble in carbon disulphide. Its crystal structure contains cyclic S_8 rings packed in a manner which leads to the formation of rhombic crystals.

2. Monoclinic, prismatic or β-sulphur. It is stable above 95·6°C. It is prepared by melting rhombic sulphur in a dish and allowing it to cool until a crust is formed at the surface. Two holes are then pierced into the crust. The liquid sulphur lying below the crust (which has not yet solidified) is poured out through one of the holes. On removing the crust, small needle-like crystals of monoclinic sulphur become visible. Its specific gravity is 1·96. It melts at 120°C. It is soluble in carbon disulphide like α-sulphur. Its crystal structure also contains cyclic S_8 rings but the mode of packing is different than that in α-sulphur. The packing in this case is such that it leads to the formation of monoclinic crystals.

3. γ-Sulphur. This allotrope of sulphur is best obtained by decomposing ethylene xanthate of copper (I) in pyridine or by chilling hot solution of sulphur in carbon disulphide. It exists in the form of pale yellow needles. Its crystal structure also consists of cyclic S_8 rings which are packed in lattice in a more compact manner than in the crystals of α or β-sulphur. Its specific gravity is 2·18. γ-sulphur slowly changes into α and β-forms of sulphur.

4. Colloidal or δ-Sulphur. When hydrogen sulphide is passed through an oxidising solution such as nitric acid, potassium permanganate, etc., sulphur separates out in the colloidal state.

$$2HNO_3 + H_2S \longrightarrow \underset{\text{Colloidal sulphur}}{S} + 2NO_2 + 2H_2O$$

Colloidal sulphur is also obtained by passing hydrogen sulphide through water containing dissolved sulphur dioxide.

$$2H_2S + SO_2 \longrightarrow 2H_2O + \underset{\text{Colloidal sulphur}}{3S}$$

5. Plastic or χ-sulphur. When molten sulphur heated to about 350°C is poured into cold water, a soft rubber-like mass, called plastic sulphur, is obtained. It hardens on standing and changes gradually into rhombic sulphur. It is dark in colour and has specific gravity of 1·95. It is soluble in carbon disulphide and has no sharp melting point. This form is a mixture of allotropes of sulphur containing cyclic S_8 rings and long helical chains of a large number of S atoms. Plastic sulphur can be converted into *fibres* when it is heated in an atmosphere of nitrogen at 300°C for a few minutes and then quenched in water. The fibres, while kept in water, can be stretched. Their structure contains open polymeric helical chains of S atoms.

Plastic sulphur is considered to be a supercooled liquid, *i.e.*, a liquid which due to rapid cooling below its freezing point had no time to settle into a cystalline form.

6. Sulphur Allotropes Containing Cyclic S_6, S_7, S_{10}, S_{12}, S_{18} and S_{20} Rings. Cyclohexasulphur (Engel's sulphur or ε sulphur) containing cyclic S_6 rings can be prepared by the following reaction :

$$S_2Cl_2 + H_2S_4 \longrightarrow S_6 + 2HCl$$

It can also be prepared by adding concentrated HCl to a cold $Na_2S_2O_3$ solution between −10°C to 0°C. The structure of cyclohexasulphur consists of closely packed, cyclic S_6 rings in chair form. As a result of this close packing the specific gravity (2·2 at −10°C) of this form of sulphur is higher than specific gravities of all the other forms. This form of sulphur is highly reactive.

Other forms of sulphur containing cyclic S_7, S_{10}, S_{12}, S_{18} and S_{20} rings in their structures are also known. These are prepared by reacting sulphur chlorides with hydrogen polysulphide, as, for example,

$$S_2Cl_2 + H_2S_8 \longrightarrow 2HCl + S_{10}$$

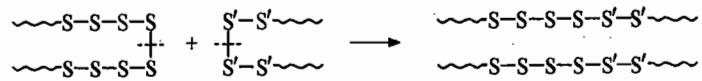
$$S_4Cl_2 + H_2S_8 \longrightarrow 2HCl + S_{12}$$

These cyclosulphurs are quite unstable with the exception of S_{18} and S_{20}.

Uncommon Features of Liquid Sulphur. When rhombic sulphur is gradually heated, it melts to give a thin, pale-yellow liquid between 113°C and 115°C. On continuing the gradual heating, the liquid becomes darker and increasingly viscous. At about 200°C the liquid becomes dark brown and so viscous that it scarcely flows even when the vessel is inverted. On further heating, the viscosity decreases rapidly till the liquid begins to flow at 444·5°C.

The above uncommon features of liquid sulphur may be accounted for as follows :

The yellow coloured liquid sulphur at 113–115°C, called **λ-sulphur**, mainly consists of *mobile* S_8 rings. Because of the mobility of S_8 rings, the viscosity of λ-sulphur is sufficiently low as a result of which it can flow easily. On further heating, the S – S bonds of the cyclic S_8 rings start breaking. The resulting linear S_8 chains then start joining together to give linear polymeric chains containing a large number of S atoms. The sulphur melt thus obtained at about 200°C is called **μ-sulphur**. Since the mobility of linear polymeric chains of μ-sulphur is much less than the mobility of cyclic S_8 chains of λ-sulphur, the viscosity of μ-sulphur becomes very high so much so that the liquid scarcely flows. The packing per unit volume of polymeric chains of μ-sulphur is much higher than that of cyclic S_8 units of λ-sulphur. Therefore, the density of μ-sulphur is much higher than that of λ-sulphur. At higher temperatures, some old polymeric chains of μ-sulphur start breaking, while some new polymeric chains start forming, as illustrated below (sulphur atoms of the second polymeric chain are labelled as S′).



At higher temperatures, the linear polymeric chains start breaking. In the initial stage, some of the fragmented linear chains reunite to form bigger linear chains. With further increase in temperature, however, there is greater fragmentation of long linear chains and lesser reunion of the smaller linear chains with the result that at about 444°C, almost all the long linear chains get broken into smaller chains. Since the mobility of smaller chains is greater than that of the longer chains, the viscosity of μ-sulphur decreases and at about 444°C it becomes so low that the melt starts flowing again.

λ-sulphur on solidification gives crystalline (α or β) sulphur soluble in carbon disulphide while μ-sulphur on solidification gives amorphous plastic sulphur insoluble in carbon disulphide.

Polyatomic Sulphide Ions. A number of polysulphide ions are known to be present in the salts of alkali and alkaline earth metals. Their melting points are lower than the melting points of corresponding salts of mono-atomic S^{2-} ions. The polyatomic ions known are S_3^{2-}, S_4^{2-}, S_5^{2-}, S_6^{2-}, etc. The S_3^{2-} ion is bent but planar. Other anions have bent but non-planar structure.

The salts of polysulphide ions can be prepared by heating stoichiometric amounts of sulphur with the element in a sealed tube or by reacting sulphur with MSH (M = alkali or alkaline earth metal) in ethanol.

Properties of Sulphur

Sulphur is a yellow solid with no taste and odour. It is freely soluble in carbon disulphide but insoluble in water and only sparingly soluble in alcohol and ether. Its vapours are poisonous for bacteria and fungi but not for animals or human beings.

Chemical Properties. 1. It burns in oxygen or air with a blue flame giving sulphur dioxide mixed with a small amount of sulphur trioxide.

2. It combines directly with carbon, phosphorus, arsenic and many of the metals at high temperatures, giving the corresponding sulphides.

3. It also combines with hydrogen and chlorine when the gases are led through boiling sulphur to form H_2S and S_2Cl_2, respectively.

4. Sulphur does not react with water in the cold but reacts with ste am when the latter is made to pass through boiling sulphur.

$$3S + 2H_2O \longrightarrow 2H_2S + SO_2$$

5. It gets oxidised by concentrated sulphuric acid and nitric acid yielding sulphur dioxide and sulphuric acid, respectively.

6. It is also attacked by concentrated alkalies forming sulphides and thiosulphates.

$$4S + 6KOH \longrightarrow K_2S_2O_3 + 2K_2S + 3H_2O$$

If sulphur is present in excess, potassium sulphide combines with it yielding potassium pentasulphide.

Uses of Sulphur. Sulphur is put to the following uses, amongst many others : 1. As a disinfectant for houses and for destroying bacteria, fungi, insects, etc. 2. For vulcanising rubber. 3. In medicine, for internal as well as external applications. 4. In dyes. 5. For the manufacture of sulphur dioxide, sulphuric acid, carbon disulphide, matches, gun powder, fire works, etc. 6. For the manufacture of bisulphites of calcium and magnesium which are required as bleaching agents.

Properties of Selenium. Selenium obtained from KCNSe is a *red amorphous powder*. On dissolving it in carbon disulphide and evaporating the solution *slowly* at a temperature around 72°C it is possible to get red α monoclinic cystalline form of selenium. If, however, the same solution is evaporated rapidly, β monoclinic form of selenium results. These forms are non-metallic and have puckered Se_8 ring structure. On keeping any of the forms at 200 – 220°C for sometime, the stable allotropic form of *grey metallic selenium*, having hexagonal crystals, is obtained. The *vitreous black selenium* is the commercial form of selenium which does not have a sharp melting point. It transforms readily into grey form when heated to 180°C.

Selenium is a poor conductor of heat and electricity. Its main use lies in emission of electrons when exposed to light. It is, therefore, used in photoelectric cells. It is also used for decolorising glass, in semiconductor devices and in pharmaceuticals.

The most important application of selenium is in the process of xeroxing.

Role of Selenium in Xerography

The word xerography in Greek means dry writing. The process of xeroxing is based on the *photoconducting* nature of selenium, *i.e.*, selenium is non-conducting in dark but becomes conducting in the presence of light. The commercial xeroxing machines make use of reusable *photoreceptor* for producing xerox copies of documents. The basic steps involved in the process of xeroxing are as follows :

1. Fabrication of Photoreceptor and its Sensitisation. The photoreceptor is prepared by vacuum-depositing a thin film of amorphous selenium, about 50 μm thick, on an aluminium sheet. The selenium layer is then sensitised in the dark by an electrostatic charge produced from a device which utilises a

field of the order of 10^5 V cm^{-1}, as shown in Fig. 5.

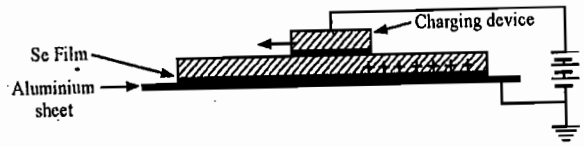


Fig. 5. Sensitisation of Photoreceptor.

2. Formation of Latent Image. The image of the document to be xeroxed, which consists of light and dark patterns, is then allowed to fall on the sensitised photoreceptor. The surface potential of the receptor gets reduced in the light regions because selenium in such regions becomes photoconducting leading to a reduction of electrostatic charge from such regions. The surface potential in the dark regions remains unaltered because Se is non-conducting in the absence of light. In this way, a latent or hidden electrostatic image of the document is formed. This is illustrated in Fig. 6.

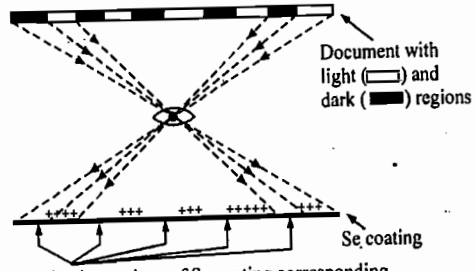

Fig. 6. Formation of latent image

3. Development of Latent Image. Coloured (usually black) *toner particles* (~ 10 μm in size) mixed with spherical *carrier beads* (~ 100 μm in size) are allowed to run over the photoreceptor. The toner particles become negatively charged due to friction and are attracted by the electrostatically charged patterns on the photoreceptor. The toner particles are not attracted by the uncharged patterns on the receptor. The adherence of the toner particles on selective parts of the photoreceptor thus leads to the formation of a visible image from the latent electrostatic image (Fig. 7).

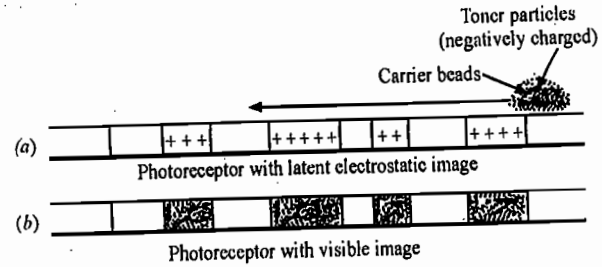

Fig. 7. Formation of visible image from latent image.

4. Transfer of the Image on Print Paper. The print paper which is kept parallel to the photoreceptor is then electrostatically charged. This process transfers the toner particles from the photoreceptor to the print paper (Fig. 8).

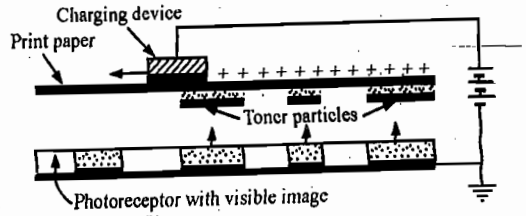

Fig. 8. Transfer of the image on print paper.

5. Fixing. The toner particles are then fixed permanently on the print paper by melting them on the surface of the print paper by electric heating.

6. Cleaning. After the image has been transferred from the photoreceptor to the print paper, any toner particles left on the photoreceptor are removed either by mechanical means or by a combination of elecrostatic and mechanical means.

7. Erasing of the Image. The photoreceptor is then exposed to bright light so that the whole of the Se layer becomes equally conducting. As a result, the surface potential on the photoreceptor attains a *uniformly low value*. The pattern of the electrostatic charge on the surface of the photoreceptor, *i.e.*, latent electrostatic image, therefore, *vanishes* and the photoreceptor is ready to be used again.

Properties of Tellurium. Tellurium obtained from anode mud resulting from electrolytic refining of copper is in *metallic form*. It consists of grey crystals. It has low electrical conductance. It is stable and is not affected by light.

The *non-metallic amorphous form* is precipitated from telluric acid by passing sulphur dioxide gas. It is less stable than the metallic form. Both the forms consist of network of spiral chains of Te atoms.

The element is added to lead to improve its resistance to heat and corrosion.

Properties of Polonium. Polonium is alpha-emitter. Its half-life period is 138·4 days. Its high activity (4·5 curies per milligram) renders it a dangerous substance.

It is a soft metal resembling lead in appearance. It exists in two crystalline forms : *cubic* and *rhombohedral*, both of which are metallic. The most common oxidation state of the metal is +4.

Polonium, intimately mixed with beryllium, serves as a useful source of neutrons.

COMPOUNDS OF GROUP 16 ELEMENTS

I. A Comparative Study

1. HYDRIDES

Hydrides of Formula H_2R. All the members of oxygen family form hydrides of the same type, *viz.*, H_2R (H_2O, H_2S, H_2Se, H_2Te and H_2Po).

Preparation. The hydride of oxygen, *viz.*, water is available in abundance in nature. The hydrides of S, Se and Te are readily obtained by the action of acids on metal sulphides, selenides and tellurides, *e.g.*,

$$FeS + H_2SO_4 \longrightarrow FeSO_4 + H_2S$$
$$K_2Se + H_2SO_4 \longrightarrow K_2SO_4 + H_2Se$$

H_2Po, on the other hand, has been prepared only in traces by dissolving magnesium foil plated with Po in 0·2 M HCl.

The hydrides of sulphur, selenium, tellurium and polonium, at ordinary temperatures, are offensive smelling gases. The hydride of oxygen (water) is an odourless and colourless liquid. The trends in their properties are discussed below.

1. Volatility. The volatility increases markedly from H_2O to H_2S and then decreases. This is evident from their boiling points given below :

H_2O	H_2S	H_2Se	H_2Te	H_2Po
100·0°C	– 60·75°C	– 41·5°C	– 1·8°C	–

The abnormally high boiling point of water is due to the association of molecules through hydrogen bonding.

2. Acid character. The hydrides are all weak acids and dissociate to varying degrees to give H^+ ions. For example, H_2S behaves as a weak diprotic acid ionising as

$$H_2S \rightleftharpoons HS^- + H^+$$
$$HS^- \rightleftharpoons S^{2-} + H^+$$

The acidic strength *increases* from H_2O to H_2Te. This is evident from the values of the dissociation constants of these hydrides as acids, given in Table 3. Evidently, this behaviour cannot be explained on the basis of the electronegativity of the central atom. However, it can be easily explained on the basis of the size of the central atom. As shown in Chapter 2, the atomic size increases gradually as we move from O to Te. As a result, the length of the X – H bond also increases gradually as we move down the group (Table 3). Since the strength of a bond is inversely proportional to its length, the strength of the X – H bond decreases as we move from O to Te. Consequently, the tendency of the hydrides to dissociate to yield H^+ ions increases as we move from H_2O through H_2S and H_2Se to He_2Te.

3. Thermal stability. The thermal stability of the hydrides decreases with rise in molar mass. Thus, while water dissociates only at 2000°C, tellurium hydride, H_2Te, decomposes even at ordinary temperatures.

4. Reducing character. All the hydrides, except water, are reducing agents. The reducing character *increases* on moving from H_2S to H_2Te. This is, evidently, due to decrease in stability in moving from H_2S to H_2Te.

5. Complex forming capability. H_2S is a much poorer ligand than H_2O. Some rare examples of species containing complexed H_2S are $[AlBr_3(SH_2)]$, $[W(CO)_5(SH_2)]$, $[Ru_3(CO)_9(SH_2)]$, $[Ru(NH_3)_5(SH_2)]^{2+}$, etc.

6. Bond angles. The bond angles H – X – H, in H_2O, H_2S, H_2Se and H_2Te are 104·5°, 92·5°, 90·0° and 89·0°, respectively. The reason for this gradation has already been discussed in Chapter 5 on the basis of electronegativities of the central atoms.

The various properties of these hydrides are summed up in Table 3.

TABLE 3

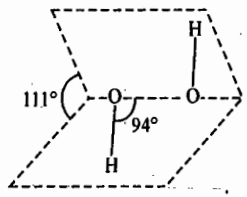
Important Properties of Hydrides of Elements of Group 16

Property	H_2O	H_2S	H_2Se	H_2Te
Melting point (°C)	0	–85·5	–65·7	–51·1
Boiling point (°C)	100·0	–60·75	–41·5	–1·8
Bond angle H – X – H	104·5°	92·5°	90°	89°
Bond length H – X (Å)	0·95	1·30	1·45	1·72
Dissociation constant as an acid at 25°C	$1·0\times10^{-14}$	$1·0\times10^{-7}$	$1·7\times10^{-4}$	$2·3\times10^{-3}$

Hydrides of Formula H_2R_2. The first two members of the family also form hydrides of the formula H_2R_2 (*viz.*, H_2O_2, H_2S_2). However, these two hydrides differ considerably from each other. Whereas H_2O_2 is fairly stable (except in the presence of certain impurities such as finely divided Cu, Pt, etc.), H_2S_2 is unstable and decomposes readily to give sulphur and hydrogen sulphide. The decomposition is accelerated by hydroxyl ions.

$$H_2S_2 \xrightarrow{OH^-} H_2S + S$$

Also, whereas H_2O_2 acts as a strong oxidising agent, H_2S_2 does not. H_2O_2, on account of hydrogen bonding, is highly associated whereas H_2S_2 forms discrete molecules. Both the hydrides have similar nonplanar skew *structures*.



The structure of H_2O_2 in gaseous phase is as shown.

For H_2O_2 in solid phase, the dihedral angles between the two planes and the lengths of OH bonds are different. This is because of the hydrogen bonding which occurs in H_2O_2 in solid phase.

The structure of H_2S_2 is similar to that of H_2O_2.

Other Hydrides. Hydrides with the formulae varying from H_2S_4 to H_2S_{18} have also been reported in literature.

2. HALIDES

The elements of Group 16 form several halides. These are given in Table 4.

TABLE 4
Halides of Group 16 Elements

Elements	Fluorides	Chlorides	Bromides	Iodides
Oxygen	F_2O_2, F_2O	Cl_2O, ClO_2, Cl_2O_6, Cl_2O_7	Br_2O, BrO_2, BrO_3	I_2O, I_2O_4, I_2O_5
Sulphur	S_2F_2, SF_4, SF_6, S_2F_{10}	S_2Cl_2, SCl_2, SCl_4	S_2Br	–
Selenium	Se_2F_2, SeF_4, SeF_6	Se_2Cl_2, $SeCl_4$	Se_2Br_2, $SeBr_4$	–
Tellurium	TeF_4, Te_2F_{10}, TeF_6	$TeCl_2$, $TeCl_4$	$TeBr_2$, $TeBr_4$	TeI_4
Polonium	–	$PoCl_2$, $PoCl_4$	$PoBr_2$, $PoBr_4$	PoI_4

Since fluorine is more electronegative than oxygen, its compounds with oxygen are called fluorides. Thus, F_2O should be written as OF_2 and named as oxygen difluoride. But since oxygen is more electronegative than chlorine, bromine and iodine, the compounds of these halogens with oxygen are called oxides. Thus, Cl_2O_7 is called chlorine heptoxide. The compounds of oxygen with halogens are discussed in details in the next chapter dealing with the halogens.

A brief general discussion of the rest of the important halides is given below.

Hexahalides. Amongst hexahalides, hexafluorides are the only stable compounds. Fluorine directly combines with S, Se and Te to form hexafluorides SF_6, SeF_6, and TeF_6, respectively.

They are formed by sp^3d^2 hybridisation and have, therefore, an **octahedral** structure.

SF_6 is extremely stable and chemically inert ; SeF_6 is slightly more reactive and TeF_6 is still more reactive. TeF_6 is completely hydrolysed in contact with water.

$$TeF_6 + 6H_2O \longrightarrow 6HF + H_6TeO_6$$

All these hexafluorides are colourless gases. Their high volatility indicates high degree of covalency. No other halogen forms the hexahalides.

Hexahalides are not formed by chlorine, bromine and iodine. As the size of the halogen atom increases, the coordination number of the elements of this group decreases. As a result, hexachlorides, hexabromides and hexaiodides are unknown. For the same reason, the number of tetrabromides is only three, all of which are unstable and the number of tetraiodides is only two.

Pentahalides. Only one pentahalide, *viz.*, pentafluoride of sulphur is known and it is a dimer S_2F_{10}. The two SF_5 units are linked through S – S bonds. The orbitals of each sulphur atom in SF_5 unit are sp^3d^2 hybridised.

Tetrahalides. Tetrafluorides cannot be obtained by direct combination of the elements with fluorine because the reaction cannot be arrested at the tetrafluoride stage. On account of the reactivity of fluorine, the end product is always the hexafluoride. The tetrafluorides can, however, be obtained indirectly. For example,

$$S + 4CoF_3 \longrightarrow SF_4 + 4CoF_2$$

$$3SCl_2 + 4NaF \xrightarrow{75°C} SF_4 + S_2Cl_2 + 4NaCl$$

$$SeCl_4 + 4AgF \longrightarrow SeF_4 + 4AgCl$$

$$SF_4 + SeO_2 \xrightarrow{100°C} SeF_4 + SO_2$$

$$Te + 2F_2 \xrightarrow{0°C} TeF_4$$

$$TeO_2 + 2SeF_4 \longrightarrow TeF_4 + 2SeOF_2$$

Out of these, SF_4 is gaseous, SeF_4 is liquid and TeF_4 is solid. They are all highly reactive fluorinating agents. Amongst the tetrachlorides, OCl_4 does not exist, SCl_4 is an unstable liquid while the other tetrachlorides are solids.

All the tetrachlorides can be easily prepared by direct combination of the elements with chlorine.

$$M + 2Cl_2 \longrightarrow MCl_4 \ (M = S, Se, Te)$$

Amongst the tetrabromides, the tetrabromide of oxygen, OBr_4, is not known. $SeBr_4$ is unstable and dissociates into diselenium dibromide and bromine as follows.

$$2SeBr_4 \longrightarrow Se_2Br_2 + 3Br_2$$

It is also readily hydrolysed as shown below.

$$SeBr_4 + 4H_2O \longrightarrow \underset{\text{unstable}}{Se(OH)_4} + 4HBr$$

$$Se(OH)_4 \longrightarrow H_2SeO_3 + H_2O$$

Tetrabromides of Te and Po are fairly stable.

O, Te and Po are the only elements which are known to form the tetraiodides. The tetraiodides of oxygen, however, are not so common.

Tetrafluorides have Lewis acid character since they readily accept electrons and change over to hexafluorides.

$$SF_4 + F_2 \longrightarrow SF_6$$

The central atom in these tetrahalides utilises five sp^3d hybrid orbitals for bonding. The fifth hybrid orbital accommodates a lone pair of electrons. This is illustrated in Fig. 9 with reference to the structure of $TeCl_4$.

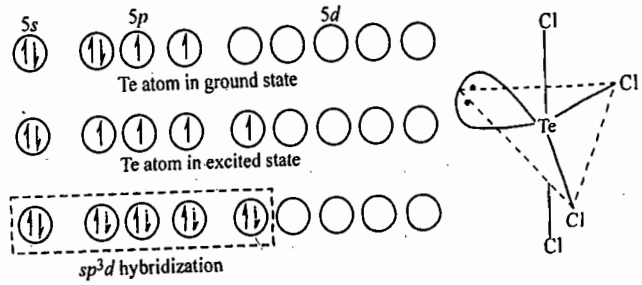


Fig. 9. Structure of $TeCl_4$ molecule formed by sp^3d hybridisation of Te orbitals.

Other tetrahalides, *viz.*, the fluorides, bromides and iodides are supposed to have similar structure.

Dihalides. All the elements except selenium form stable dichlorides and dibromides. Di-iodides are not formed. Dihalides of selenium are not stable. Amongst the dihalides, the best known is SCl_2. It is

formed by saturating S_2Cl_2 with chlorine at ordinary temperatures. $TeBr_2$ is formed by direct combination of the elements. They form bent molecules in which the central atom utilises sp^3 hybrid orbitals for bonding and for accommodating lone pair of electrons.

Since two of the four hybrid orbitals are occupied by lone pairs of electrons and since the repulsion between two lone pairs is more than the repulsion between two bond pairs or that between a lone pair and a bond pair, the tetrahedral angle of 109·5° gets distorted. Thus, the bond angle is 103° in SCl_2, 101·5° in OF_2 and 98° in $TeBr_2$.

The formation of SCl_2 molecule is illustrated in Fig. 10.

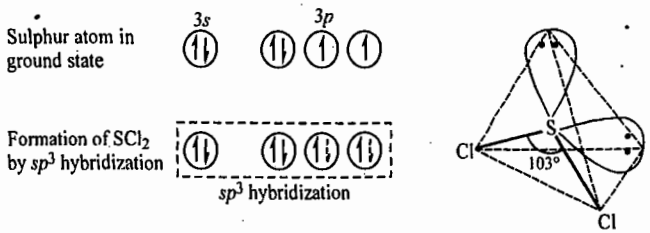

Fig. 10. Bent structure of SCl_2 molecule formed by sp^3 hybridisation of S orbitals.

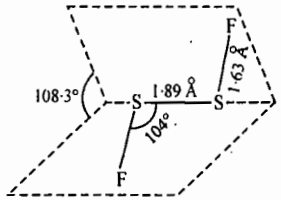
Monohalides. Amongst the monohalides, the dimeric monohalides, such as S_2F_2, Se_2Br_2 are well known. These are hydrolysed slowly and also undergo disproportionation, *e.g.*,

$$2S_2F_2 + 2H_2O \longrightarrow 4HF + SO_2 + 3S$$

$$2SeCl_2 \longrightarrow SeCl_4 + Se$$

The electron diffraction studies have shown that the structure of S_2F_2 is nonplanar and is similar to that of H_2O_2, as shown.



3. OXIDES

The elements of Group 16 form several oxides as shown in Table 5.

TABLE 5
Oxides of Sulphur, Selenium, Tellurium and Polonium

Names	Sulphur	Selenium	Tellurium	Polonium
Lower oxides	SO, S_2O, S_2O_2 S_6O, S_7O, S_8O		TeO	PoO
Dioxides	SO_2	SeO_2	TeO_2	PoO_2
Trioxides	SO_3	SeO_3	TeO_3	–
Heptoxides	S_2O_7	–	–	–

Oxides of sulphur are more stable than the corresponding oxides of other elements. Thus, SO_2 and SO_3 are more stable than the corresponding dioxides and trioxides of the other elements. Heptoxide is formed only by sulphur.

Lower Oxides. All elements, except selenium, form monoxides. Sulphur monoxide is formed by passing electric discharge through sulphur dioxide. S_2O_2, which has a life time of several seconds, is prepared by microwave irradiation of SO_2 in vacuum when a mixture of oxides containing SO, S_2O, S_2O_2 is obtained.

Other lower oxides known are S_6O, S_7O and S_8O. Tellurium monoxide and polonium monoxide are formed by heating the corresponding trioxides.

Dioxides. All the members of oxygen family (excepting, of course, oxygen) form dioxides of the formula MO_2 (SO_2, SeO_2, TeO_2 and PoO_2). These, however, differ from one another considerably in their properties and structures. SO_2 is a gas (b.p. –10°C) and forms *discrete molecules* even in the solid state. SO_2 and SeO_2 are acidic oxides and are soluble in water. TeO_2 and PoO_2 are insoluble in water. These are amphoteric oxides as they dissolve in both acids and bases. Thus, acidic character of the dioxide decreases as we go down the group. Sulphur dioxide molecule has a bent structure in which S atom utilises sp^2 hybrid orbitals for sigma bonding, as illustrated in Fig. 11.

Out of the three sp^2 hybrid orbitals of sulphur, one is occupied by a lone pair of electrons. The remaining two half-filled hybrid orbitals overlap with one of the p orbitals of each of the two oxygen atoms forming sigma bonds. This gives rise to bent structure.

Since one of the three sp^3 hybrid orbitals of S atom is occupied by a lone pair of electrons and since the repulsion between a lone pair and a bond pair is more than that between two bond pairs, the bond angle OSO is slightly reduced from 120° to 119·5°. Sulphur atom has still two half-filled orbitals (one p and one d orbital). Each oxygen atom has also one half-filled p orbital. So, p orbital of one of the oxygen atoms overlaps with p orbital of the sulphur atom forming $p\pi - p\pi$ bond. Similarly, p orbital of the second oxygen atom overlaps with d orbital of sulphur atom forming a $p\pi - d\pi$ bond. In this manner, both sulphur and oxygen atoms get all their electrons fully paired.

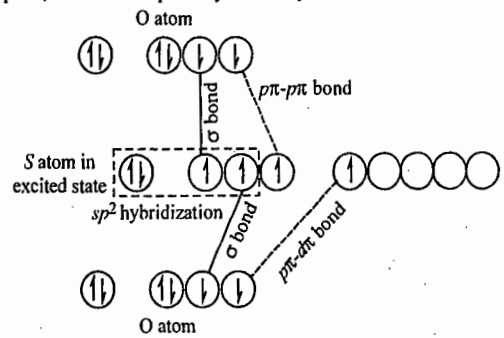


Fig. 11. Bent structure of SO_2 molecule formed by sp^2 hybridisation of S orbitals.

It is evident from the above discussion that one of the oxygen atoms is bonded to sulphur atom by $\sigma\ sp^2 - p$ and $p\pi - p\pi$ bonds while the other oxygen atom is bonded by $\sigma\ sp^2 - p$ and $p\pi - d\pi$ bonds. This would point towards two different bond lengths. But actually both the S – O bonds have exactly the same length. This is because of resonance which may be represented as below :

$$O\frac{p-sp^2}{p\pi-p\pi}S\frac{sp^2-p}{p\pi-d\pi}O \longleftrightarrow O\frac{p-sp^2}{p\pi-d\pi}S\frac{sp^2-p}{p\pi-p\pi}O$$

The multiple bonding also explains the shorter length of the S – O bond. The $p\pi - d\pi$ overlap is illustrated in Fig. 12. There is a sidewise overlap of a p orbital of oxygen atom with a d orbital of the sulphur atom. This $p\pi - d\pi$ interaction results in bringing the two atoms closer and thus accounts for the shorter length of S – O bond.

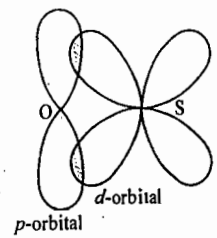

Fig. 12. Lateral overlapping of p and d orbitals.

SeO_2 is a white volatile solid (normal sublimation temperature 315°C). In the gaseous state, SeO_2 exists in the form of discrete monomeric molecules, just like SO_2, but in the solid state it has polymeric structure comprising of infinite chains, as shown in Fig. 13.

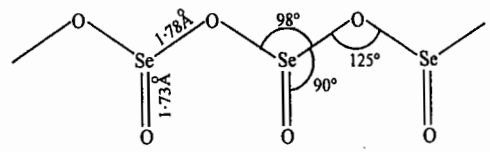

Fig. 13. Polymeric structure of SeO_2 in solid state.

TeO_2 and PoO_2 are also non-volatile crystalline ionic solids and occur in two crystalline forms each.

The dioxides also differ from one another

in their reaction with water. SO_2 dissolves giving H_2SO_3, which, however, exists only in solution and cannot be isolated.

SeO_2 dissolves giving selenious acid which can be isolated in a crystalline state. TeO_2 is almost insoluble in water. It, however, dissolves in alkalies to form tellurites and in acids to form basic salts, showing that it is amphoteric in character. PoO_2 behaves similarly.

Trioxides. Amongst the trioxides, SO_3 is the most important. SeO_3 and TeO_3 are also known. They are all acidic in nature and dissolve in water to give acids.

$$SO_3 + H_2O \longrightarrow \underset{\text{Sulphuric acid}}{H_2SO_4}$$

$$SeO_3 + H_2O \longrightarrow \underset{\text{Selenic acid}}{H_2SeO_4}$$

The strength of the acid decreases on moving down the group. Thus, H_2SO_4 is the strongest acid of the family.

The trioxides, in gaseous state, are known to have planar trigonal structure being formed by sp^2 hybridisation of S orbitals, as illustrated in Fig. 14 for the formation of **SO_3 molecule.**

The three half-filled sp^2 hybrid orbitals of sulphur overlap with one of the p orbitals of each of the three oxygen atoms forming sp^2–p sigma bonds.

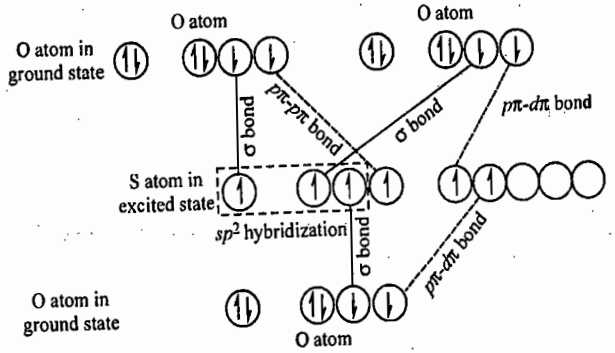

Fig. 14. Bent structure of SO_3 molecule formed by sp^2 hybridisation of S orbitals.

Sulphur atom has still three half-filled orbitals (one p and two d orbitals). Each oxygen atom has one half-filled p orbital. Therefore, p orbital of one of the oxygen atoms overlaps with p orbital of the sulphur atom forming $p\pi - p\pi$ bond. The p orbitals of the other two oxygen atoms overlap with d orbitals of sulphur atom forming the $p\pi - d\pi$ bonds, as shown in the figure.

Due to the formation of three sigma bonds, SO_3 has a planar trigonal structure.

The bond angles in SO_3 are exactly 120° each and S = O bond lengths are 1·42 Å.

In solid state, sulphur trioxide polymerises and has either a ring structure or a linear layer structure, as shown in Fig. 15.

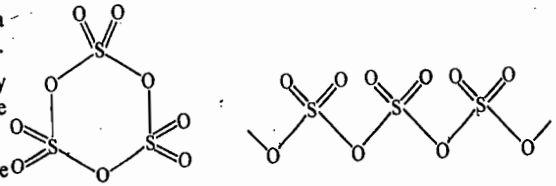

Fig. 15. Cyclic and linear layer structures of sulphur trioxide in solid state.

Sulphur trioxide exists in three forms :

1. **α-Sulphur trioxide.** This is a colourless liquid which solidifies in the form of prismatic needle-like crystals. It melts at 17°C and boils at 45°C. Its specific gravity is 1·923 at 25°C.

This form is obtained by repeated fractionation of sulphur trioxide. The molar mass of this substance, as determined by freezing point depression, is about 80.

2. **β-Sulphur trioxide.** The α form, if allowed to stand at 16°C for some time, changes gradually into the β form. This form solidifies giving asbestos-like needles at 32·5°C. Its molar mass is close to

160 which corresponds to the formula S_2O_6. When kept at a temperature between 50 and 100°C, it changes into α variety.

3. **γ-Sulphur trioxide.** It is obtained from β form on complete drying. It sublimes without melting under ordinary pressure.

SeO_3 is prepared by the direct oxidation of Se or SeO_2. It is a white hygroscopic solid (m.p.118°C). It exists as a monomer in vapour phase but as a cyclic tetramer, Se_4O_{12}, in crystalline state. The structure of the tetramer is shown in Fig. 16.

TeO_3 also exists. It is unattacked by water. At high temperatures it acts as a powerful oxidising agent.

PoO_3 has been detected on a tracer scale but has not been well characterised.

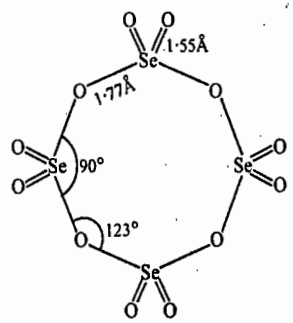

Fig. 16. The cyclic structure of tetrameric Se_4O_{12}.

Higher Oxides of Sulphur. The reaction of SO_2 or SO_3 with O_2 in silent electric discharge gives a polymer with the formula SO_{3+x} ($0 < x < 1$). It has the structure $-O-\overset{O}{\overset{\|}{S}}-O-O-S-$. Hydrolysis of this polymer yields H_2SO_4 and H_2SO_5.

4. OXOACIDS

Sulphur, selenium and tellurium form a variety of oxoacids. The more important of these are listed in Table 6.

TABLE 6

Important Oxoacids of Sulphur, Selenium and Tellurium

Sulphur	Selenium	Tellurium
Sulphurous acid, H_2SO_3	Selenous acid, H_2SeO_3	Tellurous acid, H_2TeO_3
Sulphuric acid, H_2SO_4	Selenic acid, H_2SeO_4	Telluric acid, H_6TeO_6
Permonosulphuric acid, H_2SO_5		
Perdisulphuric acid, $H_2S_2O_8$		
Thiosulphuric acid, $H_2S_2O_3$		
Dithionic acid, $H_2S_2O_5$		
Pyrosulphuric acid, $H_2S_2O_7$		

Description of some of the important oxoacids is given below.

Sulphurous Acid. This acid is obtained by dissolving SO_2 gas in water, the reaction being represented as

$$SO_2 + H_2O \rightleftharpoons H_2SO_3$$

The acid is known only in solution. It is a fairly strong acid and, being diprotic, it ionises in two stages as

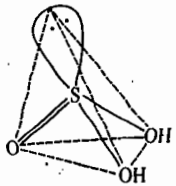
$$H_2SO_3 \rightleftharpoons H^+ + HSO_3^-$$

$$HSO_3^- \rightleftharpoons H^+ + HSO_3^{2-}$$

The acid acts as a strong reducing agent on account of the ease with which it gets oxidised to H_2SO_4 even by atmospheric oxygen. Thus, it reduces halogens to their hydracids, ferric salts to ferrous salts, acidified permanganates to Mn (II) salts, dichromates to Cr (III) salts and iodates to iodine.

Sulphurous acid (or sulphur dioxide in the presence of water) acts as a bleaching agent. The bleaching action is due to its reducing properties. Thus, the red rose leaves or fibres dyed with 'magenta'

become colourless when moistened with water and exposed to sulphur dioxide. The bleaching is believed to be due to the reduction of the coloured compounds to colourless *leuco bases*. The colour is very often restored on exposure to air for a long time due to reoxidation of the leuco bases.



Structure of Sulphurous Acid. The structure of the unionised acid is in much doubt. *It has been suggested that the molecule has pyramidal structure as shown. In this case sulphur utilises three of the four* sp^3 hybrid orbitals for *sigma bonding* and one of the sp^3 hybrid orbitals is occupied by a lone pair of electrons. In addition to this, there is a $d\pi - p\pi$ bond between S and O atoms, as shown.

Sulphuric Acid, H_2SO_4. Sulphuric acid, probably the most important 'heavy chemical,' finds extensive use in the manufacture of fertilisers, explosives, dyestuffs, plastics and lacquers, paints and pigments and a host of other valuable products. It is used in coal tar and petroleum refining, leather tanning, electroplating, textile and paper industry and in many metallurgical processes. In fact, the industrialisation of a country is judged from the amount of sulphuric acid it consumes.

The acid is manufactured these days mostly by the **contact process**. This process involves the oxidation of sulphur dioxide by air in the presence of a catalyst, to give sulphur trioxide,

$$2SO_2 + O_2 \overset{\text{catayst}}{\rightleftharpoons} 2SO_3$$

which is dissolved in 98% sulphuric acid to give oleum.

$$SO_3 + H_2SO_4 \longrightarrow \underset{\text{Oleum}}{H_2S_2O_7}$$

Sulphuric acid of any desired concentration can then be obtained by diluting oleum with water.

$$H_2S_2O_7 + H_2O \longrightarrow 2H_2SO_4$$

The maximum yield of sulphur trioxide is obtained when sulphur dioxide and oxygen present in molecular proportions of 2 : 3 are passed over a suitable catalyst (platinised asbestos or V_2O_5) at a temperature of 400–500°C under atmospheric pressure.

Properties. Pure sulphuric acid is a colourless, viscous heavy liquid (density 1·84 at 15°C). It freezes at 10·38°C and boils at 340°C with some decomposition ($H_2SO_4 \longrightarrow SO_3 + H_2O$). It forms a constant boiling mixture with water containing 98 per cent sulphuric acid boiling at 330°C. This is the common concentrated sulphuric acid. At 444°C, the vapour of sulphuric acid dissociate completely into steam and sulphur trioxide.

Concentrated sulphuric acid has strong affinity for water and a large amount of heat is produced on mixing the acid with water. The temperature may rise as high as 120°C, hence the acid is always diluted by adding the acid to water (and *not by adding water to acid*) slowly with constant stirring. The evolution of heat is due to the formation of definite hydrates such as $H_2SO_4.H_2O$ (m.p. 8·5°C) and $H_2SO_4.2H_2O$ (m.p. 38°C).

Since sulphuric acid has great affinity for water, it readily removes water not only from materials which contain it but also frequently eliminates oxygen and hydrogen from other compounds in the proportions required to form water (H_2O). Thus, paper and wood [which are largely cellulose, $(C_6H_{10}O_5)_x$ and sugar ($C_{12}H_{22}O_{11}$)] get charred by concentrated sulphuric acid as carbon is formed by their dehydration.

Similarly, oxalic acid is dehydrated to CO and CO_2 and formic acid to CO.

Dehydration of certain organic compounds yields industrially important compounds. For example, diethyl ether is obtained by the dehydration of ethyl alcohol.

Similarly, dehydration of a mixture of chlorobenzene and trichloroacetaldehyde (chloral) gives D.D.T.,

$$\underset{\text{Chlorobenzene}}{2C_6H_5Cl} + \underset{\text{Chloral}}{CCl_3CHO} \xrightarrow[-H_2O]{H_2SO_4} \underset{\text{D.D.T}}{ClC_6H_4 - CH(CCl_3) - C_6H_4Cl}$$

The dehyrating action of sulphuric acid is made use of in drying gases which do not react with the acid (*e.g.*, SO_2, Cl_2, HCl, etc.) and in eliminating water in many reactions such as esterification and nitration and in the manufacture of dyes and explosives.

Dilute sulphuric acid has no oxidising action but the hot concentrated acid acts as a strong oxidising agent. It accepts electrons provided by a reducing agent so that the general reaction may be represented as

$$6H^+ + H_2SO_4 + 6e^- \longrightarrow S + 4H_2O$$
$$6H^+ + H_2SO_4 + 8e^- \longrightarrow S^{2-} + 4H_2O$$
$$8H^+ + H_2SO_4 + 8e^- \longrightarrow H_2S + 4H_2O$$

Most of the common metals, but not the noble metals, are oxidised by sulphuric acid. The main products are the sulphate of the metal, sulphur dioxide and water.

Sulphuric acid also oxidises certain non-metals, *e.g.*, carbon and sulphur, to their oxides.

The oxidising effect of sulphuric acid is also noticeable in its reactions with bromides and iodides. The HBr formed is oxidised to Br_2 and HI formed is oxidised to iodine.

$$H_2SO_4 + KBr \longrightarrow KHSO_4 + HBr$$
$$2HBr + H_2SO_4 \longrightarrow 2H_2O + Br_2 + SO_2$$
$$H_2SO_4 + KI \longrightarrow KHSO_4 + HI$$
$$6HI + H_2SO_4 \longrightarrow 4H_2O + S + 3I_2$$
$$8HI + H_2SO_4 \longrightarrow 4H_2O + H_2S + 4I_2$$

Aromatic compounds react with sulphuric acid forming sulphonic acids. For example,

$$\underset{\text{Benzene}}{C_6H_6} + H_2SO_4 \longrightarrow \underset{\text{Benzene sulphonic acid}}{C_6H_5SO_3H} + H_2O$$

Since sulphuric acid is a dihydroxy compound ($HO-SO_2-OH$), it reacts with phosphorus pentachloride giving chlorosulphonic acid and sulphuryl chloride.

$$HO - SO_2 - OH + PCl_5 \longrightarrow \underset{\text{Chlorosulphonic acid}}{Cl - SO_2 - OH} + POCl_3 + HCl$$

$$HO - SO_2 - OH + 2PCl_5 \longrightarrow \underset{\text{Sulphuryl chloride}}{Cl - SO_2 - Cl} + 2POCl_3 + 2HCl$$

On heating crystals of potassium ferrocyanide with concentrated sulphuric acid, carbon monoxide is evolved.

$$K_4[Fe(CN)_6] + 6H_2SO_4 + 6H_2O \longrightarrow 2K_2SO_4 + FeSO_4 + 3(NH_4)_2SO_4 + 6CO$$

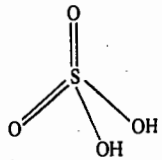
On heating potassium chlorate with concentrated sulphuric acid, chlorine dioxide is evolved with explosion.

$$2KClO_3 + 3H_2SO_4 \longrightarrow 2KHSO_4 + HClO_4 + 2ClO_2 + H_2O$$

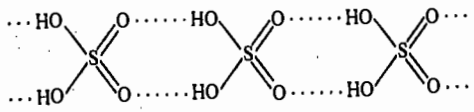
Dilute sulphuric acid gives all the reactions typical of a dibasic acid.

Uses. As already mentioned, sulphuric acid is perhaps the most important heavy chemical and finds extensive use in industry and laboratory. It is used : 1. For the preparation of fertilizers (ammonium sulphate and superphosphate). 2. In petroleum refining to remove unsaturated compounds (which darken by air oxidation of crude oil). 3. In the manufacture of other important chemicals such as hydrochloric acid, nitric acid, sulphates of metals, alums, ethers, etc. 4. In the preparation of dyes, drugs and disinfectants 5. In the 'pickling' of steel before coating it with enamel, tin or zinc. 6. In metallurgical processes for the purification of metals by electrolysis where sulphuric acid is commonly used as bath 7. In preparing paints and pigments. Many of the pigments used in paints are sulphates, *e.g.*, barium and lead sulphates. 8. In the manufacture of explosives such as nitroglycerine, gun cotton, T.N.T., etc. Sulphuric acid is used to eliminate the water formed during the organic reactions. 9. In textile and paper industry. 10. In leather industry for tanning 11. As a dehyrating agent. 12. As a laboratory reagent.

Structure of Sulphuric Acid. Sulphuric acid is a dibasic acid and has been assigned tetrahedral structure as shown.



The high boiling point and viscosity of sulphuric acid indicate association of sulphuric acid molecules due to hydrogen bonding, as shown below :



Pyrosulphuric Acid, $H_2S_2O_7$, Oleum. Pyrosulphuric acid is obtained by dissolving sulphur trioxide in concentrated sulphuric acid.

$$H_2SO_4 + SO_3 \longrightarrow H_2S_2O_7$$

This can also be obtained by distilling ferrous sulphate monohydrate crystals. The receiver should contain preferably some sulphuric acid.

$$6FeSO_4.H_2O \longrightarrow Fe_2(SO_4)_3 + 2Fe_2O_3 + 3SO_2 + 6H_2O$$

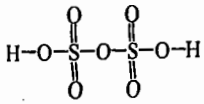
$$Fe_2(SO_4)_3 \longrightarrow Fe_2O_3 + 3SO_3$$

$$SO_3 + H_2SO_4 \longrightarrow H_2S_2O_7$$

It is a viscous brownish liquid and is believed to be a solution of sulphur trioxide in conc. sulphuric acid. It fumes in air and hence the name *fuming sulphuric acid*. This is due to the escape of sulphur trioxide. It changes into ordinary sulphuric acid on warming as the dissolved sulphur trioxide escapes into the air. It solidifies on cooling below 0°C. It is used in the manufacture of dyes and explosives and in refining of petroleum.

If forms salts, known as **pyrosulphates**. Sodium pyrosulphate, $Na_2S_2O_7$, is definitely known. This shows that the acid is a definite compound of the composition $H_2S_2O_7$.

Structure of Pyrosulphuric Acid. The structure of the acid is as shown below :

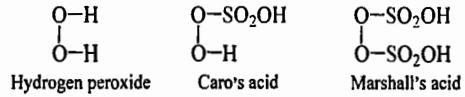


Peroxosulphuric Acids

Two peroxosulphuric acids are known. These are

1. *Peroxomonosulphuric acid*, H_2SO_5 (Caro's acid)
2. *Peroxodisulphuric acid*, $H_2S_2O_8$ (Marshall's acid)

These acids may be considered as derived from hydrogen peroxide by the replacement of one or both atoms of hydrogen by sulphonic groups :



Caro's acid, Peroxomonosulphuric acid, H_2SO_5. This is obtained

1. By the low conversion of peroxodisulphuric acid in aqueous solution or by grinding potassium peroxodisulphate crystals with conc. sulphuric acid in a freezing mixture.

$$H_2S_2O_8 + H_2O \longrightarrow H_2SO_5 + H_2SO_4$$

$$K_2S_2O_8 + H_2SO_4 \longrightarrow H_2SO_5 + K_2S_2O_7$$

2. By the reaction of chlorosulphonic acid with anhydrous hydrogen peroxide.

$$HOOH + ClSO_2OH \longrightarrow HOOSO_2(OH) + HCl$$

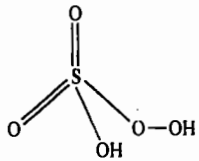
It is a white crystalline mass (m.p. 45°C). It is fairly stable. It has strong oxidising properties, as such it is stronger than peroxodisulphuric acid. Thus, it liberates iodine from potassium iodide much more readily than peroxodisulphuric acid does. This serves to distinguish between the two acids.

It also oxidises sulphur dioxide to sulphur trioxide, ferrous salts to ferric state, hydrogen chloride to chlorine, aniline to nitrosobenzene and nitrobenzene.

It precipitates peroxides from salts of copper, silver, manganese, etc.

No solid salts of Caro's acid are known. However, a solution of $KHSO_5$ is believed to be formed by the action of hydrogen peroxide on $KHSO_3$. The acid, therefore, is considered to be monobasic.

Structure. Peroxomonosulphuric acid has been assigned a tetrahedral structure as shown.



Marshall's acid, Peroxodisulphuric acid, $H_2S_2O_8$. This acid is prepared

1. By anodic oxidation of sulphuric acid. Peroxodisulphuric acid is obtained by the electrolysis of 50 per cent sulphuric acid in cold.

The reaction is represented as below :

Cathode : $H^+ + e^- \longrightarrow H$

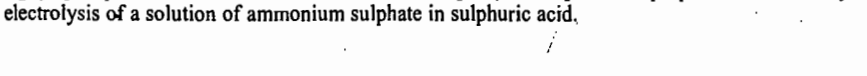
$H + H \longrightarrow H_2$

Anode : $HSO_4^- + HSO_4^- \longrightarrow H_2S_2O_8 + 2e^-$

Another explanation for the formation of peroxodisulphuric acid at the anode is that the bisulphate ions are oxidised by the nascent oxygen that appears at the anode as a result of electrolysis.

$$2HSO_4^- + H_2O + O \longrightarrow H_2S_2O_8 + 2OH^-$$

2. By sulphonation of hydrogen peroxide. Treatment of hydrogen peroxide with chlorosulphonic acid (in the molar ratio of 1 : 2), yields peroxodisulphuric acid.



Preparation of Peroxodisulphates. By the electrolysis of a saturated aqueous solution of potassium hydrogen sulphate (or that of potassium sulphate in sulphuric acid), crystals of **potassium peroxodisulphate, $K_2S_2O_8$**, separate out at the anode. **Ammonium peroxodisulphate** is prepared conveniently by the electrolysis of a solution of ammonium sulphate in sulphuric acid.

Potassium and ammonium peroxodisulphates are also prepared by the action of fluorine on potassium hydrogen sulphate or ammonium hydrogen sulphate, as the case may be.

$$2KHSO_4 + F_2 \longrightarrow K_2S_2O_8 + 2HF$$

Properties of Peroxodisulphuric acid and Peroxodisulphates. Peroxodisulphuric acid is a stable compound. It is a crystalline solid (m.p. 65°C) and is fairly soluble in water. Its salts, the peroxodisulphates, decompose on heating evolving sulphur dioxide and oxygen.

$$K_2S_2O_8 \longrightarrow K_2SO_4 + SO_2 + O_2$$

The solutions of peroxodisulphates give oxygen slowly in cold and rapidly on heating.

$$2K_2S_2O_8 + 2H_2O \longrightarrow 4KHSO_4 + O_2$$

The peroxodisulphates are powerful oxidising agents. They liberate iodine from potassium iodide solution.

$$K_2S_2O_8 + 2KI \longrightarrow 2K_2SO_4 + I_2$$

Similarly, they oxidise ferrous salts to ferric state, manganous salts to permanganates and chromic salts to dichromates in the catalytic presence of silver nitrate.

Barium peroxodisulphate is soluble in water. This fact helps in distinguishing between a peroxodisulphate and a sulphate by the addition of barium chloride when a soluble sulphate gives a precipitate of barium sulphate while a peroxodisulphate does not give any precipitate.

Some metals, *e.g.*, zinc, dissolve in an aqueous solution of peroxodisulphates giving sulphates.

$$K_2S_2O_8 + Zn \longrightarrow K_2SO_4 + ZnSO_4$$

Ammonium peroxodisulphate is used as bleaching and reducing agent.

Peroxodisulphuric acid, in aqueous solution, changes gradually into Caro's acid.

$$H_2S_2O_8 + H_2O \longrightarrow \underset{\text{Caro's acid}}{H_2SO_5} + H_2SO_4$$

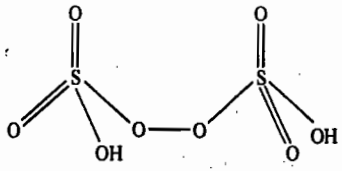
Caro's acid is further hydrolysed to give H_2O_2 and H_2SO_4.

$$H_2SO_5 + H_2O \longrightarrow H_2O_2 + H_2SO_4$$

Distinction between Caro's acid, Marshall's acid and Hydrogen peroxide. Caro's acid, Marshall's acid and Hydrogen peroxide can be distinguished from one another by the following tests.

1. Caro's acid liberates iodine almost instantaneously from potassium iodide.
2. Marshall's acid liberates iodine slowly from potassium iodide.
3. Hydrogen peroxide decolorises (reduces) potassium permanganate which is not done by either of the two peroxodisulphuric acids.

Structure. The peroxodisulphuric acid is assigned the structure, as shown.



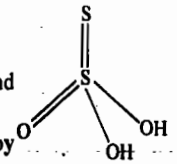
This structure accounts for its dibasic character.

Thiosulphuric acid, $H_2S_2O_3$. Thiosulphuric acid is highly unstable. It exists only in solution and there, too, it changes rapidly into sulphurous acid depositing free sulphur.

$$H_2S_2O_3 \longrightarrow H_2SO_3 + S$$

The salts, known as **thiosulphates**, as, for example, $Na_2S_2O_3$ are fairly stable and important.

Structure. Thiosulphuric acid may be regarded as derived from sulphuric acid by the replacement of one of the oxygen atoms by a sulphur atom as shown.



Dithionous acid, $H_2S_2O_4$. The acid $H_2S_2O_4$ is not known but its salts in anhydrous form (known as dithionites) are known.

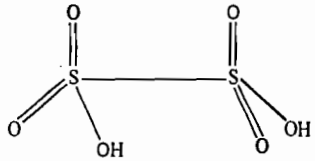
The dithionites are unstable compounds and hydrolyse rapidly.

Dithionic acid, $H_2S_2O_6$. The free acid has not been prepared. It is known only in solution. The concentrated aqueous solution of dithionic acid can be prepared by treatment of the barium salt with sulphuric acid.

$$BaS_2O_6\,(aq) + H_2SO_4\,(aq) \longrightarrow H_2S_2O_6\,(aq) + BaSO_4$$

The salts of dithionic acid, *viz.*, dithionates, are thermally stable above room temperature and are readily soluble in water.

Structure. Dithionic acid has been assigned the structure, as shown, in which the bond angles are approximately equal to normal tetrahedral angles.



Polythionic Acids and Polythionates. The free acids are not stable ; they rapidly decompose to give sulphur and sulphur dioxide. Polythionic acids and polythionates are named according to the total number of sulphur atoms present. Thus, polythionates $S_3O_6^{2-}$, $S_4O_6^{2-}$, $S_5O_6^{2-}$ and $S_6O_6^{2-}$ are named as trithionate, tetrathionate, pentathionate and hexathionate, respectively.

Mixtures of thionates are obtained by the reduction of a thiosulphate solution with SO_2 in the presence of As_2O_3. Individual members can, however, be prepared by selective methods.

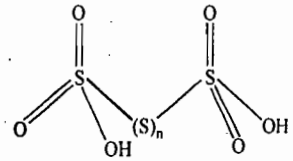
Trithionate, for example, can be prepared by the action of H_2O_2 on cold saturated solution of a thiosulphate.

$$2S_2O_3^{2-} + 4H_2O_2 \longrightarrow S_3O_6^{2-} + SO_4^{2-} + 4H_2O$$

Tetrathionates are obtained by the oxidation of a thiosulphate with iodine solution.

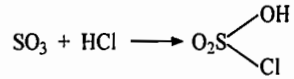
$$2S_2O_3^{2-} + I_2 \longrightarrow S_4O_6^{2-} + 2I^-$$

Structure. Polythionic acids have – S –S – linkages and their general structure may be represented as shown.



Chlorosulphonic Acid, $HOSO_2Cl$. It may be considered as a derivative of sulphuric acid in which one of the hydroxyl groups present in the acid ($HO - SO_2 - OH$) is replaced by chlorine. It can be prepared

1. By passing dry hydrogen chloride gas into fuming sulphuric acid, *i.e.*, sulphuric acid containing dissolved sulphur trioxide. Hydrogen chloride directly unites with sulphur trioxide giving chlorosulphonic acid.



The resulting product is recovered and purified by distillation.

2. By distilling a mixture of sulphuric acid and phosphorus pentachloride or phosphorus oxochloride.

$$H_2SO_4 + PCl_5 \longrightarrow ClSO_2OH + POCl_3 + HCl$$

$$2H_2SO_4 + POCl_3 \longrightarrow 2ClSO_2OH + HPO_3 + HCl$$

Properties. Chlorosulphonic acid is a colourless liquid boiling at 151°C. It strongly fumes in air.

It is rapidly hydrolysed by water with explosive violence.

$$ClSO_2OH + H_2O \longrightarrow HCl + HOSO_2OH$$

When heated at 170–180°C, its vapours decompose into sulphuryl chloride and sulphuric acid.

$$2ClSO_2OH \longrightarrow SO_2Cl_2 + H_2SO_4$$

At still higher temperatures, it breaks into Cl_2, SO_2 and H_2SO_4.

It reacts with aromatic hydrocarbons giving sulphonic derivatives. For example,

$$\underset{\text{Benzene}}{C_6H_6} + ClSO_2OH \longrightarrow \underset{\text{Benzene sulphonic acid}}{C_6H_5SO_3H} + HCl$$

It is used in organic chemistry as a sulphonating agent.

Oxoacids of Selenium and Tellurium

Selenium forms only two oxoacids, namely, selenous acid, H_2SeO_3 and selenic acid, H_2SeO_4.

Selenous acid is prepared by dissolving selenium dioxide in water and then slowly crystallising the solution. It can also be prepared by the oxidation of powdered selenium with dilute HNO_3.

$$3Se + 4HNO_3 + H_2O \longrightarrow 3H_2SeO_3 + 4NO$$

Selenous acid is a white stable solid. It can be dehydrated to selenium dioxide in a stream of dry air. It is converted to selenic acid by refluxing with hydrogen peroxide. With alkalies, selenous acid forms two types of salts, $MHSeO_3$ and M_2SeO_3 (M = alkali metal).

Selenic acid can be prepared by the following methods :

1. Oxidation of selenium with chlorine or bromine water.

$$Se + 3Cl_2 + 4H_2O \longrightarrow H_2SeO_4 + 6HCl$$

2. Oxidation of selenous acid by hydrogen peroxide or potassium permanganate :

$$H_2SeO_3 + H_2O_2 \longrightarrow H_2SeO_4 + H_2O$$

$$8H_2SeO_3 + 2KMnO_4 \longrightarrow 5H_2SeO_4 + K_2SeO_3 + 2MnSeO_3 + 3H_2O$$

Anhydrous selenic acid is a viscous liquid and crystallises to a white solid (m.p. 62°C). It resembles sulphuric acid in its chemical properties but is a much stronger oxidising agent. It can dissolve Au, Pd and even Pt in the presence of chloride ion. Like H_2SO_4, it forms several hydrates such as $H_2SeO_4.H_2O$, $H_2SeO_4.4H_2O$, etc. It forms selenates which resemble sulphates.

Tellurous acid, H_2TeO_3, was not known earlier because it could not be prepared by dissolving TeO_2 in water as TeO_2 is almost insoluble in water. These days it is obtained by the hydrolysis of a tetrahalide of tellurium. Its structure has not been established. It has also been found to form two types of salts, *viz.*, $MHTeO_3$ and M_2TeO_3 with aqueous alkalies.

Telluric acid, H_6TeO_6, on the other hand, is quite stable and is well known. It can be prepared by the oxidation of powdered tellurium with chloric acid or by the oxidation of Te or TeO_2 with a mixture of nitric acid and chromic acid.

$$5Te + 6HClO_3 + 12H_2O \longrightarrow 5H_6TeO_6 + 3Cl_2$$

It is a white solid (m.p. 136°C). It is quite different from sulphuric and selenic acids and exists as octahedral $Te(OH)_6$ molecules. It is a fairly strong oxidising agent but unlike H_2SO_4 and H_2SeO_4, it is a weak dibasic acid. The anhydrous telluric acid is stable in air upto 100°C but above 120°C, it loses water to form polymetatelluric acid.

OXOHALIDES OF SULPHUR

The two important oxohalides of sulphur are thionyl dihalides (SOX_2) and sulphuryl dihalides (SO_2X_2). Although a number of thionyl dihalides like SOF_2, SOFCl, $SOCl_2$ and $SOBr_2$ are known, the most important of these is thionyl dichloride $SOCl_2$. It is readily prepared by chlorination of SO_2 with

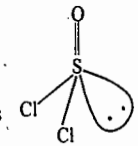
PCl_5 or by reacting SO_3 with SCl_2.

$$SO_2 + PCl_5 \longrightarrow SOCl_2 + POCl_3$$

$$SO_3 + SCl_2 \longrightarrow SOCl_2 + SO_2$$

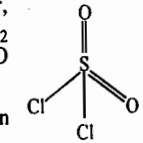
Thionyl chloride vigorously reacts with water and is used for drying some inorganic halides.

$$MX_m.nH_2O + nSOCl_2 \longrightarrow MX_m + nSO_2 + 2nHCl$$



It is widely used as a nonaqueous solvent. S in $SOCl_2$ is sp^3 hybridised. It forms one S = O bond and two S – Cl bonds and has a lone pair, as shown.

Amongst the known sulphuryl dihalides, *viz.*, SO_2F_2, SO_2FCl, SO_2Cl_2 and SO_2FBr, the most important is **sulphuryl dichloride** which is prepared by reacting SO_2 with Cl_2 using activated charcoal as catalyst. S in SO_2Cl_2 is sp^3 hybridised and forms two S = O and two S – Cl bonds, as shown.



It is a useful chlorinating agent. It is also used for introducing – SO_2Cl group in organic compounds.

NITRIDES OF SULPHUR

Tetrasulphur Tetranitride, S_4N_4. This is the most important nitride of sulphur which can be prepared by any of the following reactions :

1. $$16NH_3 + 6S_2Cl_2 \xrightarrow[CCl_4]{50°C} S_4N_4 + 8S + 12NH_4Cl$$

2. $$4NH_4Cl + 6S_2Cl_2 \xrightarrow{160°C} S_4N_4 + 8S + 16HCl$$

3. $$10S + 4NH_3 \longrightarrow S_4N_4 + 6H_2S$$

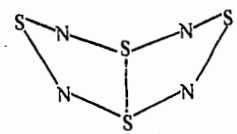
$$H_2S + 2NH_3 \longrightarrow (NH_4)_2S$$

S_4N_4 is an orange compound with a melting point of 178°C. It explodes to give S and N_2 when struck or heated. It forms adducts $S_4N_4.BF_3$ and $S_4N_4.SbCl_5$ with BF_3 and $SbCl_5$, respectively.

S_4N_4 gets hydrolysed by dilute and concentrated alkali solutions.

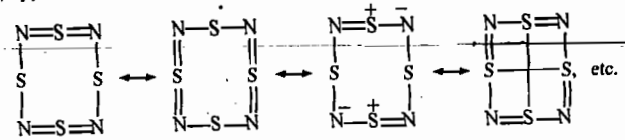
$$2S_4N_4 + 6OH^- \text{ (dilute)} + 9H_2O \longrightarrow S_2O_3^{2-} + 2S_3O_6^{2-} + 8NH_3$$

$$S_4N_4 + 6OH^- \text{ (concentrated)} + 3H_2O \longrightarrow S_2O_3^{2-} + 2S_3O_3^{2-} + 4NH_3$$



Structure of S_4N_4. Tetrasulphur tetra-nitride has a cradle-like skeletal structure as shown.

All the S–N bond distances are equal (*i.e.*, 1·60 Å) which are shorter than the calculated S – N single bond distance of 1·75 Å. This indicates some double bond character in S – N bonds. The trans annular S – S distances are shorter than twice the van der Waals radius for S atom indicating that there may be a weak association between the trans annular S atoms. The actual structure of S_4N_4 appears to be a resonance hybrid of a number of the following types of structures :

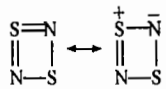


Disulphur Dinitride, S_2N_2. This compound is prepared by pumping vapours of S_4N_4 through silver wool.

$$S_4N_4 + 8Ag \longrightarrow 4Ag_2S + 2N_2$$

$$S_4N_4 \xrightarrow{Ag_2S} 2S_2N_2$$

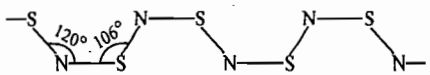
S_2N_2 is a colourless crystalline compound which explodes on heating. On slow heating, it polymerises to $(SN)_x$. It has a square planar cyclic structure, as shown :



Polythiazyl, $(SN)_x$. It is prepared by heating pure S_4N_4 at 70°C and condensing the vapour produced on glass surface at 10–30°C. It is also produced by slow heating of S_2N_2, as mentioned above.

Polythiazyl shows optical anisotropy and electrical anisotropy. It is superconducting at 0·26 K. $(SN)_x$ is a rare example of a superconducting compound obtained from a non-metal.

Its structure contains a zig-zag chain having SNS angle of 120° and NSN angle of 106°, as shown



Other sulphur-nitrogen compounds known are S_4N_2, $S_{11}N_2$ and S_5N_6. A number of cationic and anionic species such as S_2N^+, $S_3N_2^+$, $S_4N_3^+$, $S_4N_4^{2+}$, $S_4N_5^+$, $S_5N_5^+$, $S_4N_5^-$, $S_3N_3^-$, etc., are also known.

ORGANOMETALLIC COMPOUNDS

Amongst the elements of Group 16, only selenium and tellurium are known to form organometallic compounds. A detailed discussion of these compounds is beyond the scope of the book. Only a brief description is given below.

Organometallic Compounds of Selenium and Tellurium. The common organoselenium compounds are RSeX, R_2SeX_2, R_2Se and RSeH. These are prepared by the following reactions :

$$2RBr + Na_2Se \longrightarrow R_2Se + 2NaBr$$

$$R_2Se + X_2 \longrightarrow R_2SeX_2$$

$$RBr + Na_2Se_2 \xrightarrow{\text{liq. } NH_3} R_2Se_2 + 2NaBr$$

$$R_2Se_2 \xrightarrow{Zn, X_2} 2RSeX$$

$$R_2Se_2 \xrightarrow{2H} 2RSeH$$

(R is alkyl or aryl group ; X is the halogen)

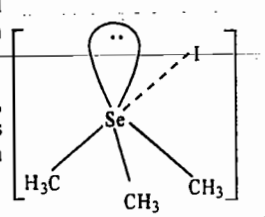
Selenium and tellurium also form compounds which are analogous to carbonyl compounds and the amides.

The structures of derivatives of seleno and tellurocarbonyls and amides are given below :

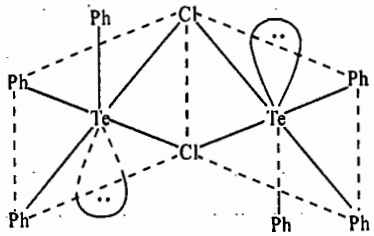
$$R-\underset{\underset{Se\ (or\ Te)}{\|}}{C}-OR \qquad Rh-\underset{\underset{Se\ (or\ Te)}{\|}}{C}-N(Me)_2$$

Telluro derivatives are more reactive than the corresponding seleno derivatives.

Both Se and Te have a tendency to increase their coordination numbers in the presence of suitable ions. Thus, the compound $[Se(CH_3)_3]^+I^-$ has I^- ion associated with Se as shown.



Similarly, the compound, commonly written as $[Ph_3Te]^+Cl^-$, is a dimer with the structure as shown.



QUESTIONS

1. Name the elements of Group 16. Discuss the gradation in the properties of the elements of Group 16 with reference to
   (*i*) ionisation energy (*ii*) catenation (*iii*) electronegativity and (*iv*) oxidation state
2. (*a*) The first member of a group differs from the remaining members. Justify the statement by taking the example of oxygen.
   (*b*) Explain the following :
   (*i*) Water is a weaker acid that H_2S.
   (*ii*) Water has a higher boiling point than H_2S.
   (*iii*) Water is weaker reducing agent than H_2S.
   (*c*) Discuss the structure of oxygen molecule.
3. (*a*) Discuss one method of preparation and structure of principal fluorides of sulphur.
   (*b*) Why is oxygen a gas while sulphur is a solid ?
   (*c*) How and why does the acid strength vary among hydrides of the elements of Group 16 ?
   (*d*) Oxygen exhibits –2 oxidation state but other members of the group show in addition to –2, other oxidation states of +2, +4 and +6 also. Why is it so ?
4. (*a*) Give one method of preparation, two important properties and structures of
   (*i*) SO_2 (*ii*) SO_3 (*iii*) H_2SO_3 (*iv*) H_2SO_4 .
   (*b*) The formula for telluric acid is H_6TeO_6 or $Te(OH)_6$. Explain as to why the analogous sulphuric acid, $S(OH)_6$ does not exist.
   (*c*) Give examples to illustrate the Lewis acid character of SF_4 and $TeCl_4$.
5. (*a*) Arrange H_2X (X = O, S, Se, Te, Po) compounds in order of increasing (*i*) acidity (*ii*) stability (*iii*) boiling point (*iv*) reducing character.
   (*b*) Why is the bond angle in H_2O more than that in H_2S ?
   (*c*) Give the structures of SO_2 and SO_3 molecules.
6. (*a*) Out of the elements of Group 16, select one with (*i*) highest ionisation energy (*ii*) highest ability to catenate (*iii*) smallest atomic radius (*iv*) highest electronegativity.
   (*b*) Name two peroxoacids of sulphur. Give their structures.
7. List the various oxoacids of sulphur. Discuss their structures.
8. What do you know about Caro's acid and Marshall's acid ? Discuss their preparation and properties.
9. How does selenium occur in nature ? How is the metal prepared ? Discuss its important properties and uses.
10. What is meant by photoconductivity ? Discuss in deails how selenium is used in xerography.
11. (*a*) How does tellurium occur in nature ? How is the metal obtained ? Describe its properties and uses.
    (*b*) Write a short note on the preparation, properties and uses of polonium.
12. Explain the following :
    (*a*) O_2 molecule is paramagnetic.
    (*b*) SF_6 is known but SCl_6 is not known.
    (*c*) H_2Te is stronger acid than H_2S.
    (*d*) The O – O bond energy in O_2 is much larger than the S – S bond energy in S_8.
    (*e*) Maximum covalency of oxygen is two.

19 THE ELEMENTS OF GROUP 17

Group 17 comprises of five elements, namely, **fluorine, chlorine, bromine, iodine** and **astatine.** They do not occur free but in the combined state they occur fairly abundantly in nature. Fluorine, chlorine, bromine and iodine constitute, respectively, 0·06 to 0·09, 0·031, 0·00016 and 0·00003 per cent of earth's crust. Astatine is radioactive and occurs very sparsely.

Fluorine, chorine, bromine and iodine have closely related properties and are known collectively as the **halogens** (Greek, *halos* = sea salts, *genes* = born) since the salts of the first three occur in sea water. On account of their close resemblance and gradual transition of physical and chemical properties, the halogens constitute a well-marked group.

Electronic Configurations. The electronic configurations of the halogens are given in Table 1.

TABLE 1
Electronic Configurations of the Halogens

Element	Atomic Number	Electronic Configuration
Fluorine, F	9	[He] $2s^2p^5$
Chlorine, Cl	17	[Ne] $3s^2p^5$
Bromine, Br	35	[Ar] $3d^{10}4s^2p^5$
Iodine, I	53	[Kr] $4d^{10}5s^2p^5$
Astatine, At	85	[Xe] $4f^{14}5d^{10}6s^2p^5$

As is evident, the halogens have the general outer electronic configurations $\mathbf{ns^2p^5}$.

GENERAL CHARACTERISTICS OF GROUP 17 ELEMENTS

Some important **physical properties** of the halogens are given in Table 2.

1. Atomic volume, atomic radius and **density** increase regularly with increase in atomic number, as expected.

2. Ionisation energy. Ionisation energies of the halogens are very high indicating that they have very small tendency to lose electrons. The values, however, decrease on moving down the group, as expected. In the case of iodine, the value is comparatively low. This enables the iodine atom to lose an electron and form I^+ ion.

3. Electronegativity. The halogens have very high electronegativities. Fluorine is the most electronegative with electronegativity = 4. The values decrease as we move down the group from fluorine to iodine indicating a gradual decline in the non-metallic character, so much so that the last element iodine, with an electronegativity of 2·6, shows some metallic character also. For instance, it forms in a few cases a positive ion and has a metallic lustre.

TABLE 2
Physical Properties of the Halogens

Property	Fluorine	Chlorine	Bromine	Iodine
Atomic Number	9	17	35	53
Atomic mass (a.m.u.)	18·998	35·453	79·909	126·904
Physical state	Gas	Gas	Liquid	Solid
M.P. (°C)	−218·6	−101·0	−7·2	113·9
B.P. (°C)	−188·1	−34·6	59·5	185·2
Density in liquid state (g cm^{-3})	1·108	1·1557	2·948	3·76 (in solid state)
Colour of vapour	Pale yellow	Greenish yellow	Orange red	Violet
Colour of liquid	Clear yellow	Amber yellow	Reddish brown	Shining dark solid
Atomic radius (Å)	0·72	0·99	1·14	1·33
Ionic radius of X^- ion (Å)	1·33	1·84	1·96	2·20
Atomic volume (c.c.)	17·1	18·7	23·5	25·7
Electronegativity (Pauling's values)	4·0	3·1	2·9	2·6
Electron affinity (kJ mol^{-1})	332·6	348·5	324·7	295·5
Ionisation energy (kJ mol^{-1})	1680·8	1255·5	1140·1	1008·8
Oxidation states	−1	−1, +1, +3 +4, +5, +6, +7	−1, +1, +3 +4, +5, +6	−1, +1, +3, +4, +5, +6, +7
Bond energy (kJ mol^{-1})	158·8	242·6	192·8	151·1
Standard electrode potential (volts)	+2·87	+1·36	+1·06	+0·53

4. Non-metallic character. On account of high electronegativities, all the halogens are non-metallic in character. The non-metallic character, however, decreases as we move down the group. The last element, iodine, has comparatively very small electronegativity and exhibits metalloidal character. It has a metallic lustre and has a tendency to lose an electron to form a positive ion (*cf.* alkali metals), as mentioned above.

5. Colour. All the halogens are coloured. This is because of the absorption of visible light by their molecules resulting in the excitation of electrons from the highest filled molecular orbitals to the lowest unoccupied molecular orbitals. The excitation energy, evidently, depends upon the size of the halogen atom. The smaller the atom, the greater is the force of attraction between the nucleus and the outer electrons and hence greater is the amount of the energy required to raise the electrons to higher levels. Consequently, the excitation energy is very large in the case of fluorine and comparatively very small in the case of iodine. Hence, fluorine absorbs violet portion of the light which is associated with higher energy and thus appears *yellow*. Iodine, on the other extreme, absorbs yellow and green radiations which are associated with lower energy and thus appears *violet*. Similarly, we can account for the *greenish yellow* colour of chlorine and *orange red* colour of bromine.

6. Electron affinity. All the elements have high electron affinities. Therefore, they have a strong tendency to gain an electron to acquire noble gas configuration, *viz.*, s^2p^6. Chlorine has the highest electron affinity which decreases gradually as we move down the group from Cl to I. The electron affinity of fluorine is lower than that of chlorine. The unexpectedly lower value is due to the small size of the atom. The addition of an extra electron in fluorine atom produces a high electron density in a relatively compact 2*p* subshell and, therefore, there is a strong electron–electron repulsion. Consequently, fluorine has lesser tendency to accept extra electron, that is, its electron affinity is low.

7. Oxidation states. It is evident from Table 1 that all the halogens have the configuration s^2p^5 in the outer shell in the ground state. These elements, therefore, tend to gain or share one electron to acquire noble gas configuration. Hence they show an oxidation state of −1 or +1, depending upon whether the element with which they combine is less electronegative or more electronegative than the halogen.

Since fluorine is the most electronegative element, it *always exhibits an oxidation state of* −1. It does not exhibit any positive oxidation state. Also, fluorine has no *d* orbitals in its valency shell and hence it cannot have any excited states. Consequently, it does not exhibit any higher oxidation state.

The other halogens exhibit higher positive oxidation states of +3, +4, +5, +6 and +7 as well because they have vacant *d* orbitals in their valency shells which allow for easy excitation of *p* as well as *p* and *s* electrons, *as* illustrated in Fig. 1.

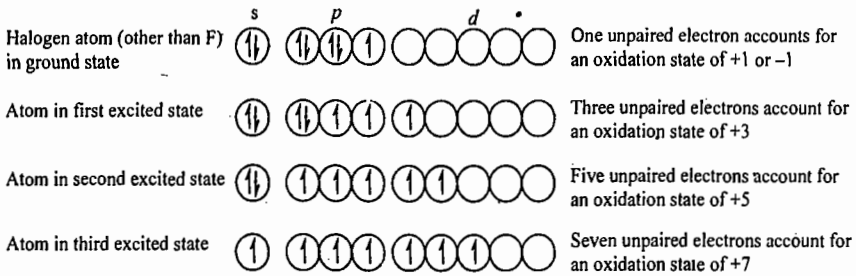


Fig. 1. Various oxidation states exhibited by the halogens other than fluorine.

In the first excited state, one pair of *p* electrons gets unpaired providing three unpaired electrons. This accounts for an oxidation state of +3. Thus, in the interhalogen compounds, ClF_3, BrF_3 and IF_3, chlorine, bromine and iodine are in +3 oxidation state.

In the second excited state, both the pairs of *p* electrons get unpaired providing five unpaired electrons which account for an oxidation state of +5. Thus, in $HClO_3$, $HBrO_3$ and HIO_3, the halogens are in +5 oxidation state.

Similarly, in BrF_5 and IF_5, bromine and iodine are in +5 oxidation states. Iodine is also in +5 oxidation state in I_2O_5.

In the third excited state, the pairs of *p* as well as *s* electrons get unpaired, providing seven unpaired electrons which account for an oxidation state of +7. Thus, in $HClO_4$ and Cl_2O_7, chlorine is in an oxidation state of +7 and in HIO_4, iodine is also in an oxidation state of +7. *Bromine does not exhibit +7 oxidation state.* Thus, compounds such as $HBrO_4$, Br_2O_7 are not known.

Chlorine and bromine exhibit oxidation states of +4 and +6 as well in their oxygen compounds, *e.g.*, ClO_2, BrO_2 and Cl_2O_6 and Br_2O_6, respectively. Iodine exhibits an oxidation state of +4 in I_2O_4.

8. Oxidising power. Since the halogens, on account of high electron affinities, have a strong tendency to pick up electrons, they act as strong oxidising agents. The oxidising character, however, decreases on moving down the group. This can be explained with the help of the **Born-Haber cycle.** The reaction

$$\frac{1}{2}X_2(s, l \text{ or } g) + e^- + aq \xrightarrow{\Delta E} X^-(aq)$$

representing the oxidising action of the halogen is actually a complicated process. It involves the following steps if we assume the halogen to be solid (*e.g.*, I_2)

1. The solid halogen (*e.g.*, I_2) changes into the liquid state. The energy required in this process is known as the heat of fusion, ΔH_f. Thus,

$$X_2(s) \xrightarrow{\Delta H_f} X_2(l)$$

2. The liquid halogen changes into the gaseous state. The energy required in this process is known as the heat of vaporisation, ΔH_v. Thus,

$$X_2(l) \xrightarrow{\Delta H_v} X_2(g)$$

3. The gaseous molecular halogen changes into the atomic state. The energy required in this case is known as the heat of dissociation, ΔH_d. Thus,

$$X_2(g) \xrightarrow{\Delta H_d} X(g)$$

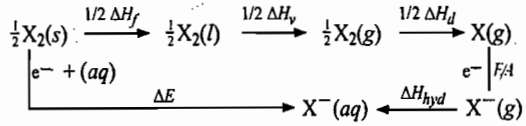
4. The gaseous atom changes into the gaseous ion. The energy involved in this process is known as electron affinity (*EA*). Thus,

$$X(g) + e^- \xrightarrow{EA} X^-(g)$$

5. The gaseous ion finally changes into the hydrated ion. The energy involved in this process is known as the heat of hydration of the ion, ΔH_{hyd}. Thus,

$$X^-(g) + aq \xrightarrow{\Delta H_{hyd}} X^-(aq)$$

In order to work out the value of ΔE for the halogen which, in fact, is a measure of its oxidising strength, the various changes are represented as follows :



(ΔH_f and ΔH_v are not involved if the halogen is a gas. ΔH_f is not involved if the halogen is liquid).

Since energy is invariably *absorbed* in converting a solid into liquid and a liquid into gaseous state and also in converting molecular halogen into the atomic state, ΔH_f, ΔH_v and ΔH_d have *positive* values. However, energy is *released* in the formation of a negative ion as well as in the process of its hydration. Hence, the numerical values of electron affinity and ΔH_{hyd} are *negative*. Consequently, from Hess's law, the net energy (ΔE) required for the reaction

$$\frac{1}{2}X_2(s) + e^- + aq \longrightarrow X^-(aq)$$

is given by the expression

$$\Delta E = \frac{1}{2}\Delta H_f + \frac{1}{2}\Delta H_v + \frac{1}{2}\Delta H_d - EA - \Delta H_{hyd}$$

ΔE is a measure of the oxidising potential, *i.e.*, the tendency of the halogen to act as an oxidising agent.

The values of ΔE calculated as above for the various halogens are given below.

Halogen	$\frac{1}{2}$ Heat of fusion (kJ)	$\frac{1}{2}$ Heat of vaporisation (kJ)	$\frac{1}{2}$ Heat of dissociation (kJ)	Electron affinity (kJ)	Heat of hydration (kJ)	ΔE (kJ)
F_2	–	–	+79	–332	–515	–768
Cl_2	–	–	+122	–348	–381	–607
Br_2	–	+15	+96	–324	–347	–575
I_2	+8	+22	+76	–295	–305	–524

Since fluorine and chlorine are gaseous at room temperature, the heats of fusion and vaporisation are not involved. Similarly, in the case of bromine, which is liquid at ordinary temperatures, the heat of fusion has been omitted.

The magnitude of ΔE is maximum in the case of fluorine and gradually decreases as we move down the group. Thus, fluorine is the strongest oxidising agent and iodine is the weakest oxidising agent. These results also explain why chlorine, which has the maximum electron affinity, is not the strongest oxidising agent. Inspection of the above table shows that the stronger oxidising character of F_2 in comparison to Cl_2 is mainly due to its relatively lower bond dissociation energy and higher heat of hydration. It is the *oxidising potential* and not the electron affinity alone *which controls the strength of the halogen to act as an oxidising agent in aqueous medium.*

9. Combination with metals and non-metals. All the halogens react with metals and also with many non-metals to form halides. Fluorine is the most reactive. The reactivity decreases as we move down the group. For instance, with sulphur, fluorine forms the hexafluoride (SF_6), chlorine forms the tetrachloride (SCl_4), bromine forms the dibromide (SBr_2) whereas iodine does not react at all.

10. Reaction with water. The interaction of halogens with water provides another illustration of gradation in properties with increase in atomic number. For example, fluorine decomposes water very energetically ; chlorine and bromine do so much less readily according to the equation

$$X_2 + H_2O \longrightarrow HOX + HX$$

while iodine scarcely reacts with water.

11. Reaction with hydrocarbons. All the halogens react with hydrocarbons but the reactivity decreases with increase in atomic number. Fluorine is the most reactive and brings about decomposition of the hydrocarbon.

$$CH_4 + 2F_2 \longrightarrow C + 4HF$$

Chlorine brings about the substitution of hydrogen atoms.

$$CH_4 + 4Cl_2 \longrightarrow CCl_4 + 4HCl$$

Bromine also brings about substitution but at a slow rate. Iodine has little or no action.

PREPARATION OF ELEMENTS OF GROUP 17

Preparation of Fluorine. Because of its extremely reactive nature, fluorine does not occur free in nature. In combined state, it is fairly and widely distributed. It constitutes nearly 0·08 per cent of lithosphere. It occurs in *fluorspar* (CaF_2), *cryolite* ($AlF_3.3NaF$) and *apatite* [$CaF_2.3Ca_3(PO_4)_2$]. In small quantities, it occurs in some of the micas. Traces of fluorine occur in sea water, some mineral springs, bones, teeth, blood, milk, plants, etc. As a matter of fact, small quantities of fluorides present in soil find their way into river water, sea and plants and from plants into bones, blood and teeth of animals and human beings. The total abundance of fluorine on the earth has been estimated to be comparable with that of carbon, nitrogen and chlorine.

Isolation of fluorine presented a tough problem to chemists for about a century. All the difficulties inherent in its production arose from its extraordinary reactivity. It attacked water giving oxygen so that its production by the electrolysis of aqueous solution of fluorides was negated. It attacked glass, carbon and almost all metals including platinum and hence the apparatus could not be made of these materials. The problem was, however, finally solved by Moissan, in 1886, who prepared fluorine by the electrolysis of a solution of potassium hydrogen fluoride (KHF_2) in anhydrous hydrogen fluoride using an apparatus made of platinum-iridium alloy using electrodes also of the same alloy.

In later years, Moissan found that platinum-iridium alloy could be safely replaced by copper. This metal, though attacked by fluorine, gets covered with a thin impervious layer of copper fluoride which resists further attack.

For laboratory preparation of fluorine, **Dennis, Veeder** and **Rochow** electrolysed perfectly dry and fused potassium hydrogen fluoride in a heavy V-shaped tube (about 5 cm in diameter) made of copper, using graphite electrodes (Fig. 2). The ends of the tube are closed by copper caps through which pass the graphite electrodes. The latter are sealed and insulated by bakelite cement which is found to resist the attack of fluorine. The tube is heated in an electric resistance furnace to fuse the potassium hydrogen fluoride.

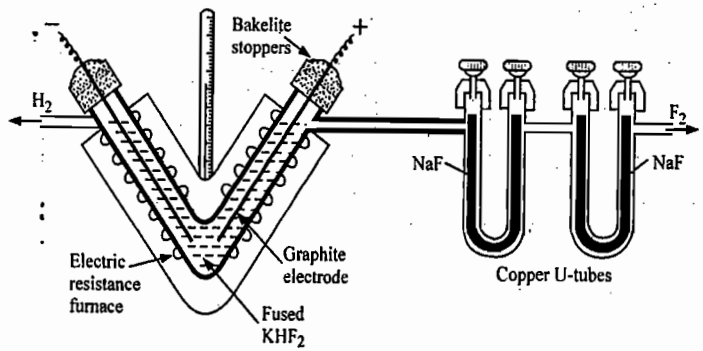


Fig. 2. Dennis apparatus for the preparation of fluorine.

For electrolysis, a current of 5 amperes at 12 volts is passed when hydrogen is liberated at the cathode and fluorine is liberated at the anode. The fluorine liberated at the anode is passed through copper U-tubes containing sodium fluoride to free it from hydrogen fluoride ($NaF + HF \longrightarrow NaHF_2$).

Commercial Preparation. Today even the commercial preparation of fluorine is no problem. Fluorine gas stored in steel tanks under pressure is offered for sale in America and other countries

The essentials of the electrolytic cell used for the industrial preparation of fluorine are shown in Fig. 3. It consists of a rectangular steel tank surrounded by a steam jacket. The tank is fitted with air-tight removable cover which carries a carbon anode, two 'slitted' copper or steel cathodes and a steel gas barrier, as shown. The cathode is 'slitted' to permit circulation of the electrolyte. The anode and the barrier are insulated from each other and also from the cathode with a special material, teflon or P.T.F.E. [polytetrafluoroethylene, $(C_2F_4)_n$] which is not attacked by fluorine. The gas barrier surrounds the anode and extends below the surface of the eletrolyte with a view to separating the products of electrolysis.

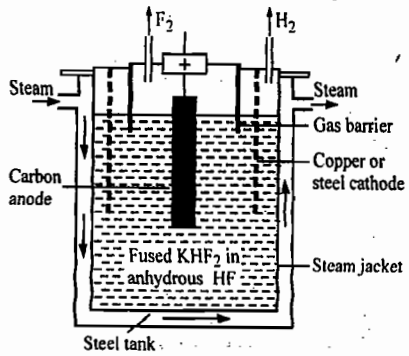

Fig. 3. Modern method for the manufacture of fluorine.

The electrolyte in this case is a 90 per cent solution of KHF_2 in anhydrous hydrogen fluoride. This is kept in the molten state by heating it to about 95°C with the help of steam passing through the steam jacket. But once the electrolysis starts, heating is no longer necessary because sufficient heat is produced during the process of electrolysis itself. On the other hand, cooling may sometimes be needed to maintain the electrolyte at about 95°C. The loss of hydrogen fluoride from the electrolyte is made good by passing in hydrogen fluoride periodically.

The fluorine obtained in this process is almost pure and is compressed into steel cylinders at a pressure of about 25 atm. If required, the small contamination of hydrogen fluoride is removed as usual by passing the gas over sodium fluoride.

Preparation of Chlorine. Chlorine constitutes nearly 0·19 per cent of lithosphere. It occurs mostly as chlorides of sodium and other alkali and alkaline earth metals. It is prepared mainly from sodium chloride which is crystallised from brine. In the **laboratory**, it is obtained by the oxidation of chloride ion in acid medium by using MnO_2 or permanganate ion as the oxidising agent.

$$2Cl^- + 4H^+ + MnO_2 \longrightarrow Mn^{2+} + 2H_2O + Cl_2$$

Bulk of chlorine required for **commercial purposes** is prepared by electrolysis of brine solution. The electrolysis is carried out primarily for the purpose of manufacturing caustic soda and chlorine is an important by-product of this process.

It is also a by-product of the manufacture of sodium (by electrolysis of fused sodium chloride) as well as of magnesium and calcium (by electrolyses of their fused chlorides)

Preparation of Bromine. Bromine, which constitutes nearly 0·01 per cent of lithosphere, occurs in combined state in sea water.

In laboratory, it can be prepared by oxidation of Br^- ion in the same way as that of Cl^- ion for the preparation of chlorine.

On a large scale, it is obtained from sea water by passing chlorine into sea water which contains bromides in sufficient amounts.

$$2Br^- + Cl_2 \longrightarrow 2Cl^- + Br_2$$

The free bromine thus liberated is blown out with air and dissolved in sodium carbonate solution to get sodium bromide and sodium bromate.

$$3CO_3^{2-} + 3Br_2 \longrightarrow 5Br^- + BrO_3^- + 3CO_2$$

Bromine is recovered from this solution by acidification.

$$6H^+ + 5Br^- + BrO_3^- \longrightarrow 3H_2O + 3Br_2$$

Preparation of Iodine. Iodine is the rarest of all the halogens. It constitutes merely 10^{-4} per cent of lithosphere. Its main source is *'kelp', viz.,* the ash obtained on burning sea-weeds in which it occurs as iodides and *chile saltpetre* in which it occurs as iodates.

The kelp containing about 0·1 percent of iodine as iodides is extracted with water. The extract is concentrated when sulphates and chlorides which are less soluble separate out while the iodides remain in solution (mother liquor). Iodine is recovered by passing chlorine through the mother liquor.

$$2I^- + Cl_2 \longrightarrow 2Cl^- + I_2$$

It is purified by sublimation.

Isolation of iodine from iodates (recovered from *chile saltpetre*) is affected by its reduction with sodium bisulphite.

$$2IO_3^- + 5HSO_3^- \longrightarrow 3HSO_4^- + 2SO_4^{2-} + H_2O + I_2$$

Preparation of Astatine. Astatine has not been found amongst the products of natural radioactive decay. Astatine of mass number 211 is the longest lived isotope. But even this has a half-life period of 7·5 hours. Astatine of mass number 211 can be made by bombarding bismuth with alpha particles.

$$^{209}_{83}Bi + ^{4}_{2}He \longrightarrow ^{211}_{85}At + 2^{1}_{0}n$$

It is isolated from bismuth by vacuum sublimation.

PROPERTIES OF ELEMENTS OF GROUP 17

Properties of Fluorine. Physical Properties. Fluorine is a pale greenish yellow gas, somewhat paler than chlorine. It possesses characteristic strong pungent odour resembling that of a mixture of ozone and chlorine. It can be condensed to a yellow liquid boiling at −188°C and a pale yellow solid melting at −223°C. The relative vapour density indicates a diatomic molecule, F_2.

Chemical Properties. Chemically, fluorine is the most reactive of all the elements. It combines directly with almost all other elements (except nitrogen and oxygen) with extreme vigour forming fluorides. It also attacks many other compounds, particularly organic compounds, breaking them down to fluorides. Organic compounds generally burn in the gas.

The more important reactions of fluorine are given below.

1. Combination with hydrogen. Fluorine directly combines with hydrogen with explosive violence even in the dark, forming hydrogen fluoride.

The fluoro-hydrogen flame has a very high temperature of about 4000°C.

2. Combination with metals. Fluorine attacks *all metals* forming fluorides, the intensity of attack depending upon the nature of the metals. Thus,

1. Alkali metals and alkaline earth metals burn spontaneously in the presence of fluorine gas to produce the corrosponding flourides.

2. Metals like magnesium, aluminium, nickel and silver require a little warming to start the reaction.

3. Metals like gold and platinum are a little resistant and are attacked on heating to about 300°C.

4. Metals like copper, steel and nickel get covered with a superficial impervious layer of fluoride which resists further attack. Hence, vessels of these metals are quite suitable for preparing and storing the gas.

5. Metals such as palladium and iridium are attacked at about 500°C.

3. Combination with non-metals. Non-metals such as carbon, sulphur, phosphorus, boron, silicon burn in fluorine forming the highest fluorides (*e.g.,* CF_4, PF_5, SiF_4, SF_6, etc.). **Metalloids** such as arsenic and antimony burn in the gas forming lower fluorides, *e.g.,*

$$2Sb + 3F_2 \longrightarrow 2SbF_3$$

4. Action of water. Fluorine reacts vigorously with water giving oxygen and ozone.

$$2F_2 + 2H_2O \longrightarrow 4HF + O_2$$

$$3F_2 + 3H_2O \longrightarrow 6HF + O_3$$

At the same time, some oxygen fluoride (OF_2) is also formed.

A jet of steam burns in an atmosphere of fluorine like an illuminating gas.

5. Oxidising action. Since fluorine readily attacks water giving oxygen and ozone, it acts as a powerful oxidising agent. In fact, fluorine is the strongest chemical oxidising agent. It oxidises chlorates

to perchlorates, chromic salts to dichromates and a warm solution of potassium bisulphate to potassium peroxodisulphate.

$$2KHSO_4 + F_2 \longrightarrow 2HF + K_2S_2O_8$$

It oxidises vigorously all the common reducing agents.

6. Action on glass and quartz. Fluorine readily attacks glass and quartz forming silicon fluoride, SiF_4. But the reaction is extremely slow when the reactants are thoroughly freed from adsorbed water. Hence, *dry fluorine* can be easily manipulated in *dry* glass apparatus.

7. Action on hydrocarbons. As already mentioned, most of the organic compounds burn or explode when brought in contact with fluorine. The reaction of fluorine with hydrocarbons is also explosive. The initial reaction in the case of methane, for example, is

$$CH_4 + 2F_2 \longrightarrow C + 4HF$$

However, by diluting fluorine with nitrogen, **fluorination of hydrocarbons** has been successfully carried out. For this purpose, a mixture of the hydrocarbon, fluorine and nitrogen is passed through a metal tube packed with copper gauze, at a temperature of 160–350°C. Fluorine attacks copper forming copper fluoride which acts as a catalyst. The resulting product is a complex mixture. For example, methane yields a mixture of CH_3F, CH_2F_2, CHF_3, CF_4, C_2F_6 and C_3F_8. These **fluoro compounds** have acquired great industrial importance as refrigerants and for use in air conditioning.

9. Action on other compounds. Fluorine also reacts with ammonia giving nitrogen and a small amount of NF_3 along with some other products. Sulphur dioxide and hydrogen sulphide are also decomposed by fluorine. It does not react with nitrogen even at a very high temperature.

10. Combination with halogens. Fluorine reacts with halogens forming a number of compounds known as *inter-halogen compounds*. For example,

1. It reacts with chlorine at 250°C forming chlorine monofluoride, ClF. With excess of fluorine, chlorine trifluoride, ClF_3, results. Both ClF and ClF_3 are colourless gases.

2. Fluorine reacts with bromine forming bromine trifluoride. BrF_3 which is a colourless liquid. With excess of fluorine, a colourless solid, bromine pentafluoride, BrF_5, is obtained.

3. Fluorine also attacks iodine forming iodine pentafluoride, IF_5, which is a colourless solid. With excess of fluorine and at 300°C, iodine heptafluoride, IF_7, is formed.

Uses. Fluorine is now extensively used for the preparation of fluorine compounds on large scale. Difluorodichloromethane, CF_2Cl_2, sold under the commercial name, **freon-12**, is a valuable fluorine compound. It is used in refrigeration and air conditioning in place of ammonia and sulphur dioxide. It has an advantage in being non-toxic and non- flammable. Freon is also used as a solvent for D.D.T. and other insecticides. A new plastic, **teflon**, which is resistant to the action of acids, alkalies and oxidising agents, is polymerised tetrafluoroethylene, $(F_2C = CF_2)_n$.

Fluroine compounds, such as sodium fluoride and cryolite, are used as insecticides. Small amounts of fluorides in drinking water are believed to be useful in preventing tooth decay. D.D.F.T., which is similar to D.D.T., is an extremely active fungicide and fumigant.

Uranium hexafluoride (UF_6) is used in the separation of isotopes of uranium. Sulphur hexafluoride (SF_6), because of its high dielectric constant and insulating properties, is used in X-ray and high voltage machines.

Peculiarities of Fluorine, the First Element of the Group

The first element, fluorine, differs considerably from the other members of the halogen family as is generally the case with the first members of other groups of *s* and *p* block elements. This difference is

due to the following characteristics of fluorine :

(*i*) *Small size*

(*ii*) *Very high electronegativity* (fluorine, in fact, is the most electronegative of all the elements).

(*iii*) *Non-availability of d orbitals* in the valency shell.

The **main points of difference** are as follows.

1. Since fluorine is the most electronegative element, it exhibits *only a negative oxidation state* of –1. *It does not show any positive oxidation state.* The remaining members, on the other hand, show negative as well as positive oxidation states. Thus, oxidation states of +1, +3, 4, +5, +6 and +7 are quite frequent amongst halogens other than fluorine.

2. Flourine is most reactive amongst the halogens. This is due to the low energy of the F – F bond, the value for which is 158·8 kJ per mole. The bond is weak because of the repulsion between the non-bonding electrons in the molecule.

The X – X bond is much stronger in Cl_2, Br_2 and I_2. This is due to the hybridisation of *p* and *d* orbitals.

3. Again, on account of high electronegativity, fluorine extensively enters into hydrogen bond formation in its hydrides. Other elements, on account of comparatively small electronegativities, do not form hydrogen bonds. Thus, while HCl, HBr and HI are gaseous under ordinary conditions, HF is a liquid (b.p. 19·5°C). This is because HF exists as associated molecule $(HF)_n$ because of hydrogen bonding.

4. Maximum covalency of fluorine is *one* because it cannot expand its valency shell beyond the octet as there are no *d* orbitals in the valency shell. Other elements, on the other hand, can exercise covalencies upto 7 because of the availability of vacant *d* orbitals.

5. The hydride of fluorine (HF) in aqueous solution behaves only as a very weak acid whereas the other hydrides under similar circumstances behave as strong acids. The cause of this behaviour has been explained in a subsequent section.

6. The salts of hydrofluoric acid (fluorides) also differ from the corresponding salts (halides) of the other hydracids. Thus, while silver fluoride (AgF) is soluble, the other silver halides are insoluble. Similarly, while calcium fluoride (CaF_2) is insoluble, the other calcium halides are soluble.

7. Most of the fluorides are ionic ; these contain the F^- ion. This is due to small size of F^- ion, its radius being 1·36 Å. Chlorides, bromides and iodides have mostly molecular lattices.

8. The fluoride ion, by a process of hydrogen bonding, forms the anion, HF_2^-. This tendency is almost absent with the other halides. Thus, the compound KHF_2, written as $K^+(F\cdots\cdots H–F)^-$, is well known but the corresponding compounds of other halogens (*e.g.*, $KHCl_2$ and $KHBr_2$) are unknown.

9. The fluoride ion has great tendency to form complex ions, *e.g.*, $[AlF_6]^{3-}$, $[FeF_6]^{3-}$, in which the metal atom exhibits a higher covalency. Aluminium and iron exhibit coordination number 6 in these complexes. The other halide ions show this tendency to a much smaller extent.

10. Fluorine, on account of its high electronegativity, readily transforms sulphur into +6 oxidation state, forming thereby a stable hexafluoride SF_6. No other halogen forms the hexahalide.

11. Fluorine, because of the absence of *d* orbitals in its valency shell, does not form any polyhalides. *Other halogens frequently associate with the halide ions forming polyhalide ions because of the vacant d orbitals in their valency shell. Thus, we have* I_3^-, Br_3^-, Cl_3^- *ions but no* F_3^- *ion.*

Properties of Chlorine, Bromine and Iodine. Some important properties of chlorine, bromine and iodine are summed up in Table 3. Properties of fluorine are also included in the table for the sake of comparison.

TABLE 3

Chemical Properties of the Halogens

Property	Fluorine	Chlorine	Bromine	Iodine
1. Combination with hydrogen	Combines most readily with explosive violence even in the dark	Combines readily with explosion in sunlight but slowly in the dark	Combines only on heating	Combines on heating and in the presence of a catalyst
2. Combination with non-metals	Combines directly with all non-metals except nitrogen	Combines directly with all non-metals except N_2, O_2 and C	Combines directly with all non-metals except N_2, O_2, C and Si	Combines only with H_2, P, As and other halogens
3. Combination with metals	Most of the metals burn to form fluorides	Many metals burn to form chlorides	Most of the metals are attacked giving bromides	Combines with metals giving iodides
4. Reaction with water	Decomposes readily giving HF, O_2 and ozone	Decomposes slowly to give HCl and O_2	Decomposes very slowly but only in sunlight giving HBr and O_2	Little or no reaction
5. Oxidising property	Oxidises energetically	Oxidises readily	Oxidises slowly	Little or no oxidising action
6. Reaction with oxidising agents	No reaction	No reaction	Reacts with ozone to a small extent	Is oxidised by ozone as well as by HNO_3 to give I_2O_5 which with water gives HIO_3
7. Reaction with alkalies	Reacts briskly giving flourides, oxygen and water	Reacts readily giving chlorides and hypochlorites in cold and chlorides and chlorates in hot solutions	Reacts less readily giving bromides and hypobromites in cold and bromides and bromates in hot solutions	Reacts slowly forming iodides and hypoiodous acid and finally an iodate.
8. Bleaching action	No reaction	Moist chlorine is a good bleaching agent	Moist bromine shows a slow beaching action	No bleaching action
9. Reaction with hydrocarbons	Hydrocarbons are decomposed	Substitution of hydrogen takes place	Substitution of hydrogentakes place slowly	Very little action

Properties of Astatine. On account of its radioactive nature and short half-life period, the chemistry of astatine has been studied chiefly by tracer techniques. It resembles iodine in being soluble in organic solvents and in forming At^- and AtO_3^- ions similar to I^- and IO_3^- ions.

COMPOUNDS OF GROUP 17 ELEMENTS

I. A Comparative Study

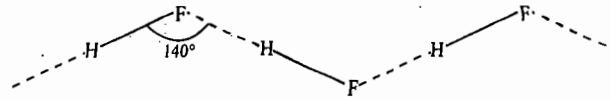
1. HYDRIDES OF THE HALOGENS (HYDROGEN HALIDES)

Formation. All the halogens combine with hydrogen to form hydrides (hydrogen halides) :

$$X_2 + H_2 \longrightarrow 2HX$$

But, the readiness with which the halogens combine with hydrogen decreases from fluorine to iodine. Thus, hydrogen combines explosively with fluorine even in the dark ; also explosively with chlorine but in the presence of light ; non-explosively with bromine and that too on heating to about 500°C and only slowly with iodine on heating in the presence of platinum as a catalyst. The reaction with iodine is reversible and incomplete.

Properties 1. Physical state. While, under ordinary conditions, HCl, HBr and HI are gases, HF is a liquid (b.p. 19·5°C). The unexpectedly high boiling point of HF is due to hydrogen bonding as a result of the high electronegativity of fluorine. Consequently, hydrogen fluoride exists as an associated species and may be described as $(HF)_n$. The crystalline HF has been found to have the following zig-zig structure :



2. Stability. The stability of the hydrides also decreases as we go down the group. Thus, hydrogen fluoride is most stable whereas hydrogen iodide is least stable. For example, while HF and HCl are not dissociated even at 1200°C, HBr is dissociated to the extent of 1 per cent and HI is dissociated to the extent of 20 per cent even at 400°C.

3. Reducing character. Since stability of hydrides decreases on moving from HF to HI, the reducing property increases in the same order. Thus, HF is not a reducing agent at all. HCl is a mild reducing agent, HBr is a stronger reducing agent while HI is the strongest reducing agent of all the hydrides.

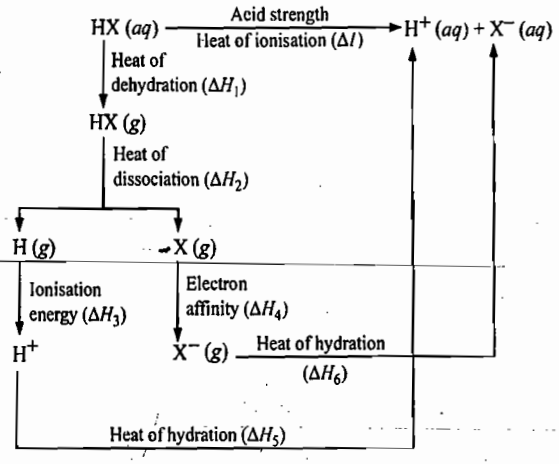
4. Nature of bonds. All the halides are essentially covalent compounds with some ionic character. The ionic character, which depends upon electronegativity difference between H and the halogen atom, decreases in the order :

$$HF > HCl > HBr > HI$$

The predominant covalent nature is indicated by their low melting and boiling points and also by the fact that the compounds in pure state are bad conductors of electricity.

5. Relative strengths as acids. Hydrogen halides in the gaseous state are essentially covalent. In aqueous solutions, however, they ionise and act as acids. HF is only slightly ionised but HCl, HBr and HI are almost completely ionised. In aqueous medium, the relative strengths of the acids have been found to follow the sequence HI > HBr > HCl > HF. In other words, of all the halogen hydracids, HF is the weakest and HI is the strongest acid .

At first sight, the above sequence appears to be rather surprising. Since fluorine is the most electronegative halogen, the electronegativity difference should be the maximum in HF and should gradually decrease as we move towards iodine through chlorine and bromine. Thus, the hydride HF should be more ionic in character than any other hydride and consequently, it should be the strongest acid. Actually, it is just the reverse. This has been explained with the help of the **Born-Haber cycle,** taking into consideration the various factors which determine the strengths of the acids in aqueous medium.



The ionisation reaction

$$HX(aq) \longrightarrow H^+(aq) + X^-(aq)$$

the extent of which determines the strength of the acid, involves different stages which can be represented in the form of **Born-Haber cycle,** as shown.

Evidently, the stages involving dehydration of HX(*aq*), dissociation of HX(*g*) into H(*g*) and X(*g*), conversion

of H(g) to $H^+(g)$ will be accompanied by the *absorption* of heat. The other stages involving conversion of X(g) into $X^-(g)$ and hydration of $H^+(g)$ and $X^-(g)$ will be accompanied by the *evolution* of heat. Hence, the heat of ionisation (ΔI) is equal to the sum of all the energy terms and will be given by the expression :

$$\Delta I = \Delta H_1 + \Delta H_2 + \Delta H_3 - \Delta H_4 - (\Delta H_5 + \Delta H_6)$$

These values in kJ per mole for the various halogen acids are given below :

Acid	ΔH_1	ΔH_2	ΔH_3	ΔH_4	$\Delta H_5 + \Delta H_6$	ΔI
HF	48	566	1312	−322	−1606	−12
HCl	18	431	1312	−384	−1472	−59
HBr	21	366	1312	−324	−1438	−63
HI	23	299	1312	−295	−1396	−57

The values of ΔI can easily explain the feasibility of the ionisation reaction. *The larger the negative value of ΔI, the greater is the feasibility of the ionization reaction and hence the greater is the strength of the halogen acid.* It is clear from the above table that the ΔI values for all the halogen acids are negative indicating that all of them can easily ionise. However, the value for HF is small compared with the values for other acids. Hence, HF is the weakest acid. The values also explain the gradually increasing strengths of HCl and HBr but they fail to explain the relative strength of HI. According to these values, the sequence of increasing strengths should be HF, HI, HCl and HBr. The discrepancy has been explained on the basis of *entropy change* ΔS accompanying the process of ionisation, the discussion of which, however, is beyond the scope of the book.

A close perusal of the data given in the above table reveals that the lower acid strength of HF in comparison to HCl, HBr and HI is largely due to its higher bond dissociation energy ΔH_2.

These compounds have been discussed further under the heading Important Compounds of Group 17 Elements.

2. OXIDES OF THE HALOGENS

All the halogens form oxides. Twelve such oxides are positively known. These are listed in Table 4 along with some of their physical characteristics. The oxides of fluorine are considered as oxygen fluorides since fluorine is more electronegative than oxygen.

TABLE 4
Oxides of the Halogens

Fluorine	Chlorine	Bromine	Iodine
OF_2 (Pale yellow gas, b.p. −145°C)	Cl_2O (orange liquid, b.p. 2°C)	Br_2O (dark-brown liquid, fr.p. − 10°C)	
O_2F_2 (yellowish orange solid, stable below − 95°C)	ClO_2 (yellowish-green liquid, b.p. 11°C)	BrO_2 (yellow solid, stable below − 40°C)	
O_3F_2 (blood-red viscous liquid, stable below −163°C)	Cl_2O_6 (dark red liquid, fr. p. 4°C)	BrO_3 (white crystalline solid, stable below − 70°C)	I_2O_5 (white solid, m.p. 300°C) decomposes to I_2 and O_2 above 300°C
O_4F_2 (reddish-brown solid, stable below −183°C)	Cl_2O_7 (colourless oily liquid, stable)		

Most of these oxides are unstable and are liable to explode. All the oxides of halogens are powerful oxidising agents.

Structures. The structures of only the monoxides would be discussed here. All the three monoxides, *viz.*, OF_2, Cl_2O and Br_2O have **angular structure** being formed by sp^3 hybridisation of oxygen orbitals.

The bonds will, evidently, be distorted because two of the four orbitals are occupied by lone pairs of electrons. The bond angle, therefore, will be different from 109·5°, the angle of regular tetrahedron. It is interesting to note that, while the bond angle FOF is less than 109·5°, being 103°, the bond angle ClOCl is more than 109·5°, being 110·9° (Fig. 4). This can be explained as follows :

In F_2O, since fluorine is more electronegative than oxygen, the bonding electrons lie nearer to the fluorine atom. Consequently, the repulsion between the bond pairs is less than the repulsion between the lone pairs and hence the bond angle is less then 109·5°.

In Cl_2O, since oxygen is more electronegative than chlorine, the bonding electrons lie closer to the oxygen atom. Consequently, the repulsion between the bond pairs is more than the repulsion between lone pairs and hence the bond angle is greater than 109·5°.

Since bromine is less electronegative than chlorine, the bonding electrons in Br_2O will be drawn all the more towards oxygen and hence the repulsion between the bond pairs will be even greater. Thus, the angle BrOBr is even greater than 110·9°.

The bond angles in various halogen monoxides are as follows :

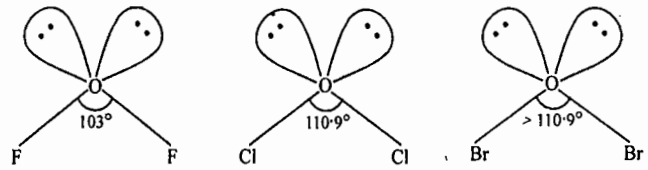


Fig. 4. Bond angles in various halogen monoxides.

3. OXOACIDS OF THE HALOGENS

Fluorine does not form oxoacids. This is because fluorine is more electronegative than oxygen. The oxoacids of chlorine and iodine, particularly containing more oxygen (*e.g.*, perchloric acid, $HClO_4$, iodic acid, HIO_3 and periodic acids HIO_4 and H_5IO_6) are fairly stable and are known in pure state. This is consistent with the observation that increase in the oxidation state of the halogen atom from +1 to +7 leads to increased stability of its oxides.

Oxoacids of bromine are known only in solution or in the form of their salts. For example, $HBrO_3$ is known only in solution and $HBrO_2$ only in the form of its salts. Perbromic acid, $HBrO_4$, is unknown.

The strength of oxoacids in which the halogens are in the same oxidation state, generally, decreases with rise in atomic number of the halogen. Thus, $HClO_3$ is the strongest while HIO_3 is the weakest of all the oxoacids in which oxidation state of the halogen is 5.

The halate ion (ClO_3^-, BrO_3^- or IO_3^-) is formed by sp^3 hybridisation and has a **pyramidal structure.**

The names, formulae, structures, stability and strengths as acids of important oxoacids of the halogens are given in Table 5.

TABLE 5
Important Oxoacids of the Halogens

Names of the acids and their salts	Oxidation state of the halogen in the acid	Oxoacids of : Cl	Br	I	Stability	Acid strength
Hypohalous, Hypohalites	+1	HClO	HBrO	HIO	Stability *decreases* on moving down	Acidity *increases* on moving down
Halous, Halites	+3	$HClO_2$				
Halic, Halates	+5	$HClO_3$	$HBrO_3$	HIO_3		
Perhalic, Perhalates	+7	$HClO_4$	$HBrO_4$	HIO_4		

Oxides and oxoacids of the halogens have been discussed further under the heading Important Compounds of Group 17 Elements.

II. Some Important Compounds of Group 17 Elements

HYDROGEN HALIDES

All the halogens give hydrogen halides, a brief discussion of which is given below.

Hydrogen Fluoride. On a small scale, hydrogen fluoride (*anhydrous*) is obtained by heating dry potassium hydrogen fluoride in a copper retort connected with a copper condenser.

$$KHF_2 \longrightarrow KF + HF$$

Industrially, hydrogen fluoride is obtained by heating *fluorspar* (CaF_2) with concentrated sulphuric acid in a lead vessel.

$$CaF_2 + H_2SO_4 \longrightarrow CaSO_4 + 2HF$$

Hydrogen fluoride distils over and the vapours are condensed in water taken in lead receivers. Aqueous hydrogen fluoride (or hydrofluoric acid) thus obtained is stored in *gutta parcha* or wax bottles. It cannot be stored in glass or silica bottles as it attacks silicates as well as silica :

$$Na_2SiO_3 + 6HF \longrightarrow Na_2SiF_6 + 3H_2O$$

$$CaSiO_3 + 6HF \longrightarrow CaSiF_6 + 3H_2O$$

$$SiO_2 + 4HF \longrightarrow SiF_4 + 2H_2O$$

This action of hydrofluoric acid on silica and silicates is used for *etching glass*.

Hydrogen Chloride. In laboratory, hydrogen chloride is prepared by heating sodium chloride with concentrated sulphuric acid. The gas is dried by passing through concentrated sulphuric acid.

Hydrogen chloride is manufactured by reacting chlorine with an excess of hydrogen.

It is highly soluble in water. It forms a constant boiling mixture having 20·4 per cent of HCl, boiling at 110°C.

Hydrogen Bromide and Hydrogen Iodide. Unlike hydrogen chloride, hydrogen bromide and hydrogen iodide cannot be prepared by heating a bromide or an iodide with concentrated sulphuric acid. The reason is that HBr and HI evolved are strong reducing agents. They reduce sulphuric acid to sulphur dioxide and get themselves oxidised to bromine or iodine, as the case may be.

This can be avoided by heating bromide or iodide with phosphoric acid instead of sulphuric acid. Since phosphoric acid is not an oxidising agent, it is not attacked by HBr or HI formed during the reaction.

Properties. All the hydrogen halides are colourless gases with pungent odour. They fume in air and are extremely soluble in water. The important physical properties of the anhydrous and aqueous hydrogen halides are given in Table 6.

TABLE 6
Properties of Anhydrous and Aqueous Hydrogen Halides

Property	Hydrogen fluoride, HF	Hydrogen chloride, HCl	Hydrogen bromide, HBr	Hydrogen iodide, HI
Physical state (15°C)	Liquid	Gas	Gas	Gas
Boiling point (°C)	19·4	–85	–67	–35·5
Melting point (°C)	–83	–111	–86	50·8
Solubility in water at 0°C (g/litre)	85·3	42·0	49·0	57·1
B.P. (°C) of constant boiling mixture	120	110	126	127
Composition of constant boiling mixture	36% HF	20·4% HCl	47% HBr	57% HI

Property	Hydrogen fluoride, HF	Hydrogen chloride, HCl	Hydrogen bromide, HBr	Hydrogen iodide, HI
Heat of formation (kJ mol^{-1})	–271·1 (gas)	–92·3 (gas)	–36·4 (gas)	+ 24·5 (gas)
Reducing action	Not a reducing agent	Has slight reducing properties	Strong reducing agent	Stronger reducing agent
Hydrogen bonding	Maximum	Little	Very little	Very little
Bond energy (kJ mol^{-1})	574·0	428·1	362·5	294·6
Stength as an acid in aqueous solution	Weak acid	Very strong acid	Very strong acid	Very strong acid
Apparent degree of dissociation in 0·1 M solution at room temperature	0·08	0·93	0·94	0·95
Solubility of silver salt (g/100 g)	172	0·00154	0·000084	0·000028
Solubility of calcium salt (g/100 g)	0·0016	42·7	58·8	67·6
Heating with a mixture of MnO_2 and H_2SO_4	—	Chlorine gas evolved by the oxidation of HCl.	Bromine (reddish-brown vapour) is evolved. Turns starch paper yellow.	Iodine (violet vapour) is evolved. Turns starch paper violet.
Addition of silver nitrate solution	No precipitate AgCl, insoluble in	White precipitate of tate of AgBr insolu- dilute nitric acid but soluble in ammonia.	Pale yellow precipi- of AgI, insoluble in ble in dilute nitric acid but partly soluble in ammonia	Yellow precipitate dilute HNO_3 as well as in ammonia.
Addition of calcium chloride solution	White precipitate of calcium fluoridesoluble in concentrated HCl (distinction from sulphate)	No. ppt.	No ppt.	No ppt.
Addition of lead acetate solution	No ppt.	White ppt. of $PbCl_2$	White ppt. of $PbBr_2$	Yellow ppt. of PbI_2
Addition of chlorine water	–	–	Bromine liberated. Add carbon disulphide, orange solution.	Iodine liberated. Add carbon disulphide, violet solution.
Confirmatory tests	Heat with conc. H_2SO_4. Hold a glass rod moistened with water in the mouth of the tube, a white film of silicic acid is formed.	Heat with $K_2Cr_2O_7 + H_2SO_4$. Chromyl chloride fumes. When passed into lead acetate solution, a yellow ppt. of lead chromate is formed	Action of chlorine water given above serves as the confirmatory test.	Action of chlorine water given above serves as the confirmatory test.

OXIDES OF FLOURINE

Only two oxides of fluorine are well known. These are described below.

Difluorine Oxide, F_2O. This is prepared by passing fluorine gas through sodium hydroxide solution.

$$2NaOH + 2F_2 \longrightarrow F_2O + 2NaF + H_2O$$

It is a pale yellow gas which is highly poisonous.

It decomposes in the presence of water to yield hydrogen fluoride.

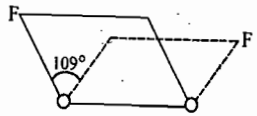
$$H_2O + F_2O \longrightarrow 2HF + O_2$$

F_2O is used as a rocket fuel.

Structure. The structure of F_2O has already been described.

The orbitals of central oxygen atom are sp^3 hybridised. Two of the sp^3 hybrid orbitals are occupied by lone pairs of electrons and the other two are involved in sigma bonding with the two fluorine atoms. The FOF angle is 103°. The reason for the angle being considerably less than the tetrahedral angle of 109·5° has already been discussed.

Difluorine Dioxide, F_2O_2. This compound is prepared by passing an electric discharge through a mixture of fluorine and oxygen at a very low temperature. It is an unstable yellowish orange solid. It is a very good fluorinating and oxidising agent.



Structure. The two planes, each containing the O – O bond and one of the two O – F bonds, are at an angle of 109° to each other, as shown.

OXIDES OF CHLORINE

Chlorine forms a number of oxides such as Cl_2O, ClO_2, Cl_2O_6 and Cl_2O_7. All of them are unstable and highly reactive. All the four oxides are discussed below in some details.

Dichlorine Oxide, Cl_2O. This is prepared by passing chlorine over freshly precipitated mercuric oxide.

$$2Cl_2 + 2HgO \longrightarrow HgO.HgCl_2 + Cl_2O$$

It is an orange liquid below 2°C. It boils at 2°C to give yellowish brown gas. At higher temperatures, the gas explodes.

It undergoes photochemical decomposition giving oxygen and chlorine.

$$2Cl_2O + h\nu \longrightarrow 2Cl_2 + O_2$$

It dissolves in water to form hypochlorous acid with which it exists in equilibrium in aqueous solution.

$$Cl_2O + H_2O \rightleftharpoons 2HOCl$$

Cl_2O is, therefore, regarded as the anhydride of hypochlorous acid.

Its gaseous mixture with ammonia explodes violently. The overall reaction may be represented as

$$3Cl_2O + 10NH_3 \longrightarrow 2N_2 + 6NH_4Cl + 3H_2O$$

Structure. As already discussed, Cl_2O has an angular structure, as shown in Fig. 5. The Cl – O – Cl bond angle is 110·9° and O – Cl bond lengths are 1·70 Å each. The oxygen orbitals are sp^3 hybridised. Two of the four sp^3 hybrid orbitals are occupied by lone pairs of electrons and the remaining two are used in forming sigma bonds with the two chlorine atoms.

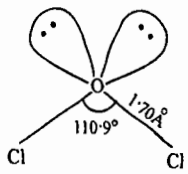


Fig. 5. Structure of Cl_2O.

Chlorine Dioxide, ClO_2. It is prepared by treating silver chlorate with dry chlorine at 90°C.

$$2AgClO_3 + Cl_2 \xrightarrow{90°} 2AgCl + 2ClO_2 + O_2$$

It can also be prepared by the action of chlorine on sodium chlorite.

$$2NaClO_2 + Cl_2 \longrightarrow 2ClO_2 + 2NaCl$$

ClO_2 is evolved as a paramagnetic yellowish-green gas which is condensed by cooling to give a coloured liquid (b.p. 11°C). It is a powerful oxidising and chlorinating agent. It dissolves in water exothermically.

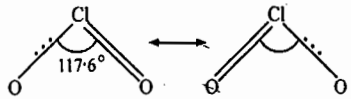
It reacts with alkalies to form chlorites and chlorates and thus can be regarded as a mixed anhydride of chlorous acid ($HClO_2$) and chloric acid ($HClO_3$).

$$2ClO_2 + 2NaOH \longrightarrow NaClO_2 + NaClO_3 + H_2O$$

The aqueous solution of ClO_2 undergoes photochemical decomposition to give a mixture of chloric acid and hydrochloric acid.

$$ClO_2 + H_2O \xrightarrow{h\nu} HCl + HClO_3$$

Structure. It has an angular structure with O – Cl – O bond angle of 117·6° and Cl – O bond length of 1·47Å. Since it contains odd number of electrons, the molecule may be considered to be having a three-electron bond in addition to a normal electron pair bond. Since both the ClO bond distances are equal, its structure is believed to be a resonance hybrid of the two structures :



The three-electron bond accounts for the shorter bond length and its paramagnetic character.

Dichlorine Hexoxide, Cl_2O_6. It is obtained by mixing chlorine dioxide with ozonised air at 0°C.

$$2ClO_2 + 2O_3 \longrightarrow 2Cl_2O_6 + 2O_2$$

It is a dark red liquid which freezes at 6°C. It is a strong oxidising agent. It reacts with alkalies to give chlorates and perchlorates.

$$Cl_2O_6 + 2NaOH \longrightarrow NaClO_3 + NaClO_4 + H_2O$$

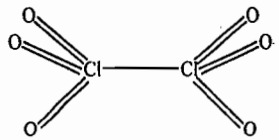
Hydrolysis of Cl_2O_6 yields a mixture of chloric and perchloric acids.

$$Cl_2O_6 + H_2O \longrightarrow HClO_3 + HClO_4$$

Liquid Cl_2O_6 is diamagnetic and gives diamagnetic solution in CCl_4. However, its vapours are paramagnetic due to its partial dissociation to chlorine trioxide having an unpaired electron.

$$Cl_2O_6 \rightleftharpoons 2ClO_3$$

The structure of Cl_2O_6 has not been known with certainty. However, its dissociation to ClO_3 supports the structure as shown containing Cl – Cl linkage. Each Cl in Cl_2O_6 molecule appears to be sp^3 hybridised.



Dichlorine Heptoxide, Cl_2O_7. It is obtained by dehydrating perchloric acid with phosphorus pentoxide.

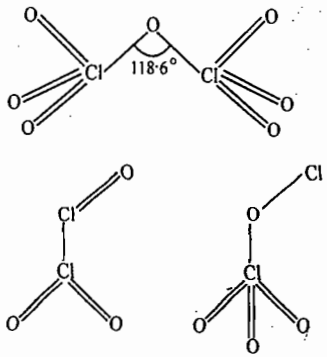
$$2HClO_4 \xrightarrow{P_2O_5} Cl_2O_7 + H_2O$$

It is a colourless oily liquid and dissolves in water giving perchloric acid.

$$Cl_2O_7 + H_2O \longrightarrow 2HClO_4$$

It is thus an anhydride of perchloric acid. Cl_2O_7 is the only exothermic oxide of chlorine and is thermodynamically more stable than any of the other oxides of chlorine. It is not so strong an oxidising agent as the other oxides of chlorine. It is less reactive than the lower oxides of chlorine.

Structure. Chlorine heptoxide has the structure, as shown, in which Cl – O – Cl angle is 118·6°.



Dichlorine trioxide and Dichlorine tetraoxide. Recently, the oxides Cl_2O_3 and Cl_2O_4 have also been synthesised. The former is a dark brown solid and decomposes into Cl_2 and O_2 at 0°C and the latter is a pale yellow liquid which decomposes at room temperature into Cl_2, O_2, ClO_2 and Cl_2O_6. The structures of Cl_2O_3 and Cl_2O_4 are as shown.

OXIDES OF BROMINE

Bromine forms a number of oxides, the most well known amongst which are Br_2O, BrO_2 and BrO_3.

Dibromine Oxide, Br_2O. It can be prepared by dropping bromine over dry HgO at 50 – 70°C.

$$2Br_2 + 2HgO \longrightarrow HgBr_2.HgO + Br_2O$$

It is a dark brown liquid which freezes at – 17·5°C. It is the anhydride of hypobromous acid, HBrO. It forms hypobromite with cold alkalies. It oxidises iodine to iodine pentoxide. Its structure is similar to that of Cl_2O.

Bromine Dioxide, BrO_2. It is obtained by passing an electric discharge through an oxygen-bromine mixture, at low pressure, at a temperature below –100°C.

It can also be prepared by low temperature ozonolysis of bromine.

$$Br_2 + 4O_3 \xrightarrow[CF_3Cl]{-78°C} 2BrO_2 + 4O_2$$

It is stable below – 40°C when it exists as a yellow solid. It dissolves in alkalies giving bromides and bromates.

$$6BrO_2 + 6NaOH \longrightarrow NaBr + 5NaBrO_3 + 3H_2O$$

Bromine Trioxide, BrO_3. It is prepared by the action of slow electric discharge on a mixture of bromine and oxygen between – 10°C and 20°C.

BrO_3 is a white crystalline solid which is stable only below – 70°C. It is a strong oxidising agent. It gives acidic solution in water.

OXIDES OF IODINE

Iodine forms oxides such as I_2O_4, I_4O_9 and I_2O_5. Among these, I_2O_5 is the most stable and is described below.

Iodine Pentoxide, I_2O_5. It is prepared by heating iodic acid to about 240°C.

$$2HIO_3 \xrightarrow{240°C} I_2O_5 + H_2O$$

It can also be prepared by heating iodine with conc. HNO_3.

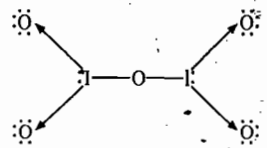
$$I_2 + 10HNO_3 \longrightarrow I_2O_5 + 10NO_2 + 5H_2O$$

It is a white solid which decomposes to iodine and oxygen above 300°C. With water, it forms iodic acid, HIO_3. It has such a strong affinity for water that the commercial I_2O_5 exists as $I_2O_5.HIO_3$. It is a strong oxidising agent. It oxidises CO to CO_2 quantitatively liberating iodine which can be titrated against sodium thiosulphate.

$$I_2O_5 + 5CO \longrightarrow I_2 + 5CO_2$$

Hence, I_2O_5 is used for the detection and estimation of carbon monoxide. This forms the basis of analytical method for determining CO in atmosphere or in other gaseous mixtures.

Structure. The structure of I_2O_5 has been determined with a fair degree of reliability from IR spectrum data. It has two pyramidal IO_3 units joined through a common oxygen atom. Each I atom in I_2O_5 has a lone pair of electrons as well.



OXOACIDS OF THE HALOGENS AND THEIR SALTS

A few of the oxaocids of the halogens and their salts are discussed below.

Hypohalous acid (HOX) and Hypohalites. Hypohalous acids (HOCl, HOBr and HOI) are unstable and are known only in solution. These are obtained in aqueous solution by mixing suspension of mercuric oxide with the halogen concerned. Thus, **hypochlorous acid (HOCl)** is obtained by shaking precipitated mercuric oxide in water with chlorine.

$$2Cl_2 + 2HgO + H_2O \longrightarrow HgO.HgCl_2 + 2HOCl$$

The halogen in these acids is present in +1 oxidation state. These are weak acids, the acid strength decreasing with increase in size of the halogen. The dissociation constants of the acids are as follows :

Acid	HOCl	HOBr	HOI
K_a	$2·9\times10^{-8}$	5×10^{-9}	$\sim 10^{-11}$

Thermal stability also decreases in the same order. Thus, HOCl is not only a stronger acid but also more stable than HOBr and HOI. HOI is not only weakest of these weak acids but is also least stable. Their salts are known as **hypohalites.** The most stable hypohalites are those of Li, Ca, Sr and Ba. NaOCl is less stable and cannot be isolated in pure form. KOCl is known only in solution.

Sodium hypochlorite, NaClO is one of the important salts of hypochlorous acid. This is used in bleaching. It is prepared by the electrolysis of brine. The following reactions take place at the cathode and anode.

At cathode : $2H^+ + 2e^- \longrightarrow H_2\,(g)$

At anode : $2Cl^- \longrightarrow Cl_2\,(g) + 2e^-$

With the discharge of H^+ ions, the concentration of OH^- ions rises at the cathode while chlorine is released at the anode. The electrolyte is kept agitated so that the OH^- ions and chlorine gas come into intimate contact and react as follows :

$$2OH^- + Cl_2 \longrightarrow ClO^- + Cl^- + H_2O$$

In this way, the solution becomes progressively richer in NaOCl and there is very little evolution (loss) of chlorine.

Hypohalite ions, XO^-, are all unstable. They disproportionate in basic solution as follows :

$$3XO^- \longrightarrow XO_3^- + 2X^-$$

The hypochlorite ion OCl^- changes to chlorate ion, ClO_3^- by the above mechanism only in *hot* solution. The conversion of hypobromite ion, BrO^- to bromate ion, BrO_3^- takes place rapidly at 50°C while that of hypoiodite ion, IO^- to iodate ion, IO_3^- takes place even at room temperature.

Structure. The hypochlorite ion, ClO^-, has a structure in which a half-filled *p* orbital of chlorine atom overlaps with a half-filled *p* orbital of oxygen atom to form the Cl – O sigma bond.

Bleaching Powder. It is obtained by passing chlorine over slaked lime.

$$Ca(OH)_2 + Cl_2 \longrightarrow CaCl(OCl) + H_2O$$

When treated with even such a weak acid as CO_2, most of the chlorine gets evolved.

$$CaCl(OCl) + H_2O + CO_2 \longrightarrow CaCO_3 + H_2O + Cl_2$$

Bleaching powder is a mixed salt of HCl and HOCl, *viz.*, Cl – Ca – OCl and is used as a convenient source of chlorine.

Halous acids (HXO_2) and Halites. Only chlorous acid, $HClO_2$, is known and that, too, in solution. It contains chlorine in +3 oxidation state. It is a stronger acid ($K_a = 1{\cdot}1\times10^{-2}$) than hypochlorous acid, ($K_a = 2{\cdot}9\times10^{-8}$).

It is obtained in aqueous solution by the action of sulphuric acid on barium chlorite.

$$Ba(ClO_2)_2 + H_2SO_4 \longrightarrow BaSO_4 + 2HClO_2$$
